Preface to the Second English Edition

The *VDI-Wärmeatlas* or *VDI Heat Atlas* has a long-lasting history and it can be considered as a standard book for heat exchanger and process engineering equipment design. It is not conceived as a textbook presenting an overall view of the theoretical or experimental findings in heat transfer sciences. The aim was and is to present and explain the state of the art of engineering methods to solve industrially relevant heat transfer problems for apparatus design and process modeling. The first German edition was published in 1963. The sixth German edition was translated into English to meet the demands of the more and more internationally acting industry. This first English edition was published in 1992. Since then, the German edition was regularly updated until the tenth edition published in 2006.

In view of today's globally acting industry, the editorial board felt the necessity to revise the English edition in order to account for the most recent state of our knowledge. Instead of only translating the latest German edition, we preferred restructuring it at the same time because this also enabled us to include new subjects and to update methods according to the recent state of the art. This new structure will also serve as a basis for the forthcoming German edition.

On behalf of the editorial board, I express my sincere thanks to the authors of the various sections for their contributions and kind cooperation. The editorial work was coordinated and assisted by Mrs. Sigrid Cuneus from Springer-Verlag, Berlin. We are indebted to her for the efficient work and pleasant collaboration. We are also grateful to Mrs. Tina Shelton from the Reference and Database Publishing group, Springer Reference Editorial, India, who handled the editorial workflow.

Professor Dr.-Ing. Peter Stephan, Editor-in-Chief
Darmstadt, May 2010

WE SUPPORT YOU

- → Heat Exchanger / Heat Transfer
- → Pressure Drop
- → Combustion
- → 2 Phase Flow
- → Properties of Gases and Fluids
- → Tube Bundle Vibration
- → Steam Generators for Chemical Plants / Power Plants

Symbols, Units and Dimensionless Numbers

A1 Symbols and Units

Matthias Kind · Holger Martin
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Introduction: Legal Units

"The International Committee for Weights and Measures" (BIPM, Paris) publishes the "SI Brochure" [1]. Most of the base and derived units used in this VDI-Heat Atlas are SI units and are assorted below. The SI units are the units that are recognized globally in order to establish a worldwide dialog and can be seen in the further reading. Although there are a variety of non-SI units for the same quantity in the literature, only some of them can be found below due to the fact that not all of them are widely used [2, 3].

As of October 2007, there are 51 Member States of the Metre Convention and 25 Associate States and Economies of the General Conference.

2 SI Base Units of Base Quantities

Quantity	Symbol of the quantity	Unit	Symbol of the unit
Length	$L, x, y, z, r, \ldots$	Meter	m
Mass	M, m	Kilogram	kg
Time	t	Second	s
Electric current	I, i	Ampere	A
Thermodynamic temperature	T	Kelvin	K
Amount of substance	N	Mol	mol
Luminous intensity	I_v	Candela	cd

3 SI Derived Units with Special Names and Symbols

Quantity	Symbol of the quantity	SI coherent derived unit[a]			
		Unit	Symbol of the unit	Expressed in terms of other SI units	Expressed in terms of SI base units
Plane angle	$\alpha, \beta, \gamma, \ldots$	Radian[b]	rad	1[b]	m/m
Solid angle	$\alpha, \beta, \gamma, \ldots$	Steradian[b]	sr[c]	1[b]	m^2/m^2
Frequency	f	Hertz[c]	Hz		s^{-1}
Force	F	Newton	N		m kg s^{-2}
Pressure, stress	p, P, σ, τ	Pascal	Pa	N/m^2	m^{-1} kg s^{-2}
Energy, work, amount of heat	E, W, Q	Joule	J	N m	m^2 kg s^{-2}
Power, heat flow	$P, \dot{Q}$	Watt	W	J/s	m^2 kg s^{-3}
Electric charge, amount of electricity	Q	Coulomb	C		s A

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_1,

Quantity	Symbol of the quantity	SI coherent derived unit[a]			
		Unit	Symbol of the unit	Expressed in terms of other SI units	Expressed in terms of SI base units
Electric potential	U	Volt	V	W/A	$m^2\ kg\ s^{-3}\ A^{-1}$
Capacitance	C	Farad	F	C/V	$m^{-2}\ kg^{-1}\ s^4\ A^2$
Electric resistance	R	Ohm	Ω	V/A	$m^2\ kg\ s^{-3}\ A^{-2}$
Electric conductance	G	Siemens	S	A/V	$m^{-2}\ kg^{-1}\ s^3\ A^2$
Magnetic flux	Φ	Weber	Wb	V s	$m^2\ kg\ s^{-2}\ A^{-1}$
Magnetic flux density	B	Tesla	T	Wb/m^2	$kg\ s^{-2}\ A^{-1}$
Inductance	L	Henry	H	Wb/A	$m^2\ kg\ s^{-2}\ A^{-2}$
Celsius temperature	ϑ	Degree Celsius[d]	°C		K
Luminous flux	I	Lumen	lm	cd sr[e]	cd
Illuminance	E	Lux	lx	lm/m^2	m^{-2} cd
Activity referred to a radionuclide[f]		Becquerel[c]	Bq		s^{-1}
Absorbed dose, specific energy (imparted), kerma		Gray	Gy	J/kg	$m^2\ s^{-2}$
Dose equivalent, ambient dose equivalent, directional dose equivalent, personal dose equivalent		Sievert[g]	Sv	J/kg	$m^2\ s^{-2}$
Catalytic activity		Katal	kat		s^{-1} mol

[a]The SI prefixes (see Sect. 7) may be used with any of the special names and symbols, but when this is done, the resulting unit will no longer be coherent.
[b]Radian and steradian are special names for the number 1 that may be used to convey information about the quantity concerned. In practice, the symbols rad and sr are used where appropriate, but the symbol for the derived unit 1 is generally omitted in specifying the values of dimensionless quantities.
[c]Hertz is used only for periodic phenomena, and Becquerel is used only for stochastic processes in activity referred to a radionuclide.
[d]Degree Celsius is the special name for Kelvin, which is used to express Celsius temperatures. Degree Celsius and the Kelvin are equal in size, so that the numerical value of a temperature difference or temperature interval is the same when expressed in either degree Celsius or Kelvin.
[e]In photometry, the name steradian and the symbol sr are usually retained in expression for units.
[f]Activity referred to a radionuclide is sometimes incorrectly called radioactivity.
[g]See http://www.bipm.org/en/CIPM/db/2002/2/ on the use of the sievert.

4 Quantities and Symbols

The following alphabetically listed symbols are generally used in the Heat Atlas. Other more specific notations and symbols, which may differ from the ones listed here are defined within the special sections if needed.

4.1 Quantities

Quantity	Symbol of the quantity	Symbol of the unit
Acceleration of gravity	g	$m\ s^{-2}$
Amount of substance	N	mol
Coefficient of thermal expansion	β	K^{-1}
Coordinate in flow direction	x	m
Coordinate perpendicular to flow direction	y	m
Coordinate perpendicular to flow direction	z	m
Cross-sectional area	A, S	m^2
Density	ρ	$kg\ m^{-3}$
Diameter	D	m
Diffusion coefficient	D_{ij}, δ_{ij}	$m^2\ s^{-1}$
Dynamic viscosity	η	Pa s
Emissivity	ε	1
Energy	E	J
Enthalpy	H	J
Enthalpy stream	$\dot{H}$	W
Entropy	S	$J\ K^{-1}$
Gibbs enthalpy	G	J
Heat	Q	J
Heat flow	$\dot{Q}$	W
Heat flux	$\dot{q}$	$W\ m^{-2}$
Heat transfer coefficient	α	$W\ m^{-2}\ K^{-1}$
Hydraulic diameter $d_h = 4 \times$ cross-sectional area/circumference	d_h	m
Individual gas constant	R	$J\ kg^{-1}\ K^{-1}$
Internal energy	U	J
Kinematic viscosity	ν	$m^2\ s^{-1}$
Length	L, l	m
Mass	M, m	kg
Mass flow rate	$\dot{M}$	$kg\ s^{-1}$

Quantity	Symbol of the quantity	Symbol of the unit
Mass flux	$\dot{m}$	kg m^{-2} s^{-1}
Mass fraction of component j in the liquid or vapor phase, respectively	x_j, y_j	kg kg^{-1}
Mass loading of component j in the liquid or vapor phase, respectively	X_j, Y_j	kg kg^{-1}
Mass transfer coefficient of a component *i*	β_i	m s^{-1}
Molar density	n	mol m^{-3}
Molar enthalpy	$\tilde{h}$	J mol^{-1}
Molar entropy	$\tilde{s}$	J mol^{-1} K^{-1}
Molar flow	$\dot{N}$	mol s^{-1}
Molar flux	$\dot{n}$	mol m^{-2} s^{-1}
Molar Gibbs enthalpy	$\tilde{g}$	J mol^{-1}
Molar heat capacity at constant pressure or volume respectively	$\tilde{c}_p$, $\tilde{c}_v$	J mol^{-1} K^{-1}
Molar internal energy	$\tilde{u}$	J mol^{-1}
Molar mass	$\tilde{M}$	kg kmol^{-1}
Molar loading of component j in the liquid or vapor phase, respectively	$\tilde{X}_j$, $\tilde{Y}_j$	mol mol^{-1}
Molar volume	$\tilde{v}$	m^3 mol^{-1}
Mole fraction of component j in the liquid or vapor phase, respectively	$\tilde{x}_j$, $\tilde{y}_j$	mol mol^{-1}
Overall heat transfer coefficient	k	W m^{-2} K^{-1}
Overall mass transfer coefficient	k'	m s^{-1}
Partial pressure of component *j*	p_j	Pa; bar
Power	P	W
Radiation coefficient	C	W m^{-2} K^{-4}
Radius	r	M
Specific enthalpy	h	J kg^{-1}
Specific entropy	s	J kg^{-1} K^{-1}
Specific Gibbs enthalpy	g	J kg^{-1}
Specific heat capacity at constant pressure or volume, respectively	c_p, c_v	J kg^{-1} K^{-1}
Specific internal energy	u	J kg^{-1}
Specific volume	v	m^3 kg^{-1}
Surface, phase interphase	A	m^2
Surface tension	σ	N m^{-1}
Temperature difference (or centigrade temperature)	θ	K
Thermal conductivity	λ	W m^{-1} K^{-1}
Thermal diffusivity	κ	m^2 s^{-1}
Thermodynamic temperature	T	K
Time	t	s
Total pressure	p	Pa; bar
Universal gas constant	$\tilde{R}$	J mol^{-1} K^{-1}
Vapor quality (ratio of vapor mass flow/total mass flow)	$\dot{x}$	1
Vapor pressure of component *j*	p_{0j}	Pa; bar
Velocity in *x*-direction	u	m s^{-1}
Velocity in *y*-direction	v	m s^{-1}
Velocity in *z*-direction	w	m s^{-1}
Velocity of sound	c	m s^{-1}
Volumetric flow rate	$\dot{V}$	m^3 s^{-1}
Voidage, gas volume fraction	ψ	1
Volume	V	m^3
Wall thickness	s	m
Work	W	J

4.2 Symbols

Latin letters

Symbol of the quantity	Unit	Quantity
A	m^2	Surface, phase interphase
A, S	m^2	Cross-sectional area
a	ms^{-1}	Velocity of sound
C	W m^{-2} K^{-4}	Radiation coefficient
c_p, c_v	J kg^{-1} K^{-1}	Specific heat capacity at constant pressure or volume respectively
$\tilde{c}_p$, $\tilde{c}_v$	J mol^{-1} K^{-1}	Molar heat capacity at constant pressure or volume respectively
D_{ij}	m^2 s^{-1}	Diffusion coefficient
D	M	Diameter
d_h	m	Hydraulic diameter $d_h = 4 \times$ cross-sectional area/circumference
E	J	Energy
G	J	Gibbs enthalpy
g	J kg^{-1}	Specific Gibbs enthalpy
$\tilde{g}$	J mol^{-1}	Molar Gibbs enthalpy
g	m s^{-2}	Acceleration of gravity
H	J	Enthalpy
$\dot{H}$	W	Enthalpy stream
h	J kg^{-1}	Specific enthalpy
$\tilde{h}$	J mol^{-1}	Molar enthalpy
k	W m^{-2} K^{-1}	Overall heat transfer coefficient
k'	m s^{-1}	Overall mass transfer coefficient
W	J	Work
$\dot{W}$	W	Power
L, l	m	Length
M	kg	Mass
$\tilde{M}$	kg kmol^{-1}	Molar mass
$\dot{M}$	kg s^{-1}	Mass flow rate
$\dot{m}$	kg m^{-2} s^{-1}	Mass flux
N	mol	Amount of substance
$\dot{N}$	mol s^{-1}	Molar flow
n	mol m^{-3}	Molar density
$\dot{n}$	mol m^{-2} s^{-1}	Molar flux
p	Pa; bar	Total pressure
p_j	Pa; bar	Partial pressure of component *j*
p_{0j}	Pa; bar	Vapor pressure of component *j*

Symbol of the quantity	Unit	Quantity
Q	J	Heat
$\dot{Q}$	W	Heat flow
$\dot{q}$	W m^{-2}	Heat flux
R	J kg^{-1} K^{-1}	Individual gas constant
$\widetilde{R}$	J mol^{-1} K^{-1}	Universal gas constant
r	m	Radius
S	J K^{-1}	Entropy
s	J kg^{-1} K^{-1}	Specific entropy
$\widetilde{s}$	J mol^{-1} K^{-1}	Molar entropy
s	m	Wall thickness
T	K	Thermodynamic temperature
t	s	Time
U	J	Internal energy
u	J kg^{-1}	Specific internal energy
$\widetilde{u}$	J mol^{-1}	Molar internal energy
u	m s^{-1}	Velocity in x-direction
V	m^3	Volume
$\dot{V}$	m^3 s^{-1}	Volumetric flow rate
v	M^3 kg^{-1}	Specific volume
$\widetilde{v}$	m^3 mol^{-1}	Molar volume
v	m s^{-1}	Velocity in y-direction
w	m s^{-1}	Velocity in z-direction
X_j, Y_j	kg kg^{-1}	Mass loading in the liquid or vapor phase
$\widetilde{X}_j$, $\widetilde{Y}_j$	mol mol^{-1}	Molar mass loading in the liquid or vapor phase of component j, respectively
x_j, y_j	kg kg^{-1}	Mass fraction in the liquid or vapor phase of component j, respectively
$\widetilde{x}_j$, $\widetilde{y}_j$	mol mol^{-1}	Mole fraction in the liquid or vapor phase
$\dot{x}$	1	Vapor quality (ratio of vapor mass flow/total mass flow)
x	m	Coordinate in flow direction
y	m	Coordinate perpendicular to flow direction
z	m	Coordinate perpendicular to flow direction

Greek letters

Symbol of the quantity	Unit	Quantity
α	W m^{-2} K^{-1}	Heat transfer coefficient
β_i	m s^{-1}	Mass transfer coefficient of a component i
β	K^{-1}	Coefficient of thermal expansion
δ_{ij}	m^2 s^{-1}	Diffusion coefficient
ε	1	Emissivity
η	Pa s	Dynamic viscosity
θ	K	Temperature difference (or centigrade temperature)
κ	m^2 s^{-1}	Thermal diffusivity
λ	W $m^{-1}K^{-1}$	Thermal conductivity
ν	m^2 s^{-1}	Kinematic viscosity
ρ	kg m^{-3}	Density
σ	N m^{-1}	Surface tension
ψ	1	Voidage, gas volume fraction

Subscripts to denote

Phase

F	Fluid phase
G	Gas phase
L	Liquid phase
S	Solid phase

Time

I	Initial value
t	Instantaneous value
F	Final value

Position

o	Outside
out	At the exit
in	At the inlet
i	Inside
loc	Local value
s	At the surface
w	At the wall

State

c	At the critical point
p	At constant pressure
r	Relative (related to the corresponding value at the critical point)
v	At constant volume
′, ″,	(Superscripts) at the phase boundaries

Process

lam	In laminar flow
turb	In turbulent flow
rev	Reversible

Others

tot	Total
LM	Logarithmic mean
m	Mean
G0	Total mass flow as gas
L0	Total mass flow as liquid

5 Non-SI Units Accepted for Use with the SI, and Units Based on Fundamental Constants

Quantity	Symbol of the quantity	Name of the unit	Symbol of the unit	Value in SI unit
Time	t	Minute	min	1 min = 60 s
		Hour[a]	h	1 h = 60 min = 3,600 s
		day	d	1 d = 24 h = 86,400 s
Plane angle	α, β, γ,. . .	Degree[b,c]	°	1° = (π/180) rad
		Minute	′	1′ = (1/60)° = (π/10,800) rad
		Second[d]	″	1″ = (1/60)′ = (π/648,000) rad
Area	A, S	Hectare[e]	ha	1 ha = 1 hm^2 = 10^4 m^2
Volume	V	Liter[f]	L, l	1 L = 1 l = 1 dm^3 = 10^3 cm^3 = 10^{-3} m^3
Mass	M, m	Ton[g]	t	1 t = 10^3 kg

[a]The symbol of this unit is included in "Resolution 7" of the 9th CGPM (1948).
[b]ISO 31 recommends that the degree be divided decimally rather than using minute and second. For navigation and surveying, however, minute has the advantage that one minute of latitude on the surface of the Earth corresponds (approximately) to one nautical mile.
[c]Gon (or grad(e), where grad is an alternative name for the gon) is an alternative unit of plane angle to the degree, defined as (π/200) rad. Thus, there are 100 gon in a right angle. The potential value of gon in navigation is that because the distance from the pole to the equator of the Earth is approximately 10,000 km, 1 km on the surface of the Earth subtends an angle of one centigon at the center of the Earth. However, gon is rarely used.
[d]For applications in astronomy, small angles are measured in arcseconds (i.e., seconds of plane angle), denoted as "milliarcseconds, microarcseconds, and picoarcseconds, denoted as mas, μas, and pas," respectively, where arcsecond is an alternative name for second of plane angle.
[e]The unit hectare and its symbol ha were adopted by the CIPM in 1879 (PV, 1879, 41). Hectare is used to express land area.
[f]Liter and the symbol lower case l were adopted by the CIPM in 1879 (PV, 1879, 41). The alternative symbol, capital L, was adopted by the 16th CPGM (1979, "Resolution 6") in order to avoid the risk of confusion between the letter l (el) and the numeral 1 (one).
[g]Ton and its symbol t were adopted by the CIPM in 1879 (PV, 1879, 41). In English-speaking countries, this unit is usually called "metric ton."

6 Other Non-SI Units Not Recommended for Use

Values in **boldface** are exact

Acceleration

Foot per second squared, 1 ft/s^2	**= 3.048 · 10^{-1}**	m/s^2
Inch per second squared, 1 in/s^2	**= 2.54 · 10^{-2}**	m/s^2

Angle

1 Mil	**= 5.625 · 10^{-2}**	°
1 Revolution®	= 6.283 185	rad

Area and second moment of area

Square foot, 1 ft^2	**= 9.290 304 · 10^{-2}**	m^2
Square inch, 1 in^2	= **6.451 6 · 10^{-4}**	m^2
Square mile, 1 mi^2	= 2.589 988 · 10^{-4}	m^2

Capacity, see volume

Density, see mass divided by volume

Electricity and magnetism

Biot, 1 Bi	**= 1.0 · 10^1**	A
Franklin, 1 Fr	= 3.335 641 · 10^{-10}	C
Gamma, 1 γ	= **1.0 · 10^{-9}**	T

Energy (includes work)

Calorie (15°C), 1 cal_{15}	= 4.185 80	J
Calorie (20°C), 1 cal_{20}	= 4.181 90	J
Electronvolt, 1 eV	= 1.602 177 · 10^{-19}	J
Erg, 1 erg	= **1.0 · 10^{-7}**	J

Energy divided by area time

Erg per square centimeter second, 1 $erg/(cm^2 \cdot s)$	= **1.0 · 10^{-3}**	W/m^2

Flow, see mass divided by time, or see volume divided by time

Force

Dyne, 1 dyn	**= 1.0 · 10^{-5}**	N
Kilogram-force, 1 kgf	= **9.806 65**	N

Force divided by area, see pressure

Force divided by length

Pound-force per foot, 1 lbf/ft	= 1.459 390 · 10^1	N/m

Heat, available energy

British thermal $unit_{IT}$ per cubic foot, 1 Btu_{IT}/ft^3	= 3.725 895 · 10^4	J/m^3

British thermal $unit_{th}$ per cubic foot, 1 Btu_{th}/ft^3	$= 3.723\,403 \cdot 10^4$	J/m^3

Heat, coefficient of heat transfer

British thermal $unit_{th}$ per second square foot degree Fahrenheit, 1 $Btu_{th}/(s \cdot ft^2 \cdot °F)$	$= 2.042\,808 \cdot 10^4$	$W/(m^2 \cdot K)$

Heat, density of heat

$Calorie_{th}$ per square centimeter, 1 cal_{th}/cm^2	$\mathbf{= 4.184 \cdot 10^4}$	J/m^2

Heat, density of heat flow rate

$Calorie_{th}$ per square centimeter minute, 1 $cal_{th}/(cm^2 \cdot min)$	$= 6.973\,333 \cdot 10^2$	W/m^2

Heat, fuel consumption

Gallon (US) per horsepower hour, 1 $gal/(hp \cdot h)$	$= 1.141\,089 \cdot 10^{-9}$	m^3/J

Heat, heat capacity and entropy

British thermal $unit_{IT}$ per degree Fahrenheit, 1 $Btu_{IT}/°F$	$= 1.899\,101 \cdot 10^3$	J/K
British thermal $unit_{th}$ per degree Fahrenheit, 1 $Btu_{th}/°F$	$= 1.897\,830 \cdot 10^3$	J/K

Heat, heat flow rate

$Calorie_{th}$ per minute, 1 cal_{th}/min	$= 6.973\,333 \cdot 10^{-2}$	W

Heat, specific heat capacity and specific entropy

$Calorie_{IT}$ per gram kelvin, 1 $cal_{IT}/(g \cdot K)$	$\mathbf{= 4.186\,8 \cdot 10^3}$	$J/(kg \cdot K)$
$Calorie_{th}$ per gram kelvin, 1 $cal_{th}/(g \cdot K)$	$= \mathbf{4.184 \cdot 10^3}$	$J/(kg \cdot K)$

Heat, thermal conductivity

$Calorie_{th}$ per centimeter second degree Celsius, 1 $cal_{th}/(cm \cdot s \cdot °C)$	$= \mathbf{4.184 \cdot 10^2}$	$W/(m \cdot K)$

Heat, thermal diffusivity

Square foot per hour, 1 ft^2/h	$= \mathbf{2.580\,64 \cdot 10^{-5}}$	m^2/s

Heat, thermal insulance

Clo, 1 clo	$= 1.55 \cdot 10^{-1}$	$m^2 \cdot K/W$
Degree Fahrenheit hour square foot per British thermal $unit_{IT}$, 1 $°F \cdot h \cdot ft^2/Btu_{IT}$	$= 1.761\,102 \cdot 10^{-1}$	$m^2 \cdot K/W$
Degree Fahrenheit hour square foot per British thermal $unit_{th}$, 1 $°F \cdot h \cdot ft^2/Btu_{th}$	$= 1.762\,280 \cdot 10^{-1}$	$m^2 \cdot K/W$

Heat, thermal resistance

Degree Fahrenheit second per British thermal $unit_{IT}$, 1 $°F \cdot s/Btu_{IT}$	$= 5.265\,651 \cdot 10^{-4}$	K/W
Degree Fahrenheit second per British thermal $unit_{th}$ 1 $°F \cdot s/Btu_{th}$	$= 5.269\,175 \cdot 10^{-4}$	K/W

Heat, thermal resistivity

Degree Fahrenheit hour square foot per British thermal $unit_{IT}$ inch $[°F \cdot h \cdot ft^2/(Btu_{IT} \cdot in)]$	= 6.933 472	$m \cdot K/W$

Length

Angström, 1 Å	$\mathbf{= 1.0 \cdot 10^{-10}}$	m
Micron, 1 µm	$= \mathbf{1.0 \cdot 10^{-6}}$	m
Mil (0.001 in), 1 mil	$= \mathbf{2.54 \cdot 10^{-5}}$	m
Mile, 1 mi	$= \mathbf{1.609\,344 \cdot 10^3}$	m
Yard, 1 yd	$= \mathbf{9.144 \cdot 10^{-1}}$	m

Light

Candela per square inch, 1 cd/in^2	$= 1.550\,003 \cdot 10^3$	cd/m^2
Lumen per square foot, 1 lm/ft^2	$= 1.076\,391 \cdot 10^1$	lx

Mass and moment of inertia

Grain, 1 gr	$= \mathbf{6.479\,891 \cdot 10^{-5}}$	kg
Ounce (avoirdupois), 1 oz	$= 2.834\,952 \cdot 10^{-2}$	kg
Ounce (troy or apothecary), 1 oz	$= 3.110\,348 \cdot 10^{-2}$	kg
Pound (avoirdupois) (*1), 1 lb	$= 4.535\,924 \cdot 10^{-1}$	kg
Pound (troy or apothecary), 1 lb	$= 3.732\,417 \cdot 10^{-1}$	kg
Ton, assay, 1 AT	$= 2.916\,667 \cdot 10^{-2}$	kg
Ton, metric, 1 t	$= \mathbf{1.0 \cdot 10^3}$	kg

Mass density see mass divided by volume

Mass divided by area

Ounce (avoirdupois) per square foot, 1 oz/ft^2	$= 3.051\,517 \cdot 10^{-1}$	kg/m^2
Ounce (avoirdupois) per square inch, 1 oz/in^2	$= 4.394\,185 \cdot 10^1$	kg/m^2
Pound per square foot, 1 lb/ft^2	= 4.882 428	kg/m^2

Mass divided by capacity see mass divided by volume

Mass divided by length

Denier, 1 denier	$= 1.111\,111 \cdot 10^{-7}$	kg/m

Mass divided by time (includes flow)

Pound per hour, 1 lb/h	$= 1.259\,979 \cdot 10^{-4}$	kg/s

Mass divided by volume (includes mass density and mass concentration)

Grain per gallon (U.S.), 1 gr/gal	= 1.711 806 · 10^{-2}	kg/m^3
Pound per cubic foot, 1 lb/ft^3	= 1.601 846 · 10^{1}	kg/m^3

Moment of force or torque

Cubic foot per minute, 1 ft^3/min	= 4.719 474 · 10^{-1}	L/s
Cubic inch per minute, in^3/min	= 2.731 177 · 10^{-7}	m^3/s
Cubic yard per minute, 1 yd^3/min	= 1.274 258 · 10^{-2}	m^3/s
Gallon (U.S.) per minute (gpm), 1 gal/min	= 6.309 020 · 10^{-5}	m^3/s

Work see **energy**

(*1) The exact conversion factor is $4.535\ 923\ 700 \cdot 10^{-1}$. All units that contain pound refer to the avoirdupois pound.
(*2) Darcy is a unit for expressing the permeability of porous solids, not area.
(*3) One technical atmosphere equals one kilogram-force per square centimeter (1 at = 1 kgf/cm^2).
(*4) Conversion factors for mercury manometer pressure units are calculated using the standard value for the acceleration of gravity and the density of mercury at the stated temperature. Additional digits are not justified because the definitions of the units do not take into account the compressibility of mercury or the change in density caused by the revised practical temperature scale, ITS-90. Similar comments also apply to water manometer pressure units.
(*5) The centigrade temperature scale is obsolete; the degree centigrade is only approximately equal to degree Celsius
(*6) In 1964, the General Conference on Weights and Measures reestablished the name "liter or litre" as a special name for the cubic decimeter. Between 1901 and 1964, liter was slightly larger (1.000 028 dm^3); when one uses high-accuracy volume data of that time, this fact must be kept in mind.

7 SI Prefixes

Decimal multipliers and parts of units can be described by means of prefixes that are written before the names of the units.

Factor	Prefix	Abbreviation
10^{24}	Yotta	Y
10^{21}	Zetta	Z
10^{18}	Exa	E
10^{15}	Peta	P
10^{12}	Tera	T
10^{9}	Giga	G
10^{6}	Mega	M
10^{3}	Kilo	k
10^{2}	Hecto	h
10^{1}	Deca	da
10^{-1}	Deci	d
10^{-2}	Centi	c
10^{-3}	Milli	m
10^{-6}	Micro	μ
10^{-9}	Nano	n
10^{-12}	Pico	p
10^{-15}	Femto	f
10^{-18}	Atto	a
10^{-21}	Zepto	z
10^{-24}	Yocto	y

Fundamentals of Heat Transfer

B1 Fundamentals of Heat Transfer

Peter Stephan
Technische Universität Darmstadt, Darmstadt, Germany

1 Introduction

The term *heat* is defined by the first law of thermodynamics as the energy that is transported across the boundary of a thermodynamic system due to a temperature difference between the system and its surroundings. The first law of thermodynamics in a general form can be written as follows:

$$\Delta E = W + Q + E_{\mathrm{M}}. \tag{1}$$

The right hand side of this equation summarizes the three different forms of energy that can be transported across the system boundary: heat Q, work W, and energy E_{M} that is tied to a mass transport. As a result of such energy transfer across the system boundary the energy inside the system changes by ΔE, written on the left hand side of the equation. The transport process related to the transfer of heat is called *heat transfer*. Applying the second law of thermodynamics, one can derive that heat is always transferred in the direction of decreasing temperature. But thermodynamics does not tell us how the amount of heat transferred depends on this driving temperature difference or temperature gradient. Nor does it tell us how it depends on the geometry of a heat exchanger, or on material or process properties, including the duration of the process. Before these dependencies can be described in detail some general relations and definitions must be given.

The heat transferred per unit of time is referred to as the *heat flow rate* $\dot{Q}$ (SI-unit W),

$$\dot{Q} = \frac{\mathrm{d}Q}{\mathrm{d}t}. \tag{2}$$

The *heat flux* $\dot{q}$ (SI-unit W/m^2) is defined by

$$\dot{q} = \frac{\mathrm{d}\dot{Q}}{\mathrm{d}A} \tag{3}$$

and describes the heat transferred per unit of time and per unit area perpendicular to the heat flow. Generally, three modes of heat transfer are distinguished:

- *Conduction*,
- *Convection*, and
- *Radiation*.

The detailed description of calculation procedures for heat transfer related to all these modes in general and for many specific technical applications is subject of the *VDI Heat Atlas*

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_3,

(Parts E–N). Additionally, fundamental heat exchanger design and construction methods as well as information on material properties are presented (Parts C, D, and O). In the following Chapters of Part B, the fundamentals of the three heat transfer modes and primary rules of calculation procedures are presented and applied in an exemplary manner to some basic configurations. For further details, the reader is referred to the specific parts of the *VDI Heat Atlas*.

2 Heat Transfer Modes and Basic Principles of Their Description

2.1 Heat Conduction

Conduction is the transfer of energy due to molecular interactions between neighbouring molecules caused by their random motion. Thus, heat conduction can take place in solids, liquids, or gases, but it does not require any macroscopic motion or flow of the substance. With increasing temperature the random motion of molecules is intensified, and with this the kinetic energy on the molecular level. Collisions between neighboring molecules cause a transfer of energy from those with higher kinetic energy to those with lower kinetic energy. In metals, the energy transported by free electrons additionally contributes to heat conduction.

Fortunately, we do not need to look closely into the details and statistics of these molecular processes to derive calculation procedures for heat conduction. It is sufficient to know a single material property together with the local driving temperature gradient. Considering a temperature gradient $\partial T/\partial x$ in direction of a coordinate x, the heat flux $\dot{q}$ depends only on the single material property called *thermal conductivity* λ. The relation

$$\dot{q} = -\lambda \frac{\partial T}{\partial x} \tag{4}$$

is well-known as Fourier's law, named after Jean Baptiste Joseph Fourier, who expressed this relation first in 1822 [1]. The minus sign results from the fact that positive heat transfer is directed toward decreasing temperature. For isotropic materials, i.e., materials with equal thermal conductivities in any direction, Fourier's law can be written in vector form as

$$\vec{\dot{q}} = -\lambda \operatorname{grad} T. \tag{5}$$

The thermal conductivity λ [SI-unit W/(K m)] is typically highest for solids, followed by liquids and gases.

For *gases* under normal conditions λ is approximately in the range

$$0.015\,\mathrm{W/(K\,m)} \le \lambda_{\mathrm{gas}} \le 0.15\,\mathrm{W/(K\,m)}$$

with, e.g., hydrogen at the upper end and carbon dioxide at the lower end of the range. The thermal conductivity of air at atmospheric conditions is, e.g., $\lambda_{\mathrm{air}} \approx 0.0246\,\mathrm{W/(K\,m)}$.

For *liquids* (except liquid metals) under normal conditions λ is approximately in the range

$$0.1\,\mathrm{W/(K\,m)} \le \lambda_{\mathrm{liquid}} \le 0.65\,\mathrm{W/(K\,m)}$$

with, e.g., water at the upper end and carbon dioxide or some organic liquids at the lower end of the range. The thermal conductivity of liquid water at atmospheric conditions is, e.g., $\lambda_{\mathrm{water,liq.}} \approx 0.6\,\mathrm{W/(K\,m)}$.

For *solids* under normal conditions λ is approximately in the range

$$1\,\mathrm{W/(K\,m)} \le \lambda_{\mathrm{solid}} \le 450\,\mathrm{W/(K\,m)}$$

with, e.g., metallic materials such as silver and copper at the upper end and nonmetallic materials such as coal, glass, or ice at the lower end of the range. The thermal conductivity of ice (solid water) at 0°C is, e.g., $\lambda_{\mathrm{water,ice}} \approx 2.2\,\mathrm{W/(K\,m)}$, values for some metallic materials are $\lambda_{\mathrm{copper}} \approx 395\,\mathrm{W/(K\,m)}$, $\lambda_{\mathrm{aluminum}} \approx 220\,\mathrm{W/(K\,m)}$, or $\lambda_{\mathrm{st.steel,18Cr8Ni}} \approx 21\,\mathrm{W/(K\,m)}$.

Further data and details such as dependency on temperature or pressure can be found in Part D.

2.2 Convective Heat Transfer

Convection refers to the heat transport mode in a macroscopically flowing fluid. It is a superposition of conductive heat transport in the fluid and the energy transport due to the macroscopic movement of the fluid, which includes the transport of enthalpy and kinetic energy. Thus, convective heat flux depends not only on material properties, but also on process properties, such as, e. g., fluid velocity.

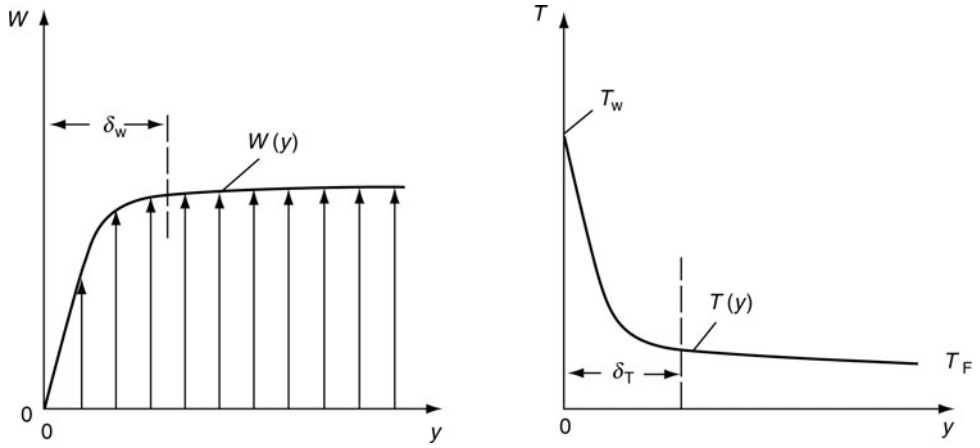
For the design of technical devices the descriptions of convective heat transfer from a moving bulk fluid to the solid fluid boundary (wall) or vice versa are of special interest. A situation with a bulk fluid temperature T_{F}, a bulk fluid velocity w_{F} parallel to the wall, and a wall temperature T_{W}, will result in a velocity and a temperature profile in the fluid near the wall as shown in Fig. 1 where y is the direction normal to the wall. The near wall region with high velocity gradients and high temperature gradients are known as *velocity boundary layer* and *temperature boundary layer*. The underlying *boundary layer theory* was formulated first by Prandtl [2].

The convective heat transport normal to the wall in this boundary layer is directed towards the lower temperature, thus for $T_{\mathrm{F}} > T_{\mathrm{W}}$ the wall is heated by the fluid, for $T_{\mathrm{F}} < T_{\mathrm{W}}$ the wall is cooled by the fluid. The heat flux $\dot{q}$ depends on the temperature difference but also on the temperature and velocity profiles in the boundary layer, which can be very complex and even nonstationary, e.g., for turbulent boundary layer flows. However, the simple relation

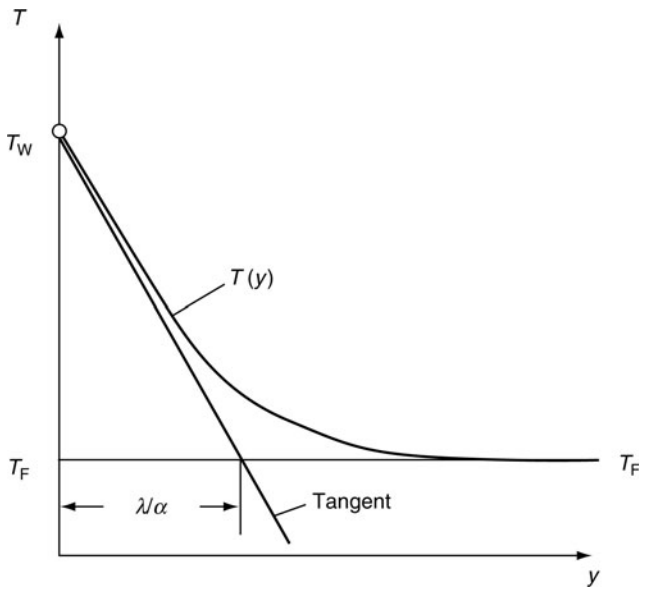
$$\dot{q} = \alpha(T_{\mathrm{W}} - T_{\mathrm{F}}) \tag{6}$$

allows to calculate the heat flux. Herein, α is the *heat transfer coefficient* [SI-unit $\mathrm{W/(m^2K)}$]. This quantity depends on the relevant fluid and process properties as well as geometrical configurations of the wall or surface roughness, etc.

The thickness of the thermal boundary layer δ_{T} can be approximated as the thickness of a fictitious nonmoving fluid layer adjacent to the wall that results in the same heat flux as the convective one given by Eq. (6). Figure 2 demonstrates this relationship. The temperature profile caused by convective heat transfer is approximated by a linear temperature drop $T_{\mathrm{W}} - T_{\mathrm{F}}$ in the fictitious nonmoving fluid layer and a constant



B1. Fig. 1. Boundary layers (left: velocity, right: temperature).



B1. Fig. 2. Thickness $\delta_T \approx \lambda/\alpha$ of the thermal boundary layer.

fluid temperature T_F outside. As the fluid is definitely at rest at the wall surface ($y = 0$) due to the nonslip condition Fourier's law for conduction [Eq. (4)] delivers the relation between heat flux and temperature gradient at the wall surface:

$$\dot{q} = -\lambda \left.\frac{\partial T}{\partial y}\right|_{y=0} . \tag{7}$$

Comparing Eqs. (6) and (7) the thickness of the fictitious nonmoving fluid layer adjacent to the wall follows as λ/α, where λ is the thermal conductivity of the fluid. With this the heat transfer coefficient can also be interpreted as

$$\alpha = -\lambda \frac{\left.\frac{\partial T}{\partial y}\right|_{y=0}}{T_W - T_F} \tag{8}$$

and the thermal boundary layer thickness can be approximated by $\delta_T \approx \lambda / \alpha$.

Based on this theoretical approach the heat transfer coefficient α can be determined for some special cases. However, in general it is determined experimentally and correlations for many technical configurations were derived from such experiments. The basis for the description of the heat transfer coefficient is the use of *similarity methods*.

These descriptions allow the considerable reduction of the number of influencing parameters and for the expression of the general heat transfer laws for geometrically similar bodies and different substances. For this purpose a dimensionless heat transfer coefficient, called *Nusselt number* named after Wilhelm Nusselt, who first formulated dimensionless numbers in this context [3], is defined by

$$\mathrm{Nu} = \frac{\alpha L}{\lambda}, \tag{9}$$

where L is a characteristic length of the system and λ the thermal conductivity of the fluid. To derive correlations for the Nusselt number two situations have to be distinguished: *forced convection* and *natural convection*.

In forced convection, the fluid motion is caused by outer forces, e.g., by the pressure increase in a pump. In natural convection, the fluid motion is caused by density differences in the fluid and the corresponding buoyancy effects in a gravitational field. These density differences usually arise due to temperature differences, rarely due to pressure differences. In mixtures, density differences are also caused by concentration differences.

The flow characteristics in forced convection are generally described by the *Reynolds number*

$$\mathrm{Re} = \frac{w L}{\nu}, \tag{10}$$

where w is the bulk fluid velocity and ν the kinematic viscosity of the fluid.

The flow characteristics in natural convection are generally described by the *Grashof number*

$$\mathrm{Gr} = \frac{L^3 g \beta \Delta T}{\nu^2}, \tag{11}$$

where g is the gravitational acceleration, β the thermal volume expansion coefficient at a reference temperature [typically, $(T_W + T_F)/2$], and $\Delta T = T_W - T_F$ the difference between wall and bulk fluid temperature.

Further some fluid properties can be summarized in the dimensionless form of a *Prandtl number*

$$\mathrm{Pr} = \frac{v}{a}, \tag{12}$$

where $a = \lambda/(\rho\, c_\mathrm{p})$ is the thermal diffusivity, ρ the density, and c_p the constant pressure specific heat.

Based on these dimensionless numbers the heat transfer coefficient α can be expressed by correlations in the following form:

$$\mathrm{Nu} = f_1(\mathrm{Re}, \mathrm{Pr}) \tag{13}$$

for forced convection and

$$\mathrm{Nu} = f_2(\mathrm{Gr}, \mathrm{Pr}) \tag{14}$$

for natural convection.

Typical values of α for different situations are:

2–25	W/m^{2}K	For free convection in gases
10–1,000	W/m^{2}K	For free convection in liquids
25–250	W/m^{2}K	For forced convection in gases
50–20,000	W/m^{2}K	For forced convection in liquids
2,500–100,000	W/m^{2}K	For boiling and condensing fluids

2.3 Thermal Radiation

The energy emitted by any matter to its surroundings in the form of electromagnetic waves is called *radiation*. Unlike conduction or convection the energy transport from a location A to a location B by radiation is not bounded to any interlinking transport medium because electromagnetic waves can travel through a vacuum.

Every matter or body emits radiation corresponding to its surface temperature (To be more precise one should write "Every matter or body with $T > 0$ K emits ...," but as known from thermodynamics other bodies do not exist.). The maximum radiation possible for a given temperature is emitted by a *black body*. A black body can be experimentally approximated by a blackened surface (e.g., with soot) or by a hollow space, whose walls have the same temperature everywhere, that has a small opening to let radiation out. The total radiation emitted by a black body per unit area is

$$\dot{e}_\mathrm{b} = \sigma\, T^4, \tag{15}$$

where $\dot{e}_\mathrm{b}$ is the energy emitted per unit surface area of the black radiator (SI-unit W/m^2), simply called the *emission*, and $\sigma = 5.67 \times 10^{-8}$ W/(m^{2}K^4) is the *radiation coefficient*, also called the *Stefan–Boltzmann constant*. The above relation is called the *Stefan–Boltzmann law*. It was found 1879 by Josef Stefan as a result of many experiments and later in 1884 derived theoretically by his scholar Ludwig Boltzmann [4].

The emission $\dot{e}_\mathrm{b}$ is an energy flux and thus the related heat flux emitted by a black body follows as

$$\dot{q}_\mathrm{b} = \dot{e}_\mathrm{b} = \mathrm{d}\dot{Q}_\mathrm{b}/\mathrm{d}A. \tag{16}$$

The radiation emitted by *real surfaces* is less than the radiation emitted by a black body at the same temperature. The reduced radiative energy or heat flux of a real body $\dot{e}$ compared to a black body is expressed by

$$\dot{e} = \varepsilon \cdot \dot{e}_\mathrm{b} = \varepsilon \cdot \sigma\, T^4, \tag{17}$$

where ε is the *emissivity* of the real surface with $0 \le \varepsilon \le 1$. The emissivity is generally a function of the surface material. It can also be a function of the surface morphology, its temperature, the direction of the radiation, and the wave length of the radiation. However, many surfaces can be treated in good approximation as *grey bodies*, which are defined by $\varepsilon = \text{const}$. Typical values for the emissivity are: $\varepsilon \approx 0.96$ for dead oxidized steel, $\varepsilon \approx 0.3$ for polished steel, $\varepsilon \approx 0.04$ for polished aluminium. Further values are given in Part K.

3 Heat Conduction and Overall Heat Resistances

3.1 One-Dimensional, Steady State Heat Conduction Through a Wall

The heat conduction through a wall under steady state conditions can be analyzed on the basis of Fourier's law [see Eqs. (4) or (5)]. For simple geometries, such as a plane wall or a tube wall, and one-dimensional heat transfer analytical solutions can be derived.

3.1.1 Conduction Through a Plane Wall

If different temperatures T_1 and T_2 are prescribed on two surfaces of a plane wall with the thickness δ, according to Fourier's law the heat

$$Q = \lambda A \frac{T_1 - T_2}{\delta}\, t \tag{18}$$

flows through the area A in the time t. The heat flow rate follows as

$$\dot{Q} = \lambda A \frac{T_1 - T_2}{\delta} \tag{19}$$

and the heat flux as

$$\dot{q} = \lambda \frac{T_1 - T_2}{\delta}. \tag{20}$$

Similar to electric conduction, where a current I flows only when a voltage U exists to overcome the resistance R_el, heat flows only when a temperature difference $\Delta T = T_1 - T_2$ exists:

$$\dot{Q} = \frac{\lambda A}{\delta} \Delta T. \tag{21}$$

Ohm's law for an electrical current flow says $I = U/R_\mathrm{el}$. Analogous to the electrical resistance R_el one can define a *thermal resistance* or *heat resistance*, which is defined by

$$R = \frac{\Delta T}{\dot{Q}} \tag{22}$$

in general (SI-unit K/W). In the case considered above, conduction through the plane wall, the *conductive heat resistance* follows as

$$R_{\text{cond}} = \frac{\delta}{\lambda A}. \tag{23}$$

3.1.2 Conduction Through a Tube Wall

According to Fourier's law, the heat flow rate through a cylindrical area of radius r and length L is

$$\dot{Q} = -\lambda 2\pi r L \frac{\mathrm{d}T}{\mathrm{d}r}. \tag{24}$$

Under steady state conditions, the heat flow rate is the same for all radii and thus $\dot{Q} = \text{const}$. It is therefore possible to separate the variables T and r and to integrate from the inner surface of the cylinder, $r = r_\text{i}$ with $T = T_\text{i}$, to an arbitrary location r with temperature T. The temperature profile in a tube wall of thickness $r - r_\text{i}$ becomes

$$T_\text{i} - T = \frac{\dot{Q}}{\lambda 2\pi L} \ln \frac{r}{r_\text{i}}. \tag{25}$$

With temperature T_o at the outer surface at radius r_o, the heat flow rate through a tube of thickness $r_\text{o} - r_\text{i}$ and length L becomes

$$\dot{Q} = \lambda\, 2\pi\, L \frac{T_\text{i} - T_\text{o}}{\ln(r_\text{o}/r_\text{i})}. \tag{26}$$

In order to get formal agreement with Eq. (19), it is also possible to write

$$\dot{Q} = \lambda A_\text{m} \frac{T_\text{i} - T_\text{o}}{\delta} \tag{27}$$

where $\delta = r_\text{o} - r_\text{i}$ and $A_\text{m} = \frac{A_\text{o} - A_\text{i}}{\ln(A_\text{o}/A_\text{i})}$, if $A_\text{o} = 2\pi r_\text{o} L$ is the outer and $A_\text{i} = 2\pi r_\text{i} L$ is the inner surface of the tube. A_m is the logarithmic mean between outer and inner tube surface.

With this the thermal resistance of the tube can be derived as $R_{\text{cond}} = \delta/(\lambda A_\text{m})$ or

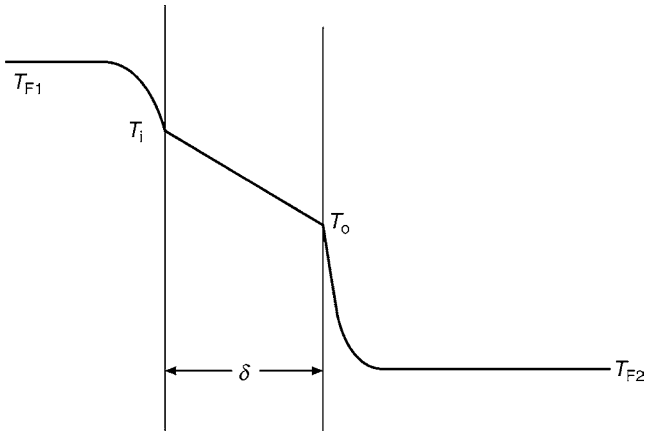
$$R_{\text{cond}} = \frac{\ln(r_\text{o}/r_\text{i})}{\lambda\, 2\pi L}. \tag{28}$$

3.2 Heat Transmission, Overall Heat Resistances, and Overall Heat Transfer Coefficients

Heat transmission through a plane wall

If heat is transferred from a fluid at bulk temperature T_{F1} to a wall by convection, conducted through the wall to the other side, and then transferred to a second fluid at bulk temperature T_{F2}, this process is called *heat transmission* through a wall. The related temperature profile for the case of a plane wall is plotted in Fig. 3.

In case of one-dimensional heat transfer perpendicular to the wall, as assumed above in Sect. 3.1, the two convective heat



B1. Fig. 3. Heat transmission through a plane wall.

transfer processes and the heat conduction process are connected in series. Thus, analogous to electrical resistances, one can add the individual thermal resistances and thereby write an equation for an *overall heat resistance* as

$$R = \frac{1}{\alpha_\text{i} A} + \frac{\delta}{\lambda A} + \frac{1}{\alpha_\text{o} A} \tag{29}$$

with the two *convective heat resistances* defined by

$$R_{\text{conv}} = \frac{1}{\alpha A}. \tag{30}$$

The heat flow passing through the plane wall then can be written as

$$\dot{Q} = \frac{T_{\text{F1}} - T_{\text{F2}}}{R} \tag{31}$$

or

$$\dot{Q} = k A (T_{\text{F1}} - T_{\text{F2}}) \tag{32}$$

with the quantity k called the *overall heat transfer coefficient* or *heat transmission coefficient* [SI-unit W/(m^{2}K)]. It follows

$$R = \frac{1}{k A}. \tag{33}$$

If the wall consists of several homogeneous layers with thicknesses $\delta_1, \delta_2, \ldots$ and thermal conductivities $\lambda_1, \lambda_2, \ldots$, Eq. (29) holds likewise with the overall heat resistance

$$R = \frac{1}{k A} = \frac{1}{\alpha_\text{i} A} + \sum_j \frac{\delta_j}{\lambda_j A} + \frac{1}{\alpha_\text{o} A}. \tag{34}$$

Of course this analogy to electrical resistances is not restricted to serial circuits but hold also for parallel circuits. In case of parallel heat conduction resistances under the assumption of one-dimensional heat transfer, e.g., the overall heat conduction resistance yields

$$\frac{1}{R} = \frac{1}{\sum_j R_j} = \frac{1}{\sum_j \frac{\delta_j}{\lambda_j A_j}}. \tag{35}$$

Example:

The wall of a cold store consists of a 5 cm thick internal concrete layer [λ = 1 W/(K m)], a 10 cm thick cork stone insolation [λ = 0.04 W/(K m)], and a 50 cm thick external brick wall. The

inner heat transfer coefficient is $\alpha_i = 7\,\mathrm{W/(m^2K)}$ and the outer one $\alpha_o = 20\,\mathrm{W/(m^2K)}$. What is the heat flow rate through 1 $\mathrm{m^2}$ of the wall if the temperatures inside and outside are –5°C and 25°C, respectively?

According to Eq. (34) the overall heat resistance is

$$\frac{1}{kA} = \left(\frac{1}{7\cdot 1} + \frac{0.05}{1\cdot 1} + \frac{0.1}{0.04\cdot 1} + \frac{0.5}{0.75\cdot 1} + \frac{1}{20\cdot 1}\right)\mathrm{K/W} = 3.41\,\mathrm{K/W}$$

The heat flow is $\dot{Q} = \frac{1}{3.41}(-5-25)\,\mathrm{W}$, $|\dot{Q}| = 8.8\,\mathrm{W}$.

3.2.1 Heat Transmission Through a Tube Wall

For one-dimensional heat transmission through tubes, Eqs. (31) and (32) again hold, where the heat resistance is the sum of the individual resistances

$$R = \frac{1}{kA} = \frac{1}{\alpha_i A_i} + \frac{\delta}{\lambda A_m} + \frac{1}{\alpha_o A_o}, \tag{36}$$

where $\delta = r_o - r_i$ and $A_m = \frac{A_o - A_i}{\ln(A_o/A_i)}$ with the outer and inner tube surfaces A_o and A_i, respectively. It becomes obvious that the overall heat transfer coefficient k must be related to a single surface A. This is usually the outer tube surface $A = A_o$, which is often easier to determine.

If the tube consists of several homogeneous layers with thicknesses δ_1, δ_2, ... and thermal conductivities λ_1, λ_2, ... Eq. (34) holds likewise with the overall heat resistance

$$R = \frac{1}{kA} = \frac{1}{\alpha_i A_i} + \sum_j \frac{\delta_j}{\lambda_j A_{mj}} + \frac{1}{\alpha_o A_o}. \tag{37}$$

With the mean logarithmic areas $A_{mj} = (A_{oj} - A_{ij})/\ln(A_{oj}/A_{ij})$.

3.3 Transient Heat Conduction

During transient heat conduction, the temperatures vary with respect to time. Assuming constant thermal conductivity (isotropy) Fourier's heat conduction equation follows as

$$\frac{\partial T}{\partial t} = a\,\nabla^2 T + \dot{q}_s \tag{38}$$

with the volumetric heat source term $\dot{q}_s$ (SI-unit $\mathrm{W/m^3}$) and the quantity a which is a material property and defined as *thermal diffusivity* $a = \lambda/(\rho c)$ (SI-unit $\mathrm{m^2/s}$).

The Laplace operator yields

$$\nabla^2 T = \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}$$

for Cartesian coordinates,

$$\nabla^2 T = \frac{1}{r}\frac{\partial}{\partial r}\left(r\frac{\partial T}{\partial r}\right) + \frac{1}{r^2}\frac{\partial^2 T}{\partial \varphi^2} + \frac{\partial^2 T}{\partial z^2}$$

for cylindrical coordinates, and

$$\nabla^2 T = \frac{1}{r^2}\frac{\partial}{\partial r}\left(r^2\frac{\partial T}{\partial r}\right) + \frac{1}{r^2\sin^2\Theta}\frac{\partial^2 T}{\partial \varphi^2} + \frac{1}{r^2\sin\Theta}\frac{\partial}{\partial \Theta}\left(\sin\Theta\frac{\partial T}{\partial \Theta}\right)$$

for polar coordinates.

For plane walls with heat flow in the direction of the x-axis and no heat source, Eq. (38) reduces to

$$\frac{\partial T}{\partial t} = a\,\frac{\partial^2 T}{\partial x^2}. \tag{39}$$

Thus, in a plane wall with prescribed surface temperatures, the temperature profile is no longer linear as the heat transfer into the wall differs from the heat transfer out. The difference between heat transfer in and out increases (or decreases) the internal energy of the wall and thus, its temperature as a function of time.

For the solution of Fourier's equation, it is suitable to introduce – as in other heat transfer problems – dimensionless quantities, which reduce the number of variables. Equation (39) is considered in order to demonstrate the basic procedure. The dimensionless temperature is set to $\Theta = (T - T_c)/(T_0 - T_c)$, where T_c is a characteristic constant temperature and T_0 the initial temperature. If the cooling of a plate with an initial temperature T_0 in a cold environment is considered, T_c could be, for example, the ambient temperature T_{env}. All lengths are related to a characteristic length X, e.g., half of the plate thickness. Furthermore, it is suitable to introduce the dimensionless time, which is called *Fourier number*, as $\mathrm{Fo} = at/X^2$. The solution of the heat conduction equation then has the dimensionless form

$$\Theta = f(x/X, \mathrm{Fo}). \tag{40}$$

In many problems, the heat conducted internally to the surface of a solid body is transferred by convection to the surrounding fluid of temperature T_{env}. The energy balance then holds at the surface (index w = wall)

$$-\lambda\left(\frac{\partial T}{\partial x}\right)_w = \alpha\,(T_w - T_{env}) \tag{41}$$

or

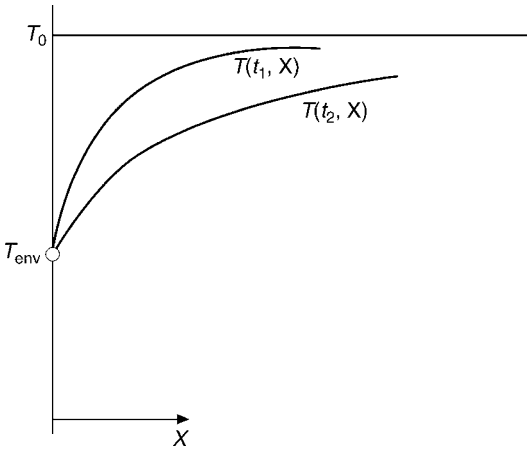
$$\frac{1}{\Theta_w}\left(\frac{\partial \Theta}{\partial \xi}\right)_w = -\frac{\alpha X}{\lambda}, \tag{42}$$

where $\xi = x/X$, $\Theta = (T - T_{env})/(T_0 - T_{env})$ and $\Theta_w = (T_w - T_{env})/(T_0 - T_{env})$. The solution is also a function of the dimensionless quantity $\alpha X/\lambda$, which is defined as the *Biot number* Bi, where the thermal conductivity λ of the solid body is assumed to be constant, and α is the heat transfer coefficient between the body and surrounding fluid. Solutions of Eq. (39) considering the Biot number have the form

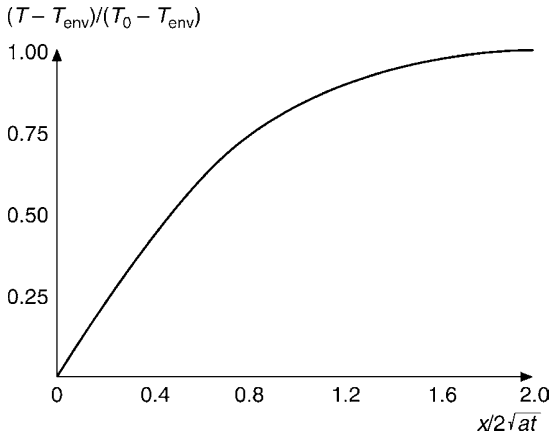
$$\Theta = f(x/X, \mathrm{Fo}, \mathrm{Bi}). \tag{43}$$

3.3.1 Semi-Infinite Body

Temperature changes may also take place in a region that is thin in comparison to the overall dimensions of the body. Such a body is called semi-infinite. In this case, a semi-infinite plane wall (Fig. 4) with a constant initial temperature T_0 is considered. At time $t = 0$, the surface temperature of the wall is reduced to $T(x = 0) = T_{env}$ and then remains constant. The temperature



B1. Fig. 4. Semi-infinite body.



B1. Fig. 5. Temperature profile in a semi-infinite body.

profiles normal to the surface at different times t_1, t_2. ... are given by:

$$\frac{T - T_{env}}{T_0 - T_{env}} = f\left(\frac{x}{2\sqrt{a\,t}}\right) \tag{44}$$

with the Gaussian error function $f\left(x/\left(2\sqrt{a\,t}\right)\right)$, see Fig. 5. The heat flux at the surface results from the differentiation $\dot{q} = -\lambda(\partial T/\partial x)_{x=0}$ which yields

$$\dot{q} = \frac{b}{\sqrt{\pi\,t}}\,(T_{env} - T_0). \tag{45}$$

The heat penetration coefficient $b = \sqrt{\lambda\rho c}$ [SI-unit W $s^{1/2}$/(m^2K)], is a measure for the heat transfer that has penetrated into the body at a given time if the surface temperature was suddenly changed by the amount $T_{env} - T_0$ as compared to the initial temperature T_0. Some typical values for b are: approximately 36,000 W $s^{1/2}$/(m^2K) for copper, 1,600 W $s^{1/2}$/(m^2K) for concrete, 1,400 W $s^{1/2}$/(m^2K) for water, or 6 W $s^{1/2}$/(m^2K) for gases. For details see Part D.

Example:

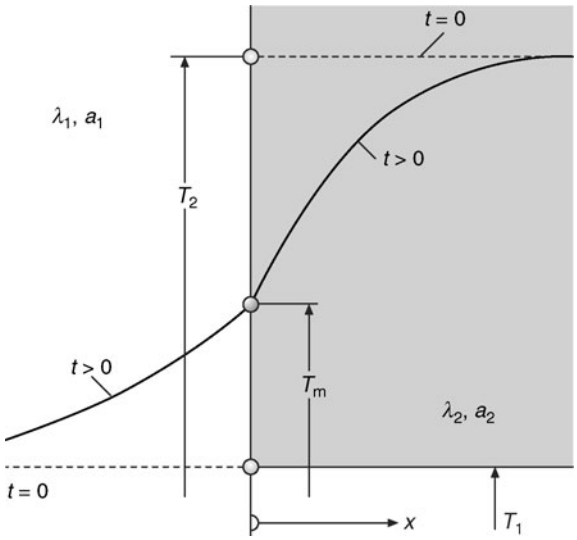
A sudden change in weather causes the temperature at the earth's surface to drop from +5 to –5°C. How much does the temperature decrease at a depth of 1 m after 20 days? The thermal diffusivity of the soil is $a = 6.94 \times 10^{-7}$ m/s. According to Eq. (44), the decrease is:

$$\frac{T - (-5)}{5 - (-5)} = f\left(\frac{1}{2(6.94 \times 10^{-7} \cdot 20 \cdot 24 \cdot 3{,}600)^{1/2}}\right) = f(0.456)$$

Figure 5 gives $f(0.456) = 0.48$, thus, $T = -0.2$°C.

3.3.2 Finite Heat Transfer at the Surface

Let us assume, heat transfer is by convection from the surface of a body to the fluidic environment. At the surface, the relation $\dot{q} = -\lambda(\partial T/\partial x) = \alpha(T_w - T_{env})$ holds, with the ambient temperature T_{env} and the time dependent variable wall temperature $T_w = T(x = 0)$. In this case, Eqs. (44) and (45) no longer hold. Instead, the heat flux is given by



B1. Fig. 6. Contact temperature T_m between two semi-infinite bodies.

$$\dot{q} = \frac{b}{\sqrt{\pi\,t}}\,(T_{env} - T_0)\,\Phi(z), \tag{46}$$

where

$$\Phi(z) = 1 - \frac{1}{2z^2} + \frac{1 \cdot 3}{2^2 z^4} - \cdots + (-1)^{n-1}\frac{1 \cdot 3 \ldots (2n-3)}{2^{n-1} z^{2n-2}}$$

and $z = \alpha\sqrt{a\,t}/\lambda$.

3.3.3 Two Semi-Infinite Bodies in Thermal Contact

Two semi-infinite bodies of different, but initially constant, temperatures T_1 and T_2 with the thermal properties λ_1, a_1 and λ_2, a_2 are suddenly brought into contact at time $t = 0$ (Fig. 6). After a very short time at both sides of the contact area, a temperature T_m is present and remains constant. This temperature is given by:

$$\frac{T_m - T_1}{T_2 - T_1} = \frac{b_2}{b_1 + b_2}. \quad (47)$$

The contact temperature T_m is closer to the temperature of the body with the higher heat penetration coefficient b. One of the values b can be determined by measuring T_m, if the other value is known.

3.3.4 Temperature Equalization in Simple Bodies

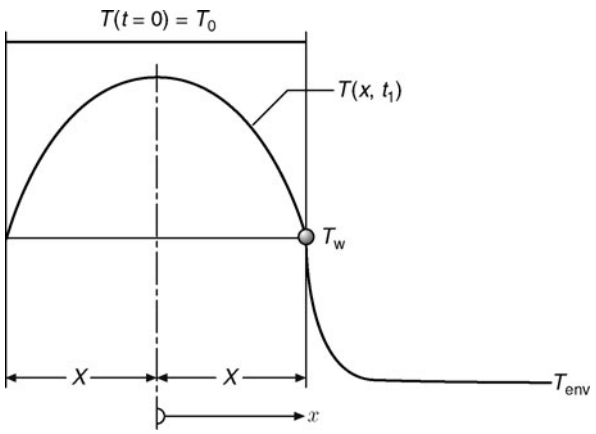
A simple body such as a plate, a cylinder, or a sphere may have a uniform temperature T_0 at time $t = 0$. Afterwards, however, it is cooled or heated due to heat transfer between the body and a surrounding fluid of temperature T_{env} given by the boundary condition $-\lambda(\partial T/\partial n)_w = \alpha(T_w - T_{env})$, where n is the coordinate perpendicular to the body surface.

3.3.5 Plane Plate

The temperature profile shown in Fig. 7 is described by an infinite series. However, for Fourier numbers (or dimensionless times) $at/X^2 \geq 0.24$, the following relation provides a good approximation

$$\frac{T - T_{env}}{T_0 - T_{env}} = C \exp\left(-\delta^2 \frac{at}{X^2}\right) \cos\left(\delta \frac{x}{X}\right) \quad (48)$$

with less than a 1% error in temperature. The constants C and δ depend, according to Table 1, on the Biot number $Bi = \alpha X/\lambda$. Where $x = X$, Eq. (48) leads to the surface temperature T_w at the wall, and x = 0 leads to the temperature in the center of the wall. The heat transfer rate follows from $\dot{Q} = -\lambda A(\partial T/\partial x)_{x=X}$.



B1. Fig. 7. Cooling of a plane plate.

3.3.6 Cylinder

The radial coordinate r replaces coordinate x in Fig. 7, and the radius of the cylinder is R. Again, the temperature profile is described by an infinite series, which can be approximated for Fourier numbers $at/R^2 \geq 0.21$ by

$$\frac{T - T_{env}}{T_0 - T_{env}} = C \exp\left(-\delta^2 \frac{at}{R^2}\right) I_0\left(\delta \frac{r}{R}\right) \quad (49)$$

with less than 1% error. The term I_0 is a Bessel function of zeroth order. Its values are presented in tables in many textbooks for mathematics, e.g., in [5]. The constants C and δ depend, according to Table 2, on the Biot number. When $r = R$, the surface temperature at the cylinder results from Eq. (49), and for r = 0 the temperature in the center of the cylinder. The heat transfer rate results from $\dot{Q} = -\lambda A(\partial T/\partial r)_{r=R}$, where the first derivative of the Bessel function $I_0' = I_1$ appears. The Bessel function of first order I_1 is also given in [5].

3.3.7 Sphere

The cooling or heating of a sphere of radius R is also described by an infinite series. For Fourier numbers $a\,t/R^2 \geq 0.18$, temperature profile can be approximated by:

$$\frac{T - T_{env}}{T_0 - T_{env}} = C \exp\left(-\delta^2 \frac{at}{R^2}\right) \frac{\sin\left(\delta \frac{r}{R}\right)}{\delta \frac{r}{R}} \quad (50)$$

with less than 2% error. The constants C and δ depend, according to Table 3, on the Biot number.

4 Convective Heat Transfer and Nusselt Numbers

The desired convective heat transfer coefficient α in $\dot{q} = \alpha\Delta T$ is obtained from the Nusselt number [Eq. (9)] by $\alpha = Nu\lambda/L$ with Eq. (13)

$$Nu = f_1(Re, Pr)$$

for forced convection and Eq. (14)

$$Nu = f_2(Gr, Pr)$$

for natural convection. As stated above in Sect. 2.2, the heat transfer coefficient α and also the functions f_1 and f_2 can be determined theoretically only for special cases. In general, they must be determined through experimentation and depend on the shape of the cooling or heating areas (even, vaulted, smooth, rough, or finned), the flow structure, and usually to a minor extent, on the direction of the heat transfer (heating or cooling).

In the following some frequently encountered configurations are presented in an *exemplary manner*. Further details, configurations and related Nusselt correlations including references are given in Parts F–J.

4.1 Single Phase Forced Convection

4.1.1 Laminar Flow Along a Flat Plate

According to Pohlhausen, for the mean Nusselt number of a plate of length L, the following relation holds

$$\mathrm{Nu} = 0.664\,\mathrm{Re}^{1/2}\,\mathrm{Pr}^{1/3}, \tag{51}$$

where $\mathrm{Nu} = \alpha L/\lambda$, $\mathrm{Re} = wL/\nu < 10^5$, and $0.6 \le \mathrm{Pr} \le 2{,}000$. The material properties must be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} - T_\infty)/2$, where T_w is the wall temperature and T_∞ the free-stream temperature far beyond the wall surface.

4.1.2 Turbulent Flow Along a Flat Plate

From about $\mathrm{Re} = 5 \times 10^5$ the boundary layer becomes turbulent. The mean Nusselt number of a plate of length L in this case is

$$\mathrm{Nu} = \frac{0.037\,\mathrm{Re}^{0.8}\,\mathrm{Pr}}{1 + 2.443\,\mathrm{Re}^{-0.1}\left(\mathrm{Pr}^{2/3} - 1\right)}, \tag{52}$$

where $\mathrm{Nu} = \alpha L/\lambda$, $\mathrm{Re} = wL/\nu$, $5 \times 10^5 < \mathrm{Re} < 10^7$ and $0.6 \le \mathrm{Pr} \le 2{,}000$. The material properties must be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} + T_\infty)/2$. T_w is the wall temperature and T_∞, the free-stream temperature far beyond the wall surface.

4.1.3 Flow Through Pipes in General

Below a Reynolds number of Re = 2,300 ($\mathrm{Re} = wd/\nu$, where w is the mean cross-sectional velocity and d is the pipe diameter), the flow is laminar, while above $\mathrm{Re} = 10^4$, the flow is turbulent. In the range $2{,}300 < \mathrm{Re} < 10^4$, whether the flow is laminar or turbulent depends on the roughness of the pipe, the means of inflow, and the shape of the pipe in the inflow section. The mean heat transfer coefficient α over the pipe length L is defined by $\dot{q} = \alpha \Delta T_\mathrm{m}$, with the mean logarithmic temperature difference described by

$$\Delta T_\mathrm{m} = \frac{(T_\mathrm{w} - T_\mathrm{in}) - (T_\mathrm{w} - T_\mathrm{out})}{\ln \frac{T_\mathrm{w} - T_\mathrm{in}}{T_\mathrm{w} - T_\mathrm{out}}}, \tag{53}$$

where T_w is the wall temperature, T_in is the temperature at the inlet, and T_out is the temperature at the outlet cross section.

4.1.4 Laminar Flow Through Pipes

A flow is termed hydrodynamically developed if the velocity profile no longer changes in flow direction. In a laminar flow of a highly viscous fluid, the velocity profile adopts the shape of a Poiseuillean parabola after only a short distance from the inlet. The mean Nusselt number at constant wall temperature can be calculated exactly via an infinite series (Graetz solution), which, however, converges poorly. According to Baehr and Stephan [4], as an approximate solution for the hydrodynamically developed laminar flow, the following equation holds

$$\mathrm{Nu}_0 = \frac{3.657}{\tanh(2.264X^{1/3} + 1.7X^{2/3})} + \frac{0.0499}{X}\tanh X, \tag{54}$$

where $\mathrm{Nu}_0 = \alpha_0 d/\lambda$, $X = L/(d\,\mathrm{Re}\,\mathrm{Pr})$, $\mathrm{Re} = wd/\nu$, and $\mathrm{Pr} = \nu/a$. This equation is valid for laminar flow ($\mathrm{Re} \le 2{,}300$) in the entire range $0 \le X \le \infty$ and the maximum deviation from the exact values of the Nusselt number is 1%. The fluid properties must be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} + T_\mathrm{B})/2$ where $T_\mathrm{B} = (T_\mathrm{in} + T_\mathrm{out})/2$.

If a fluid enters a pipe at an approximately constant velocity, the velocity profile changes along the flow path until it reaches the Poiseuillean parabola after a distance L_entry described by the equation $L_\mathrm{entry}/(d\,\mathrm{Re}) = 5.75 \times 10^{-2}$. According to [4], for this case, that of a hydrodynamically developed laminar flow, the following equation holds for the range $0.1 \le \mathrm{Pr} \le \infty$

$$\frac{\mathrm{Nu}}{\mathrm{Nu}_0} = \frac{1}{\tanh\left(2.43\,\mathrm{Pr}^{1/6}\,X^6\right)}, \tag{55}$$

where $\mathrm{Nu} = \alpha d/\lambda$ and the quantities are defined as above. The error is less than 5% for $1 \le \mathrm{Pr} \le \infty$ but is up to 10% for $0.1 \le \mathrm{Pr} \le 1$. The fluid properties must be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} + T_\mathrm{B})/2$ where $T_\mathrm{B} = (T_\mathrm{in} + T_\mathrm{out})/2$.

4.1.5 Turbulent Flow Through Pipes

For a hydrodynamically developed flow ($L/d \geq 60$) the following equation holds in the range $10^4 \leq \mathrm{Re} \leq 10^5$ and $0.5 \leq \mathrm{Pr} \leq 100$,

$$\mathrm{Nu} = 0.024\,\mathrm{Re}^{0.8}\,\mathrm{Pr}^{1/3}\,. \tag{56}$$

The fluid properties have to be evaluated at the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{w} + T_\mathrm{B})/2$ where $T_\mathrm{B} = (T_\mathrm{in} + T_\mathrm{out})/2$.

For hydrodynamically undeveloped flow and for developed flow, Petukhov's equation (modified by Gnielinski) holds in the range $10^4 \leq \mathrm{Re} \leq 10^6$ and $0.6 \leq \mathrm{Pr} \leq 1{,}000$,

$$\mathrm{Nu} = \frac{\mathrm{Re}\,\mathrm{Pr}\,\zeta/8}{1 + 12.7\sqrt{\zeta/8}\,(\mathrm{Pr}^{2/3} - 1)}\left[1 + \left(\frac{d}{L}\right)^{2/3}\right], \tag{57}$$

where the friction factor $\zeta = (0.78\ln\mathrm{Re} - 1.5)^{-2}$, $\mathrm{Nu} = \alpha d/\lambda$, and $\mathrm{Re} = wd/\nu$. The fluid properties must be evaluated at the mean temperature $T_\mathrm{m} = (T_\mathrm{w} + T_\mathrm{B})/2$. Under otherwise similar conditions, the heat transfer coefficients are larger in pipe bends than in straight pipes with the same cross section. For a pipe bend with a bend diameter D, he following equation holds, according to Hausen, for turbulent flow

$$\alpha = \alpha_\mathrm{straight}\left[1 + \left(21\,\mathrm{Re}^{0.14}\right)(d/D)\right]. \tag{58}$$

4.1.6 Single Pipe Placed Transversely in a Flow

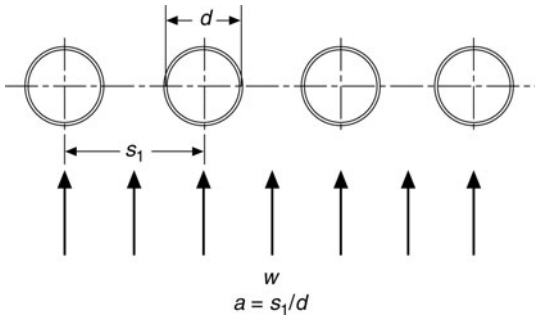
The heat transfer coefficient for a pipe placed transversely in a flow can be determined from Gnielinski's equation

$$\mathrm{Nu} = 0.3 + \left(\mathrm{Nu}_\mathrm{lam}^2 + \mathrm{Nu}_\mathrm{turb}^2\right)^{1/2}, \tag{59}$$

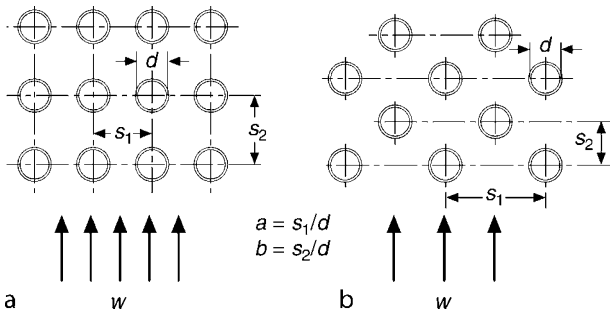
where the Nusselt number Nu_lam of the laminar plate flow is described according to Eq. (51), $\mathrm{Nu}_\mathrm{turb}$ of the turbulent plate flow is described according to Eq. (52), and $\mathrm{Nu} = \alpha L/\lambda$, $1 < \mathrm{Re} = wL/\nu < 10^7$, and $0.6 < \mathrm{Pr} < 1{,}000$. For length L, the overflowed length $L = d\pi/2$ must be inserted. The fluid properties must be evaluated at the mean temperature $T_\mathrm{m} = (T_\mathrm{in} + T_\mathrm{out})/2$. This equation holds for mean turbulence intensities of 6–10%, which can be expected in technical applications.

4.1.7 Row of Pipes Placed Transversely in a Flow

Mean heat transfer coefficients for a single row of pipes placed transversely in a flow (Fig. 8) can also be determined using Eq. (59). Now, however, the Reynolds number must be calculated with the mean velocity w_m in the pipe row placed transversely in the flow. The Reynolds number is described by the equation: $\mathrm{Re} = w_\mathrm{m}L/\nu$ where $w_\mathrm{m} = w\psi$, w is the far field velocity, and $\psi = 1 - \pi/(4a)$ is the void space fraction, where $a = s_1/d$ (Fig. 8).



B1. Fig. 8. A row of pipes placed transversely in a flow.



B1. Fig. 9. Arrangement of pipes in pipe bundles: (**a**) in straight lines and (**b**) staggered.

4.1.8 Pipe Bundle

If the pipes are placed in straight lines (Fig. 9a), the axes of all pipes are consecutively in the flow direction. If the arrangement is staggered (Fig. 9b), the axes of a pipe row are shifted in comparison to the axes of the row in front. The heat transfer depends additionally on the crosswise and longwise division of the pipes, $a = s_1/d$ and $b = s_2/d$. The determination of the heat transfer coefficient starts with the calculation of the Nusselt number for a single pipe placed transversely in the flow, according to Eq. (59), in which the Reynolds number contains the mean velocity w_m in the pipe bundle: $\mathrm{Re} = w_\mathrm{m}L/\nu$, where $w_\mathrm{m} = w/\psi$, w is the far field velocity of the pipe row, ψ is the void space fraction $\psi = 1 - \pi/(4a)$ for $b > 1$, and $\psi = 1 - \pi/(4ab)$ for $b < 1$. The characteristic length is $L = d\pi/2$. The Nusselt number determined in this way must be multiplied with an arrangement factor f_A. This leads to the Nusselt number $\mathrm{Nu}_\mathrm{B} = \alpha_\mathrm{B}L/\lambda$ of the bundle:

$$\mathrm{Nu}_\mathrm{B} = f_\mathrm{A}\,\mathrm{Nu}. \tag{60}$$

For a straight arrangement

$$f_\mathrm{A} = 1 + 0.7\,\frac{b/a - 0.3}{\psi^{3/2}\,(b/a + 0.7)^2} \tag{61}$$

and for a staggered arrangement

$$f_\mathrm{A} = 1 + 2/(3b). \tag{62}$$

The heat flux is $\dot{q} = \alpha\Delta T_\mathrm{m}$ with ΔT_m according to Eq. (53). Equations (61) and (62) hold for pipe bundles consisting of 10 or more pipe rows. For heat exchangers with fewer pipe rows, the heat transfer coefficient (Eq. 60) must be multiplied by a factor $(1 + (n-1)f_\mathrm{A}/n)$, where n is the number of pipe rows.

4.2 Single Phase Natural Convection

The heat transfer coefficient for natural convection at a vertical wall can be calculated with the equation of Churchill and Chu

$$\mathrm{Nu} = \left(\frac{0.825 + 0.387\,\mathrm{Ra}^{1/6}}{\left[1 + (0.492/\mathrm{Pr})^{9/16}\right]^{8/27}} \right)^2, \tag{63}$$

in which the mean Nusselt number $\mathrm{Nu} = \alpha L/\lambda$ is formed with the wall height L, and the *Rayleigh number* is defined as

$$\mathrm{Ra} = \mathrm{Gr}\,\mathrm{Pr}, \tag{64}$$

where the Grashof number is defined by

$$\mathrm{Gr} = \frac{gL^3}{\nu^2} \frac{\rho_\infty - \rho_\mathrm{w}}{\rho_\mathrm{w}}.$$

If natural convection is caused solely by temperature differences, the Grashof number can be written according to Eq. (11) as

$$\mathrm{Gr} = \frac{gL^3}{\nu^2} \beta (T_\mathrm{w} - T_\infty),$$

where the volume expansion coefficient is denoted by β, where $\beta = 1/T_\mathrm{w}$ holds for ideal gases. Equation (63) holds in the range $0 < \mathrm{Pr} < \infty$ and $0 < \mathrm{Ra} < 10^{12}$. The fluid properties must be evaluated at the mean temperature $T_\mathrm{m} = (T_\mathrm{w} - T_\infty)/2$. A similar equation holds according to Churchill and Chu also for natural convection in a horizontal cylinder

$$\mathrm{Nu} = \left(\frac{0.60 + 0.387\,\mathrm{Ra}^{1/6}}{\left[1 + (0.559/\mathrm{Pr})^{9/16}\right]^{8/27}} \right)^2. \tag{65}$$

The same definitions used in Eq. (65) hold over the range of validity is $0 < \mathrm{Pr} < \infty$ and $10^{-5} \le \mathrm{Ra} \le 10^{12}$, and the characteristic length is the diameter d. For horizontal rectangular plates, the following holds for $0 < \mathrm{Pr} < \infty$:

$$\mathrm{Nu} = 0.766\,(\mathrm{Ra}\,f_2)^{1/5} \quad \text{if } \mathrm{Ra}\,f_2 < 7 \times 10^4 \tag{66}$$

and

$$\mathrm{Nu} = 0.15\,(\mathrm{Ra}\,f_2)^{1/3} \quad \text{if } \mathrm{Ra}\,f_2 > 7 \times 10^4, \tag{67}$$

where

$$f_2 = \left[1 + (0.322/\mathrm{Pr})^{11/20}\right]^{-20/11},$$

where $\mathrm{Nu} = \alpha L/\lambda$, if L is the shorter side of the rectangle.

4.3 Heat Transfer in Condensation and Boiling

4.3.1 Condensation

If the temperature of a wall surface is lower than the saturation temperature of adjacent vapor, the vapor is condensed at the wall surface. Depending on the wetting characteristics, the condensate forms drops or a continuous liquid film. The heat transfer coefficients are usually larger for *dropwise condensation* than for *film condensation*. However, in order to maintain dropwise condensation for a certain amount of time, particular measures such as the application of dewetting agents are necessary. Dropwise condensation therefore appears rather seldom in technical applications. Calculation methods are presented in Part J3.

If the condensate flows as a laminar film on a vertical wall of height L, the mean heat transfer coefficient α is according to Nusselt's film condensation theory [4]

$$\alpha = 0.943 \left[\frac{\rho_\mathrm{l}(\rho_\mathrm{l} - \rho_\mathrm{v})\, g\, \Delta h_\mathrm{v} \lambda_\mathrm{l}^3}{4\,\eta_\mathrm{l}\,(T_\mathrm{s} - T_\mathrm{w})} \frac{1}{L} \right]^{1/4}, \tag{68}$$

where g is the gravitational acceleration, ρ the densities of the liquid (index l) and the vapor (index v) phase, respectively, Δh_v the latent heat of vaporization, η_l the dynamic viscosity of the liquid, λ_l its thermal conductivity, and T_s and T_w the saturation temperature and the wall temperature, respectively.

For condensation on horizontal single pipes with an outer diameter d, the following relation holds:

$$\alpha = 0.728 \left[\frac{\rho_\mathrm{l}(\rho_\mathrm{l} - \rho_\mathrm{v})\, g\, \Delta h_\mathrm{v} \lambda_\mathrm{l}^3}{\eta_\mathrm{l}\,(T_\mathrm{s} - T_\mathrm{w})} \frac{1}{d} \right]^{1/4}. \tag{69}$$

The equations require that no noticeable shear stress is exerted by the vapor on the condensate film.

At Reynolds number $\mathrm{Re}_\delta = w_\mathrm{m}\delta/\nu$ (where w_m is the velocity of the condensate, δ the film thickness, and ν the kinematic viscosity) between 75 and 1,200 the transition to turbulent flow in the condensate film gradually takes place. In the transition range

$$\alpha = 0.22\,\lambda_\mathrm{l} \left(\nu_\mathrm{l}^2/g\right)^{1/3}, \tag{70}$$

whereas for turbulent film flow ($\mathrm{Re}_\delta > 1{,}200$), the following relation according to Grigull holds

$$\alpha = 0.003 \left[\frac{\lambda_\mathrm{l}^3\, g\,(T_\mathrm{s} - T_\mathrm{w})}{\rho_\mathrm{l} \nu_\mathrm{l}^3\, \Delta h_\mathrm{v}} L \right]^{1/2}. \tag{71}$$

Equations (70) and (71) are valid also for vertical pipes and plates but not for horizontal pipes.

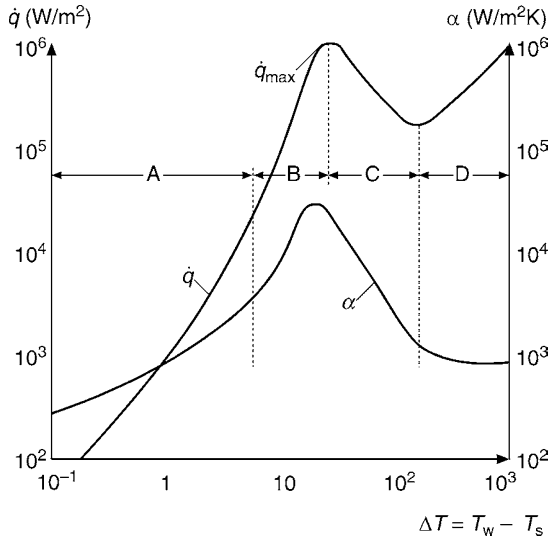
4.3.2 Boiling

If a liquid in a container is heated, evaporation starts after the saturation temperature T_s is exceeded. For small excess wall temperatures $T_\mathrm{w} - T_\mathrm{s}$ the liquid evaporates only on its free surface (*silent boiling*). Heat is transported by conduction and the buoyancy flow from the heating surface to the free surface of the liquid. For higher, excess wall temperatures vapor bubbles are formed at the heating surface (*nucleate boiling*) and rise. They increase the movement of the liquid and thus the heat transfer. With increasing excess wall temperature, the bubbles merge more and more into a continuous vapor film, whereby the heat transfer is decreased (*transition boiling*). Figure 10 shows the different heat transfer ranges for such *pool boiling* situations. The heat transfer coefficient α is defined as

$$\alpha = \dot{q}/(T_\mathrm{w} - T_\mathrm{s}) \tag{72}$$

where the heat flux is $\dot{q}$ in W/m^2.

Industrial evaporators work in the range of silent boiling or, more often, in the nucleate boiling range. In the silent boiling range the laws for heat transfer in natural convection hold (see Sect. 4.2. and Part F).



B1. Fig. 10. Boiling ranges for water of 1 bar. A – natural convection (silent boiling), B – nucleate boiling, C – transition boiling, D – film boiling.

In the nucleate boiling region, the general relation $\alpha = c\dot{q}^n F(p)$ with $0.5 < n < 0.8$ holds.

For water at boiling pressures between 0.5 and 20 bar, according to Fritz, the following relation holds:

$$\alpha = 1.95\, \dot{q}^{0.72}\, p^{0.24} \tag{73}$$

with α in W/(m²K), $\dot{q}$ in W/m², and p in bar. According to Stephan and Preußer, for arbitrary liquids the following relation is valid for nucleate boiling close to ambient pressure

$$\mathrm{Nu} = 0.0871 \left(\frac{\dot{q}\, d}{\lambda_l\, T_s}\right)^{0.674} \left(\frac{\rho_v}{\rho_l}\right)^{0.156} \left(\frac{\Delta h_v d^2}{a_l^2}\right)^{0.371} \left(\frac{a_l^2 \rho_l}{\sigma\, d}\right)^{0.350} \mathrm{Pr}_l^{-0.162}\,. \tag{74}$$

Properties of the liquid and vapor are taken at saturation conditions. $\mathrm{Nu} = \alpha d/\lambda_l$ is formed with the detachment diameter of the vapor bubbles $d = 0.851\beta_0[2\sigma/g(\rho_l - \rho_v)]^{1/2}$, where the contact angle is $\beta_0 = 45°$ for water, 1° for low boiling and 35° for other liquids. The equations above are not valid for boiling in forced flow. Detailed calculation procedures for *pool boiling* are given in Chap. H2.

If boiling occurs in a forced flow, e.g. in a pipe heated externally, both, boiling heat transfer and forced convective heat transfer are driving the transport process. *Flow boiling* calculation procedures are presented in Chap. H3.

5 Thermal Radiation and Radiative Heat Exchange

5.1 Emission, Absorption, and Transmission

As stated in Sect. 2.3. real bodies emit less than black radiators, where the energy emitted from real surfaces is, according to Eq. (17),

$$\dot{e} = \varepsilon \cdot \dot{e}_b = \varepsilon \cdot \sigma\, T^4.$$

In limited temperature ranges, many engineering surfaces (with the exception of shiny metal) can be interpreted as grey radiators. The energy radiated by them is distributed over the wave lengths in the same way as it is for black radiators. However, it is reduced by a factor $\varepsilon < 1$. Strictly speaking, $\varepsilon = \varepsilon(T)$ holds true for grey radiators. For small temperature ranges, however, it is admissible to assume ε as constant.

Assuming a body emits the energy flow per unit area $\dot{e}$, and this energy flux strikes another body, this second body absorbs the energy flow or rather the heat flow

$$\mathrm{d}\dot{Q}_a = a\, \mathrm{d}\dot{Q} = a\, \dot{e}\, \mathrm{d}A. \tag{75}$$

The *absorptivity* a defined by this equation depends on the temperature T of the origin of the incident radiation and on the temperature T' of the receiving surface. For black bodies, this value is $a = 1$, as all radiation striking the surface is absorbed. For surfaces which are not black, this value is $a < 1$. For grey radiators, the absorptivity is $a = \varepsilon$. According to *Kirchhoff's law*, the emissivity is equal to the absorptivity, $\varepsilon = a$, for each surface which is in thermal equilibrium with its environment so that the temperature of the surface does not change in time.

The remaining fractions of $\mathrm{d}\dot{Q}$ are reflected at the surface, $\mathrm{d}\dot{Q}_r = r\, \mathrm{d}\dot{Q}$, or transmitted through the body, $\mathrm{d}\dot{Q}_d = d\, \mathrm{d}\dot{Q}$. It follows

$$r + d + a = 1. \tag{76}$$

A body that reflects radiation completely ($r = 1$, $d = a = 0$) is called an ideal mirror, a body that absorbs radiation completely ($a = 1$, $r = d = 0$) is called a black body. A body is called diathermal ($d = 1$, $r = a = 0$) if radiation passes completely through. Examples for this are gases such as O_2, N_2, and others.

5.2 Heat Exchange Between Two Bodies

If two bodies emit radiation to each other the heat transfer between the bodies is equal to the net result of the radiation balance. Assuming, e.g., two parallel black surfaces of temperatures T_1 and T_2, and area A, which is very large in comparison to their distance, the net heat flow rate

$$\dot{Q}_{12} = \sigma A \left(T_1^4 - T_2^4\right) \tag{77}$$

is transferred by radiation. Between two such grey surfaces with the emissivities ε_1 and ε_2, the heat flow rate is

$$\dot{Q}_{12} = C_{12} A \left(T_1^4 - T_2^4\right) \tag{78}$$

with the *radiation exchange number*

$$C_{12} = \frac{\sigma}{\frac{1}{\varepsilon 1} + \frac{1}{\varepsilon_2} - 1}. \tag{79}$$

Between an internal pipe with the outer surface A_1 and an external pipe with the inner surface A_2, which are both grey radiators with emissivities ε_1 and ε_2, a heat flow rate is given according to Eq. (78), however, with:

$$C_{12} = \frac{\sigma}{\frac{1}{\varepsilon_1} + \frac{A_1}{A_2}\left(\frac{1}{\varepsilon_2} - 1\right)}. \tag{80}$$

If $A_1 << A_2$, e.g., for a pipe in a large room, the equation holds that $C_{12} = \sigma\varepsilon_1$.

For a number of more complex geometrical configurations with two bodies, specific radiation exchange numbers are given in Chap. K1.

More general relationships for the radiative heat transfer between two grey surfaces, which are arbitrarily arranged in space, make use of the definition of so-called *view factors* φ that depend on the geometric arrangement of the surfaces. A view factor φ_{ij} is defined as the fraction of the radiative energy leaving body *i* that strikes body *j*. Details for such arrangements as well as for enclosed spaces with multiple surfaces involved in radiative heat exchange are given in Chap. K2.

5.3 Gas Radiation

Most gases are transparent to thermal radiation and neither emit nor absorb radiation. Exceptions are some gases such as carbon dioxide, carbon monoxide, hydrocarbons, water vapor, sulfur dioxide, ammonia, hydrochloric acid, and alcohols. They emit and absorb radiation only in certain wave length regions. Emissivity and absorptivity of these gases depend not only on temperature, but also on the geometric shape of the gas body. Details are given in Chap. K3.

A2 Dimensionless Numbers

Holger Martin
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Introduction

The equations in the VDI-Heat Atlas are often given in dimensionless forms. The dimensionless numbers used in these equations are presented below in tabular form with notation, name, and definition, and by a numerical example for each of these numbers.

2 Dimensionless Numbers

Notation	Name	Definition
Ar	Archimedes number	$gl^3\Delta\rho/(\rho\nu^2)$
Bi	Biot number	$\alpha_a l/\lambda_i$
Fo	Fourier number	$\kappa t/l^2$
Fr	Froude number	$w^2/(gl)$
Ga	Galilei number	$g\,l^3/\nu^2$
Gr	Grashof number	$g\beta\Delta T\,l^3/\nu^2$
Gz	Graetz number	$l^2/(\kappa\,t_r)$
Hg	Hagen number	$(\Delta p/\Delta L)\,l^3/(\rho\nu^2)$
Ka	Kapitza number	$g\eta^4/(\rho\sigma^3)$
Le	Lewis number	κ/δ_{ij}
Nu	Nusselt number	$\alpha l/\lambda$
Pe	Péclet number	$w\,l/\kappa$
Pr	Prandtl number	ν/κ
Ra	Rayleigh number	$g\beta\Delta T\,l^3/(\nu\kappa)$
Re	Reynolds number	$\rho w l/\eta$
Sh	Sherwood number	$\beta\,l/\delta_{ij}$
Sc	Schmidt number	ν/δ_{ij}
St	Stanton number	$\alpha/(\rho c_p w)$
We	Weber number	$w^2 l\rho/\sigma$

3 Examples of Usage

The **Archimedes number**, Ar, is often used in equations describing the motion of particles (solid particles, drops, or bubbles) in gases or liquids (as in Chaps. L3.2 and M5). Usually, it appears in these equations together with the Reynolds number, Re. The number $\mathrm{Ar}/\mathrm{Re}^2$ can be interpreted as the ratio of weight minus buoyancy and the inertial force:

$$\mathrm{Ar}/\mathrm{Re}^2 = (\Delta\rho/\rho)/\mathrm{Fr} = gl^3\Delta\rho/(\rho w^2 l^2)$$

The diameter of the particles, drops, or bubbles is usually chosen as the characteristic length l.

Example
Quartz sand, with an average size $d = 500$ µm and a solid density $\rho_S = 2{,}610$ kg/m^3, is to be fluidized in air at a pressure of $p = 1$ bar und $T = 300$ K. With the gas density $\rho = 0.6072$ kg/m^3 and the kinematic viscosity of $\nu = 48.09 \cdot 10^{-6}$ m^2/s (Chap. D2) from the definition of Ar, with $l = 500 \cdot 10^{-6}$ m, $\rho = 0.6072$ kg/m^3, $\nu = 48.09 \cdot 10^{-6}$ m^2/s, and $\Delta\rho = (2{,}610 - 0.6)$ kg/m^3 = 2,609 kg/m^3, the result is Ar = 2,278.

The **Biot number**, Bi, may be seen as a ratio of two heat transfer resistances in series: $(l/\lambda_i)/(1/\alpha_a)$. It is often very useful in calculations of transient heating or cooling processes of solid bodies in liquid, or gas flows (Chap. E2).

Example
Spherical PVC particles with a heat conductivity $\lambda_i = 0.15$ W/m K and a radius of $R = 2$ cm shall be cooled in an airstream. The heat transfer coefficient (surface-to-ambient air) was determined to be $\alpha_a = 60$ W/m^2 K.

With $l = R = 2 \cdot 10^{-2}$ m, the Biot number becomes Bi = 8.00, which means that the internal conductive resistance is eight times the outer heat transfer resistance in this case. The transient conduction inside the particles is rate-controlling.

The **Fourier number**, Fo, as a dimensionless time is commonly used in transient conduction problems (see Sect. B and Chap. E2).

Example
A steel ball with the thermal diffusivity $\kappa = 7.0 \cdot 10^{-6}$ m^2/s and the radius $R = 1$ cm is cooled in water for 1 min.

Using $t = 1$ min $= 60$ s and $l = R = 10^{-2}$ m, the Fourier number turns out to be Fo = 4.2.

The **Froude number**, Fr, which can be seen as a ratio of inertial force and gravity, appears in problems of forced motion when gravity has some additional influence, for example, with free liquid (or granular solid) surfaces and in other multiphase flow problems.

Example
A water–steam mixture flows through a horizontal tube of internal diameter $d_i = 25$ mm with an average liquid-phase velocity of $w_L = 5$ m/s. With the characteristic length $l = d_i = 25 \cdot 10^{-3}$ m, the Froude number for the liquid phase is Fr = 102.

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_2,

The **Galilei number**, Ga, may be written in terms of the Reynolds and Froude numbers: $Ga = Re^2/Fr$. It is also a factor in Ar and Gr: $Ar = Ga\ \Delta\rho/\rho$; $Gr = Ga\ \beta\ \Delta T$

Example
In the example for the Archimedes number, Ga = 0.5302 und $\Delta\rho/\rho$ = 4,297.

The **Grashof number**, Gr, is formed similarly to the Archimedes number, Ar. The term $\Delta\rho/\rho$, being the relative difference of densities of two different phases, such as solid–gas, for Ar, is replaced by the term $\beta\ \Delta T$ in the Grashof number (where β is the thermal expansion coefficient, and ΔT a characteristic spatial temperature difference). It is a relative difference of densities within one phase only (liquid or gaseous), which occurs because of a spatial temperature difference ΔT. For an ideal gas, $\beta = 1/T$. The Grashof number is important in describing heat transfer in natural convection flow problems (Sects. B and F).

Example
A flat, vertically mounted heater of a height l = 60 cm in a room at a temperature T_∞ = 20°C has a surface temperature of T_s = 60°C. At a reference temperature of $T_m = (T_s + T_\infty)/2$ = 40°C, the relevant physical properties, β, the thermal expansion coefficient, and ν, the kinematic viscosity are found to be

$$\beta_{40°C} = 1/313.15\,\mathrm{K} = 3.1 \cdot 10^{-3}\mathrm{K}^{-1},$$

$\nu_{40°C} = 16.92 \cdot 10^{-6}$ m²/s, and the Grashof number becomes Gr = $9.47{\cdot}10^8$.

The **Graetz number**, Gz, is the reciprocal of a Fourier number, Fo. It is mainly used in calculations for steady flow, in which the time t_r (the residence time of the fluid in a heated or cooled portion of a channel) is usually expressed via the length L and the mean flow velocity w. The characteristic length l in this case is the diameter, d, of the flow channel:

$$Gz = d^2/(\kappa t_r) = wd^2/(\kappa L) = Pe_d\, d/L = Re_d Pr\, d/L$$

Example
Waster at an average temperature of 30°C flows with a velocity of w = 1.5 m/s through a tube with the internal diameter of d_i = 18 mm. The tube is heated over a length of L = 3.0 m. With $\kappa_{30°C} = 0.148 \cdot 10^{-6}$ m²/s, $t_r = L/w$ = 2 s and $l = d_i = 18 \cdot 10^{-3}$ m the result is Gz = 1,095.

The **Hagen number**, Hg, though not as widely used in the relevant literature so far, has proven to be a very useful generalization of the two similarly built Archimedes and Grashof numbers. It works for both the forced convection and the natural convection flow problems. It can be seen as a dimensionless pressure gradient, $(\Delta p/\Delta L)/(\rho\nu^2/l^3)$. In case of natural convection flows, $\Delta p/\Delta L$ is the static pressure gradient $g\,\Delta\rho$ or $g\,\rho\,\beta\,\Delta T$ in a gravity field, and the Hagen number becomes an Archimedes number or a Grashof number. The linear Hagen-Poiseuille law of fully developed forced laminar tube flow (Re ≤ 2,300) simply reads as Hg = 32 Re, if the internal tube diameter is used as the characteristic length l.

Example
In a tube of the internal diameter d = 0.022 m a pressure drop of Δp = 103 Pa was measured over the length of ΔL = 10 m. Water at 20°C is flowing inside: ρ = 998.21 kg/m³, $\nu = 1.004 \cdot 10^{-6}$ m²/s. With the internal diameter, d, as the characteristic length, l, a Hagen number of Hg = 1 058 227 is obtained. With such a high value of Hg, a turbulent tube flow can be expected, because the critical Hagen number for the transition of laminar to turbulent flow is Hg_{crit} = 73,600 (Hg = 32 · Re, corresponding to a critical Reynolds number of Re_{crit} = 2,300).

The **Kapitza number**, Ka, contains only the physical properties, viscosity, density, and surface tension, apart from the acceleration of gravity, g. It plays a certain role in liquid film flows, as for example in film condensation. Ka can be written in terms of Weber, Froude, and Reynolds numbers, We, Fr, and Re, respectively as: $Ka = We^3/(Fr\ Re^4)$.

Example
With the data for water at 20°C and 1 bar from Chap. D2, the result is $Ka = 2.57{\cdot}10^{-11}$.

The **Lewis number**, Le, is the ratio of two physical properties, that is the quotient of thermal diffusivity and the (mass) diffusion coefficient. It occurs in problems of coupled heat and mass transfer, as for example, in drying or in evaporative cooling. The Lewis number can also be written in terms of Prandtl and Schmidt numbers: Le = Sc/Pr.

Example
For the evaporation of water in (dry) air at a total pressure of p = 1 bar and a temperature of T = 273.15 K with a diffusivity of $\delta_{water-air} = 22.6 \cdot 10^{-6}$ m²/s and a thermal diffusivity of $\kappa = 19.1 \cdot 10^{-6}$ m²/s, a Lewis number of Le = 0.845.

The **Nusselt number**, Nu, is a dimensionless heat transfer coefficient. For steady-state conduction through a stagnant plane layer of thickness l and conductivity λ the heat transfer coefficient, defined as $\alpha = \dot{q}/\Delta T$, is simply $\alpha = \lambda/l$. The Nusselt number $\alpha l/\lambda$, in this case, by definition, has a value of Nu = 1.

As the characteristic length l, the internal diameter of a flow channel (as in Chap. G1), the length (in flow direction) of a plate in parallel flow (in Chap. G4), or the quantity $(\nu^2/g)^{1/3}$, having the dimension of a length can be chosen (see Sect. B and Chap. J1). In any case, the definition of α, the choice of the characteristic length l, and the reference temperature for the physical properties must be specified.

Example
For a cylinder with an outer diameter of d = 25 mm in a crossflow of air, from Chap. G6, a Nusselt number Nu_l = 126.3 has been calculated. The reference temperature turns out to be T_m = 100°C, so that $\lambda = 31.81 \cdot 10^{-3}$ W/m K. The characteristic length for (long) cylinders in crossflow, following Chap. G6, is $l = (\pi/2)\ d = 39.27 \cdot 10^{-3}$ m. So, to get the heat transfer coefficient, $\alpha = (\lambda/l) \cdot Nu_l = 102.3$ W/(m² K) needs to be calculated.

The **Péclet number**, Pe, can be written as the product of Re and Pr: Pe = Re Pr. It does not contain the viscosity, as this property is found in Pr in the numerator, and in Re in the denominator. The Péclet number is found in forced convection flow problems with heat transfer (see also the numbers Gz, Re, and Pr). It can be seen as a ratio of convective

enthalpy transport (with the flow) to heat transfer (by conduction) to the fluid.

Example
At a Reynolds number of Re = 1,400, the Péclet number for air at 0°C (Pr = 0.7) has a value of Pe = 1,400 · 0.7 = 980; for water at 0°C (Pr = 13.0) one gets Pe = 1,400 · 13.0 = 18,200.

The **Prandtl number**, Pr, like Le and Sc, is a ratio of physical properties; with $\nu = \eta/\rho$ und $\kappa = \lambda/(\rho c_p)$ it can also be written in the form $Pr = \eta c_p/\lambda$.

Example
Liquid benzene at 50°C has the physical properties $\eta = 43.6 \cdot 10^{-5}$ Pas, $c_p = 1.821 \cdot 103$ J/kg K, and $\lambda = 0.134$ W/(m K). One obtains a Prandtl number of Pr = 5.93.

The product Gr Pr is also known as the **Rayleigh number**, Ra.

The **Reynolds number**, Re, can be seen as a ratio of inertial forces to frictional forces. The numerical value of Re is the crucial criterium to decide whether a flow remains in a stable laminar mode, or it may undergo a transition to turbulent flow: For the fluid flow in a circular tube, the critical Reynolds number is $Re_{cr} = 2{,}300$. For $Re < Re_{cr}$ the flow is laminar, for $Re > Re_{cr}$ it may become turbulent. The characteristic length l in this case is usually taken as the inner diameter of the tube (Chap. G1). For parallel flow over a flat plate (see Chap. G4), the characteristic length l is the length x in flow direction, measured from the leading edge. The critical Reynolds number for this flow is about $Re_{x,crit} = 5 \cdot 10^5$. In liquid film flow, the stability does not depend on Re alone, but also from a number that contains the surface tension, such as Ka or We.

Example
Water, at a mass flow rate of $\dot{M} = 8{,}000$ kg/h passes a tube with the internal diameter $d_i = 52$ mm. The temperature is 10°C, so that the density is $\rho = 999.8$ kg/m^3. The flow velocity is

$$w = \dot{M}/\left(\rho d^2 \pi/4\right) = 1.05\, m/s,\ l = d_i = 52 \cdot 10^{-3}\ \mathrm{m},$$
$$\nu = 1.300 \cdot 10^{-6}\ \mathrm{m^2}/s,$$
$$\mathrm{Re} = 41\,900.$$

The **Sherwood number**, Sh – corresponding to the Nusselt number – is formed as a dimensionless mass transfer coefficient. The equations in the form Nu = Nu (Re, Pr, ...) used to calculate the heat transfer coefficient α can also be applied to predict the mass transfer coefficient β: Just replace Nu by Sh and Pr by Sc (this is called the "analogy between heat and mass transfer").

Example
The diffusivity of steam (subscript "1") in air (subscript "2") at 1 bar and 25°C is $\delta_{12} = 26.5 \cdot 10^{-6}$ m^2/s. With $\nu = 15.6 \cdot 10^{-6}$ m^2/s one arrives at a Schmidt number of Sc = 0.589. Using this value, in place of Pr, in Eq. (5) of Chap. G4 with $Re_1 = 104$, one gets (in place of Nu) the value $Sh_l = 73.8$. The mass transfer coefficient β is obtained from this with $l = 10$ cm (the flow velocity of air ought to be $w = 1.56$ m/s to make $Re_1 = 104$) as $\beta = (\delta_{12}/l) \cdot Sh_l = 19.6$ mm/s.

The **Schmidt number**, Sc, is the mass transfer analog of the Prandtl number, Pr. For its use and calculation see the example at the Sherwood number, Sh. The Schmidt number can also be obtained from Sc = Le Pr.

The ratio $Nu/Pe = \alpha/(\rho c_p w)$ is also known as the **Stanton number**, St.

The **Weber number**, We, as the Kapitza number, Ka, contains the surface tension σ. So it plays a role for flow problems with free surfaces, for drop formation, and for the atomization of liquids. It can be expressed in terms of Ka, Fr, and Re: $We = (Ka\ Fr\ Re^4)^{1/3}$.

Example
A drop of water with a diameter of $d = 5$ mm is falling in stagnant air (20°C, 1 bar) with a velocity of $w = 11$ m/s. The Weber number, with $\rho_G = 1.188$ kg/m^3, the characteristic length $l = d = 5 \cdot 10^{-3}$ m, and with $\sigma_{20°C} = 72.78 \cdot 10^{-3}$ N/m, is We = 9.88.

Part C

Fundamentals of Heat Exchanger Design

C1 Thermal Design of Heat Exchangers

Wilfried Roetzel[1] · *Bernhard Spang*[2]

[2]BUCO Wärmeaustauscher International GmbH, Geesthacht, Germany

1 Introduction

Widely different tasks are involved in designing heat exchangers. They range from thermal rating or dimensioning through mechanical analysis and costing, to the optimization of heat exchangers and systems. This chapter is restricted to steady state thermal design of heat exchangers in which two fluids are separated by fixed walls [1].

2 Nomenclature, Definitions, and Basic Equations

A schematic diagram of a heat exchanger showing the main parameters is presented in Fig. 1.

The local heat flux $\dot{q}$ at the heat transfer surface can be expressed in terms of the local temperature difference $(\vartheta_1 - \vartheta_2)$ between the two fluids and the local overall heat transfer coefficient k_{loc}, i.e.,

$$\dot{q} = k_{\mathrm{loc}}(\vartheta_1 - \vartheta_2) \tag{1}$$

The total heat flow rate $\dot{Q}$ is obtained by integrating the local heat flux over the entire area of the heat transfer surface, i.e.,

$$\dot{Q} = \int_A \dot{q}\,\mathrm{d}A \tag{2}$$

With the introduction of a mean overall heat transfer coefficient k and a mean temperature difference $\Delta\vartheta_{\mathrm{m}}$ Eqs. (1) and (2) can be replaced by

$$\dot{Q} = kA\Delta\vartheta_{\mathrm{m}} \tag{3}$$

One of these two mean values must be defined separately. The following definition of the mean temperature difference is chosen:

$$\Delta\vartheta_{\mathrm{m}} = \frac{1}{A}\int_A (\vartheta_1 - \vartheta_2)^*\,\mathrm{d}A \tag{4}$$

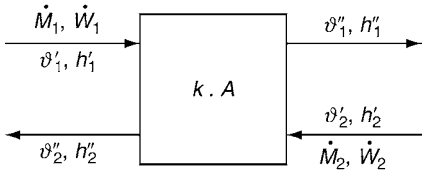
in which $(\vartheta_1 - \vartheta_2)^*$ is the hypothetical local temperature difference if the heat capacities and the mean value k are constant. The mean value k is then defined by Eq. (3). Its determination is dealt with in ➲ Chap. C2. In the special case of constant local overall heat transfer coefficient k_{loc} and of constant heat capacities over the entire heat transfer surface area, it is $k = k_{\mathrm{loc}}$.

Both the heat flow rate $\dot{Q}$ and the mean temperature difference are considered to be positive if heat is transferred from fluid 1 to fluid 2, i.e., if $\vartheta_1' > \vartheta_2'$. The mean temperature difference depends on the flow arrangement of the heat exchanger and on the degree and direction of mixing within the two fluid streams. Its (implicit or explicit) determination allows for a simple method of calculating the heat flow rate transferred over a given area or the area required to transfer a given heat flow rate.

Using the energy balance equations for the two fluids in the heat exchanger, the heat flow rate transferred in steady state operation can be expressed in terms of the changes in enthalpy within the two streams. Thus,

$$\dot{Q} = \dot{M}_1\left(h_1' - h_1''\right) = -\dot{M}_2\left(h_2' - h_2''\right) \tag{5}$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_4,



C1. Fig. 1. Schematic diagram of a heat exchanger.
$\dot{M}_1$, $\dot{M}_2$ = mass flow rates
$\dot{W}_1$, $\dot{W}_2$ = heat capacity rates
h_1, h_2 = specific enthalpies
ϑ_1, ϑ_2 = temperatures

In Eq. (5), heat flow to the surroundings, kinetic and potential energies, and all energy transferred into the system from the outside (e.g., energy dissipated by an agitator) are ignored. It is valid for temperature changes in single-phase systems, changes in phase, and chemical reactions. In single-phase systems, the change in enthalpy can be expressed as a change in temperature by introducing the heat capacity rate $\dot{W}$:

$$\dot{W}_i = \frac{\dot{M}_i\left(h'_i - h''_i\right)}{\vartheta'_i - \vartheta''_i} = \dot{M}_i c_{pm,i} \quad (i = 1, 2) \tag{6}$$

If the enthalpy is independent of pressure (e.g., as in an ideal gas) or if the pressure drop in flow direction can be neglected (isobaric change of state), $c_{pm,i}$ is the mean specific heat capacity at constant pressure between the inlet and the outlet temperatures. If a phase change occurs in a system that consists of only one pure substance (and the pressure remains constant), the heat capacity flow rate becomes infinite. Equations (3), (5), and (6) can then be combined to

$$\dot{Q} = kA\Delta\vartheta_m = \dot{W}_1\left(\vartheta'_1 - \vartheta''_1\right) = \dot{W}_2\left(\vartheta''_2 - \vartheta'_2\right) \tag{7}$$

The following dimensionless numbers are useful in the design of heat exchangers. They are obtained by dividing Eq. (7) by the absolutely largest temperature difference $\left(\vartheta'_1 - \vartheta'_2\right)$ in the heat exchanger and by the heat capacity flow rate $\dot{W}_1$ or $\dot{W}_2$.

(a) Dimensionless mean temperature difference

$$\Theta = \frac{\Delta\vartheta_m}{\vartheta'_1 - \vartheta'_2} \tag{8}$$

where $0 \leq \Theta \leq 1$.

(b) Dimensionless temperature changes in the two streams 1 and 2

$$P_1 = \frac{\vartheta'_1 - \vartheta''_1}{\vartheta'_1 - \vartheta'_2} \tag{9}$$

$$P_2 = \frac{\vartheta''_2 - \vartheta'_2}{\vartheta'_1 - \vartheta'_2} \tag{10}$$

where $0 \leq P_i \leq 1$ $(i = 1,2)$.

(c) Number of transfer units in streams 1 and 2

$$NTU_1 = \frac{kA}{\dot{W}_1} \tag{11}$$

$$NTU_2 = \frac{kA}{\dot{W}_2} \tag{12}$$

where $0 \leq NTU_i \leq \infty$ $(i = 1,2)$.

(d) Heat capacity rate ratios

$$R_1 = \frac{\dot{W}_1}{\dot{W}_2} \tag{13}$$

$$R_2 = \frac{\dot{W}_2}{\dot{W}_1} = \frac{1}{R_1} \tag{14}$$

where $0 \leq R_i \leq \infty$ $(i = 1,2)$.

The following relationships between the dimensionless numbers can be derived from Eq. (7):

$$\frac{P_1}{P_2} = \frac{NTU_1}{NTU_2} = \frac{1}{R_1} = R_2 \tag{15}$$

$$\Theta = \frac{P_1}{NTU_1} = \frac{P_2}{NTU_2} \tag{16}$$

3 Design Concepts

There are many methods for designing heat exchangers. They differ from one another in their field of application, physical and mathematical complexity, and accuracy. The most accurate but also most involved are the numerical finite difference or step-by-step methods. At the outset, not only the temperature field but also the flow field may be unknown. In this case, the equation of continuity and the momentum balance equations as well as the energy balance equation have to be solved numerically. The results depend greatly on the quality of the equations and mathematical models adopted for the calculation (turbulence models, equations for the flow resistance of fittings, etc.). In view of the tremendous expenditure and the uncertainty involved, the use of such methods in the design of heat exchangers is only rarely justified. Those methods are not discussed in this chapter. A much easier method has been developed by Gaddis and Schlünder [2, 3] for rating baffled shell-and-tube heat exchangers.

3.1 Cell Method

The method consists of subdividing the heat transfer area into a finite number of area elements over which the two fluid streams or their branches successively flow in the same or in a different sequence. By this, the entire heat exchanger is represented by a system of interconnected but nonoverlapping modules or cells with individual flow arrangements.

If the inlet temperatures for any one cell are given and the corresponding value of kA is known, the outlet temperatures can be determined from the equations for the appropriate flow arrangement (see Sect. 4). If the two streams pass through all the cells in series or in parallel, two equations can be derived for the relationship between the inlet and outlet temperatures of both streams in each cell. The temperature of each stream at the inlet to the respective first cell is known. If there are n cells, a total of $2n$ equations can be drawn up to determine the $2n$ unknown outlet temperatures for both streams. The system of equations can then be solved to yield all unknown temperatures including the outlet temperatures of the complete heat exchanger.

By means of the intermediate temperatures between the cells, individual values of the thermophysical properties and hence for the heat transfer coefficients in each cell may be determined, making the cell method more sophisticated. Differences in the correlations for the heat transfer coefficients, the heat transfer areas, and the flow arrangement in each cell can thus be embraced.

To illustrate this method, an example is given. Consider a shell-and-tube heat exchanger with n tube-side and one shell-side passes and with z baffles on the shell side. In the model shown in Fig. 2, it is $n = 2$ and $z = 2$. For simplification, it is assumed that each cell has the same number of transfer units (NTU). Let the number of transfer units in the entire heat exchanger be $\mathrm{NTU}_{1\mathrm{tot}}$ and $\mathrm{NTU}_{2\mathrm{tot}} = R_1\mathrm{NTU}_{1\mathrm{tot}}$. Then, the following applies for the individual cells:

$$\mathrm{NTU}_i = \frac{\mathrm{NTU}_{i,\mathrm{tot}}}{n(z+1)} \quad i = 1, 2 \tag{17}$$

The dimensionless temperature changes P_1 and P_2 in the cells can then be obtained from the individual flow arrangement (e.g., cross-flow with lateral mixing on the shell-side and no mixing on the tube-side, see Sect. 4) and from NTU_1 and $R_1 = \mathrm{NTU}_2/\mathrm{NTU}_1$.

The dimensionless temperatures for the streams are

$$T_1 = \frac{\vartheta_1 - \vartheta_2'}{\vartheta_1' - \vartheta_2'} \text{ and } T_2 = \frac{\vartheta_2 - \vartheta_2'}{\vartheta_1' - \vartheta_2'} \tag{18}$$

Hence the following applies for the cell j in Fig. 3:

$$(1 - P_1)T_{1\mathrm{p}}'' - T_{1\mathrm{j}}'' + P_1 T_{2\mathrm{q}}'' = 0 \tag{19}$$

and

$$P_2 T_{1\mathrm{p}}'' - T_{2\mathrm{j}}'' + (1 - P_2)T_{2\mathrm{q}}'' = 0 \tag{20}$$

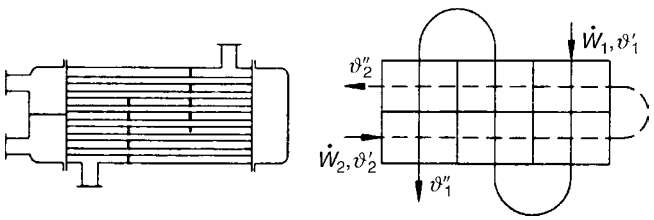
If the entire flow arrangement is fixed, cell j can be uniquely tied in with the adjacent cells p and q. If j is the cell in which the streams 1 and/or 2 enter into the complete heat exchanger, it is

$$T_{1\mathrm{p}}'' = 1 \text{ and } T_{2\mathrm{q}}'' = 0 \tag{21}$$

If Eqs. (19) and (20) are written for all $n(z+1)$ cells, a system of linear equations is obtained for the $2n(z+1)$ unknown cell outlet temperatures which can be solved by known methods. If stream 1 leaves the entire heat exchanger from cell m, the relevant dimensionless temperature change is given by

$$P_{1\mathrm{tot}} = 1 - T_{1\mathrm{m}}'' \tag{22}$$

The cell method can be recommended for the thermal design of flow arrangements for which none of the analytical solutions described below can be applied. It is also recommended for studying effects for which no allowance can be made in the analytical solutions, e.g., small number of baffles in shell-and-tube heat exchangers (see Sect. 4.3). It is to observe that the results obtained from the cell method are of no higher accuracy than the heat transfer coefficients used, even if the exchanger is subdivided into a large number of cells. An example is presented in Sect. 6.1 to illustrate the application of the cell method in rating an existing heat exchanger.



C1. Fig. 2. Shell-and-tube heat exchanger with one shell-side and two tube-side passes and two shell-side baffles; longitudinal section and cell model.

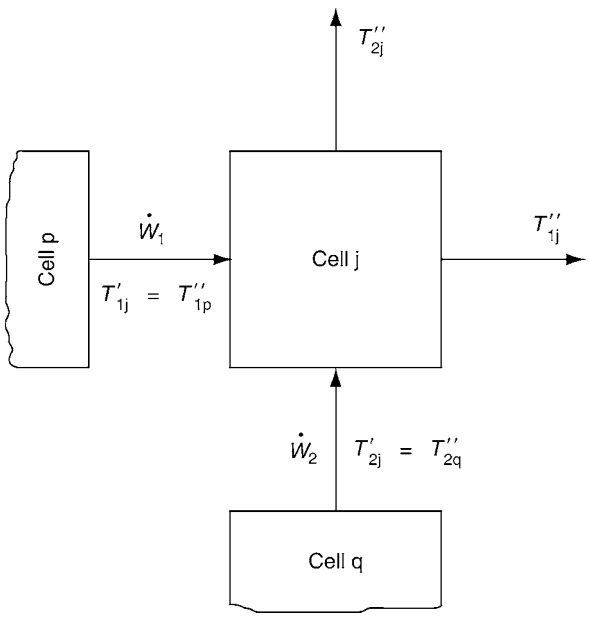
3.2 Mean Temperature Difference Concept

Usually, simple mathematical methods based on the mean temperature difference concept for the complete heat exchanger yield results with sufficient accuracy for the design. The charts and equations involved are easy to use.

The equations are derived by integrating the local energy balances as given by Eqs. (1)–(4) for a given flow arrangement. The flow arrangements are characterized by idealizing assumptions concerning the flow direction and the degree of lateral and axial mixing. The real flow pattern can greatly deviate from the ideal flow, as occurs, e.g., in baffled shell-and-tube heat exchangers. Nevertheless, the design equations derived for the ideal flow arrangements are usually sufficiently accurate. Only under extreme conditions, such as high NTUs or small number of baffles, more complex calculation models, such as the cell method [2, 3] (Sect. 3.1) or the axial dispersion model [4, 5] are recommended.

In addition to the idealizations of the flow arrangements, the following simplifying assumptions are made.

- The heat exchanger is operated in steady state.
- The only parameter that changes the enthalpy of the streams is the heat flux that is transferred, that is, heat losses to the surroundings and kinetic and potential energies are ignored.



C1. Fig. 3. Cell j in the heat exchanger.

– If no phase change occurs, the specific heat capacities, and thus their rates, are constant. Allowance for the change in heat capacity with temperature is discussed in Chap. C2.
– If a change in phase does occur, the local heat capacity flow rate is assumed to be constant as well, which implies a linear relationship between enthalpy flow rate and temperature. The analysis of heat exchangers in which superheating or subcooling occurs as well as a change in phase is explained in Sect. 5.3.
– The effects of conduction and mixing in the direction of flow are ignored, except in the case of a stirred tank (Sect. 4.1).

Another assumption that must be made in determining the temperature fields in the equipment is that the overall heat transfer coefficient is constant. It is unnecessary for the calculation of outlet temperatures if the mean coefficient as defined by Eqs. (3) and (4) is taken (Chap. C2).

Equations for common flow arrangements are presented in Sect. 4. Since the dimensionless temperature change P_1 is expressed as a function of NTU_1 and R_1, the equations can be applied directly to the rating of existing heat exchangers. Only in some cases these equations can be solved for NTU_1. Hence heat exchanger design usually involves iterative solution of the equation $P_1 = f(NTU_1, R_1)$. If the flow arrangement is symmetric, the subscript 1 of P, NTU, and R may be replaced by the subscript 2. In the equations for these flow arrangements, the subscript attached to the dimensionless numbers is i, where $i = 1$ or $i = 2$.

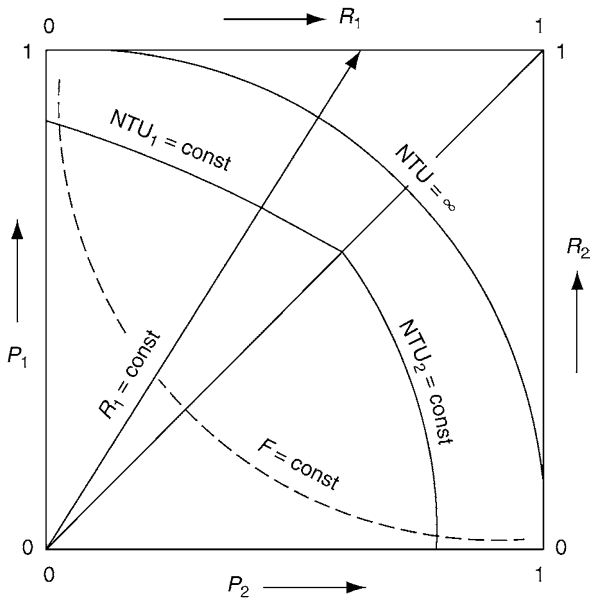
Most of the 31 design charts presented in Figs. 15–45 were plotted from the equations listed in the tables of Sect. 4. A few were plotted from the results of analytical or numerical methods due to the lack of closed-form solutions; the same assumptions as those listed above were made in their determination.

3.3 Key to the Design Charts

The design charts can be explained with Fig. 4 [6]. The flow arrangements involved, together with the geometrically defined streams 1 and 2, are sketched alongside the respective charts. The coordinate axes represent the dimensionless temperature changes P_1 and P_2 of the two streams. If the flow arrangements are symmetric, the charts will also be symmetrical about the $P_1 = P_2$ axis. In this case, P_1 and P_2 can be interchanged, as is indicated in the diagrams by the subscripts 1,2 and 2,1, the first or second digit of which is respectively valid for the particular case in question.

The scale at the top of each chart represents the heat capacity rate ratio R_1 ($0 \le R_1 \le 1$); and that on the right-hand margin, the heat capacity rate ratio $R_2 = 1/R_1$ ($0 \le R_2 \le 1$). The straight line connecting the scale on the margin to the origin is the geometric location of the respective heat capacity rate ratio marked on the scale.

Two different sets of curves are plotted in the charts. The full-line curves apply for NTU_1 = const. above the diagonal, and for NTU_2 = const. below the diagonal. As is evident from Eq. (15), the curves intersect on the diagonal at $NTU_1 = NTU_2$.



C1. Fig. 4. Schematic diagram of the design charts.

The only curve with a smooth transition at the diagonal is that for the limiting curve $NTU = \infty$, which is valid for infinitely large heat transfer areas. Temperature changes beyond this curve are usually impossible. Only a few special flow arrangements, e.g., the mixed–mixed cross-flow (Fig. 32), can attain higher temperature changes with two finite values of NTU. In these cases, the locus of the maximum possible dimensionless temperature changes has been designated as P_{max} and included in the chart. No operating points are possible above the limiting curve $NTU = \infty$ or the P_{max} curve. The limiting curve $NTU = \infty$ for some flow arrangements, e.g., pure countercurrent flow (Fig. 17), coincides with the right-hand and upper margins, i.e., $P_1 = 1$ and $P_2 = 1$.

The second set of curves, which are shown as dashed lines in the charts, are those for constant values of the correction factor F for the logarithmic mean temperature difference. The factor F is defined by

$$F = \frac{\Theta}{\Theta_C} = \frac{NTU_{iC}}{NTU_i} (i = 1, 2) \qquad (23)$$

where Θ_C is the dimensionless temperature difference and NTU_C is the number of transfer units in a pure countercurrent heat exchanger in which the dimensionless temperature changes P_1 and P_2 are the same as that attained for Θ and NTU_i in the flow arrangement investigated. If flow is purely countercurrent, the relationship $F = 1$ applies over the entire range of the chart. For all other flow arrangements, the limiting curve $NTU = \infty$ coincides with the $F = 0$ curve.

3.4 General Approximation Equation for the Estimation of *F*

For flow arrangements in which axial mixing or dispersion does not occur, the following generally valid approximation equation with individual empirical coefficients for each flow arrangement

can be recommended for the estimation of the logarithmic mean temperature difference correction factor [7]:

$$F = \frac{1}{\left(1 + aR_1^{db}\mathrm{NTU}_1^{b}\right)^{c}} \tag{24}$$

The coefficients *a*, *b*, *c*, *d* were determined through least square fits for numerous flow arrangements [7], based on the data calculated for the design charts. The values of *a*, *b*, *c*, *d* are given in Table 1. For symmetric flow arrangements, $d = ½$. Coefficients for additional flow arrangements can be found in the works by B. Spang and W. Roetzel [7].

With the correction factor *F*, the dimensionless temperature changes can be calculated using the known formula for counterflow.

C1. Table 1. Values of the coefficients *a*, *b*, *c*, and *d* for Eq. (24)

Flow arrangement	*a*	*b*	*c*	*d*
Pure cocurrent flow	0.671	2.11	0.534	0.500
Shell-and-tube heat exchanger with one shell-side and two tube-side passes; $\varepsilon = 1/2$	0.317	2.09	0.543	0.500
Shell-and-tube heat exchanger with one shell-side and four tube-side passes	0.274	2.08	0.624	0.508
Shell-and-tube heat exchanger with one shell-side and six tube-side passes	0.262	2.07	0.650	0.509
Shell-and-tube heat exchanger with one shell-side and eight tube-side passes	0.258	2.07	0.661	0.509

Plate heat exchanger with two passes for stream 1 and four passes for stream 2 in overall countercurrent flow arrangement	0.0748	1.87	0.525	0.317

For $R_i \neq 1$

$$P_i = \frac{1 - \exp[(R_i - 1)\mathrm{NTU}_i F]}{1 - R_i \exp[(R_i - 1)\mathrm{NTU}_i F]} \tag{25}$$

and for $R_i = 1$, $\mathrm{NTU}_1 = \mathrm{NTU}_2 = \mathrm{NTU}$

$$P_1 = P_2 = \frac{\mathrm{NTU}F}{1 + \mathrm{NTU}F} \tag{26}$$

For the m,$2m$ shell-and-tube heat exchanger with $m \geq 2$ (Figs. 28 and 29), the correction factor could also be calculated using the formula for $m = 1$ (1,2-shell-and-tube heat exchanger). One has to merely divide the total NTU by m:

$$F_{m,2m} = F_{1,2}\left(\frac{\mathrm{NTU}_i}{m}; R_i\right) \tag{27}$$

The presented coefficients are valid for $1 \geq \mathrm{F} \geq 0.25$ and $0 \leq R_i \leq \infty$. The maximum relative error in F falls below 5% and in P below 3%. In the generally recommended range $1 \geq \mathrm{F} \geq 0.7$ below 1% and 2%, respectively.

The general approximation Eqs. (24–27) are mainly suitable for rating purposes. For the design from given temperature changes iterations are required: first the required NTU_{1C} for pure countercurrent flow is calculated, then the required $\mathrm{NTU}_1 = \mathrm{NTU}_{1C}/F$ can be introduced in the approximation Eqs. (24–27) with a guessed value of F, yielding an improved value of F, etc.

4 Analytical Design Formulae for Common Flow Arrangements

4.1 Stirred Tank

The stirred tank is the only heat exchanger in which mixing and heat conduction are assumed to take place in the direction of flow. In one-sided tanks (Fig. 16), stream 2 is completely mixed in both the flow and transverse directions, but stream 1 is mixed only in the transverse direction. In two-sided tanks (Fig. 15), both streams are completely mixed in all directions. The flow arrangement is symmetric in two-sided tanks, but not in one-sided.

The NTU_j = const. curves for the stream j that is completely mixed in the flow direction merge into the coordinate axis at points given by

$$P_j = \frac{\mathrm{NTU}_j}{1 + \mathrm{NTU}_j} \tag{28}$$

The curves for the stream i that is not mixed in the flow direction merge into the coordinate axis at points given by

$$P_i = 1 - \mathrm{e}^{\mathrm{NTU}_i} \tag{29}$$

The end points described by Eq. (29) apply to all the flow arrangements that are dealt with below, because all of them are analyzed under the idealized assumption that mixing and heat conduction do not occur in the direction of flow.

Mixing in the flow direction reduces the performance of a heat exchanger. Hence, if it is anticipated, the heat exchanger concerned should be designed as a stirred tank in order to obtain results on the safe side. Schematic flow diagrams and design charts for the two types of stirred tanks are presented in Figs. 15 and 16, and the design formulae are summarized in Table 2.

4.2 Countercurrent and Cocurrent Flow

The best-known flow arrangements are those for countercurrent and cocurrent flow. Both are symmetrical. If the NTU is given, countercurrent flow reaches the highest values of P; and if P is given the smallest required NTUs. The thermal efficiency of cocurrent flow is very poor, only the two types of stirred tanks have a lower efficiency.

The mean temperature difference, as defined by Eq. (4), is both in cocurrent and countercurrent flow the logarithmic mean of the local temperature differences $\Delta\vartheta_a$ and $\Delta\vartheta_b$ at both ends of the heat exchanger, i.e.,

$$\Delta\vartheta_m = \frac{\Delta\vartheta_a - \Delta\vartheta_b}{\ln\frac{\Delta\vartheta_a}{\Delta\vartheta_b}} \tag{30}$$

In the limiting case of $\Delta\vartheta_a \to \Delta\vartheta_b$, which arises for $R_1 \to 1$ in countercurrent flow and for $\mathrm{NTU} \to 0$ in cocurrent flow, the logarithmic approaches the arithmetic mean:

$$\Delta\vartheta_m = \frac{1}{2}(\Delta\vartheta_a + \Delta\vartheta_b) \tag{31}$$

The equations in dimensionless notation that correspond to Eqs. (30) and (31) are listed in Table 3, and the charts for the two flow arrangements are shown in Figs. 17 and 18.

4.3 Multipass Shell-and-Tube Heat Exchangers

For asymmetric flow arrangements, subscript 1 is allotted to the shell-side stream and subscript 2 to the tube-side stream.

The simplest case with one shell-side and one tube-side pass and a sufficiently large number of baffles on the shell side, or none at all, is the countercurrent or cocurrent flow according to Sect. 4.2.

Charts for multipass flow arrangements are shown in Figs. 19–29. That for the shell-and-tube heat exchanger with one shell-side and five tube-side passes (1,5-HEX, cf. Fig. 23)

C1. Table 2. Equations for stirred tanks

Flow arrangement	$P = f(\mathrm{NTU}, R)$	$\mathrm{NTU} = f(P, R)$	Limiting curve
Two-sided stirred tank; $i = 1, 2$	$P_i = \frac{\mathrm{NTU}_i}{1 + \mathrm{NTU}_i(1 + R_i)}$	$\mathrm{NTU}_i = \frac{P_i}{1 - P_i(1 + R_i)}$	$P_{i\infty} = \frac{1}{1 + R_i}$
One-sided stirred tank, stream 2 mixed	$\frac{1}{P_1} = R_1 + \frac{1}{1 - \mathrm{e}^{-\mathrm{NTU}_1}}$	$\mathrm{NTU}_1 = -\ln\left(1 - \frac{P_1}{1 - R_1 P_1}\right)$	$P_{1\infty} = \frac{1}{1 + R_1}$

C1. Table 3. Equations for countercurrent and cocurrent flow

Flow arrangement	$P = f(\mathrm{NTU}, R)$	$\mathrm{NTU} = f(P, R)$	$\Theta = f(P_1, P_2)$	Limiting curve
Pure counter current flow i = 1, 2	$P_i = \frac{1-\exp[(R_i-1)\mathrm{NTU}_i]}{1-R_i\exp[(R_i-1)\mathrm{NTU}_i]}$ for $R_i \neq 1$ $P_i = \frac{\mathrm{NTU}}{1+\mathrm{NTU}}$ for $R_i \neq 1$	$\mathrm{NTU}_i = \frac{1}{1-R_i}\ln\frac{1-R_iP_i}{1-P_i}$ $\mathrm{NTU} = \frac{P}{1-P}$	$\Theta = \frac{P_1-P_2}{\ln\frac{1-P_2}{1-P_1}}$ $\Theta = 1-P$	$P_{i\infty} = \begin{cases} 1; & R_i \leq 1 \\ \frac{1}{R_i}; & R_i > 1 \end{cases}$
Pure cocurrent flow i = 1, 2	$P_i = \frac{1-\exp[-\mathrm{NTU}_i(1+R_i)]}{1+R_i}$	$\mathrm{NTU}_i = -\frac{\ln[1-P_i(1+R_i)]}{1+R_i}$	$\Theta = \frac{-(P_1+P_2)}{\ln[1-(P_1+P_2)]}$	$P_{i\infty} = \frac{1}{1+R_i}$

was obtained by an analytical design method [8, 9]; and that in Fig. 27 for double split flow by a closed-form equation [10]. The equations for the other flow arrangements are listed in Table 4.

The NTU-ratio ε that occurs in the equations for the 1,2- and 1,3-HEX is defined by

$$\varepsilon = \frac{(kA)_{\mathrm{cocurr.pass}}}{(kA)_{\mathrm{tot}}} \tag{32}$$

The ratio ε allows for differences in the heat transfer area and in the heat transfer coefficient for the various passes (with the restriction that the product kA is the same in each of the two counterflow passes in the 1,3-HEX).

The heat transfer coefficient on the tube side depends on temperature. In the 1,2-HEX, this can be allowed for by determining separate heat transfer coefficients for each pass. The reference temperature in this case is the arithmetic mean of the inlet and outlet temperatures in the pass concerned. The intermediate temperature ϑ_{2z}, i.e., at the outlet of the first pass and at the inlet to the second, is required for its determination. Concerning the flow direction in the tube-side passes, two layouts I and II are possible. In layout I, the first pass is countercurrent to the shell-side stream, in layout II cocurrent. The equations for the determination of the temperatures ϑ^{I}_{2z} and ϑ^{II}_{2z} are given in Table 4.

The 1,2-HEX can be adopted as an approximate model for a 1,n-HEX with $n = 2m$ tube-side passes (m = 1, 2, 3, ...) of roughly the same area [8, 9]. The areas of the countercurrent and the cocurrent passes in the 1,2-model must be the same as those in the actual 1,2m-HEX. In the normal case the areas are the same in all the passes and a constant mean heat transfer coefficient can be adopted for the complete heat exchanger. Under these circumstances, a ratio of ε = ½ can be taken for the 1,2-HEX, and of ε = 1/3 for the 1,3-HEX. The charts in Figs. 19 and 21 are also calculated with these values.

The flow arrangement obtained with one shell-side pass and an infinite number of equal tube-side passes (1,n-HEX with $n \rightarrow \infty$) corresponds to that of mixed–mixed cross-flow (cf. Sect. 4.4) [17]. It can also serve as an approximation for a large even number of tube-side passes (1,2m-system with m = 2, 3, ...). The results from this approximation are more on the safe side than those obtained from the approximation with the equations for the 1,2-system. An upper limit for the error of the approximation can be derived from a comparison with the chart (Fig. 20) or the equation (Table 4) for the 1,4-HEX.

Shell-and-tube heat exchangers with an odd number of tube-side passes can be approximately described by the equations for the 1,3-system with two countercurrent passes of the same area if the NTU-ratio ε is formed from the sum of the areas of all the cocurrent passes; for instance, ε = 3/7 for a total of seven passes of the same area, four of which are countercurrent.

As has already been mentioned, the first of a number of tube-side passes may flow countercurrent (layout I) or cocurrent (layout II) to the shell-side stream. If the number is odd, layout I is always the more advantageous, because the countercurrent passes predominate. If there is an even number of tube-side passes of the same area and if the calculation is based on constant values for the heat transfer coefficient, the same results are obtained for both layouts. However, a more accurate calculation with varying heat transfer coefficients reveals that the more favorable layout is that in which the coefficients for the countercurrent passes are higher than those for the cocurrent [8, 9]. Hence, the following rule can be derived for an even number of equal tube-side passes.

If a liquid is to be heated in the tubes, the first tube-side pass should be cocurrent to the shell-side stream (layout II); if it is to be cooled, countercurrent (layout I). The opposite applies if a gas flows in the tubes.

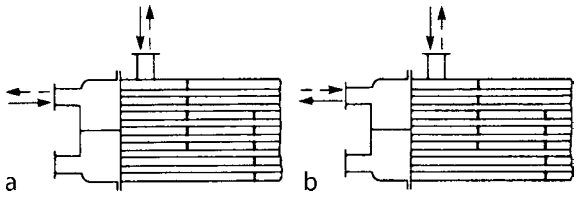
A number m of identical 1,n-HEXs can be connected in series {m,(m×n)-HEXs} in order to achieve higher temperature changes. The equations that apply in this case are those given in Sect. 5.1 for the countercurrent coupling of identical individual heat exchangers. Charts for n = 2 and m = 2 and 4 are shown in Figs. 28 and 29. Also the Eq. (27) can be applied for the m,2m-HEX.

Strictly speaking, the equations and charts presented in this section are valid only if there is an infinite number of baffles on the shell side, or none at all. The equations and charts allow a good approximation if the number of baffles is sufficiently large, i.e., at least ten for countercurrent flow and at least five for 1,2-HEXs (according to Gardner and Taborek [18]). If the number of baffles is small, allowance must be made for the fact that both streams are in cross-flow between two baffles. This can be done by subdividing the system into cells, as described in Sect. 3.1. The equations to be adopted in the calculations for each cell are those for cross-flow with one tube row (Sect. 4.4) and laterally mixed stream 1 on the shell side (which corresponds to stream 1 on the tube-side as conventionally designated in cross-flow heat exchangers).

For a finite number of baffles, there are two layouts A and B with different positions of the inlet and outlet relative to one another (Fig. 5). In both layouts they are adjacent. In layout A they exert a certain cocurrent effect, in layout B a

C1. Table 4. Equations for shell-and-tube heat exchangers, stream 1 on shell side, stream 2 inside the tubes

Flow arrangement	Equation	Limiting curve
One shell-side and two tube-side passes [8, 9] $i = 1, 2$	$\frac{1}{P_i} = \frac{1}{2}\left(1 + R_i + S\coth\left(\frac{1}{2}S\mathrm{NTU}_i\right)\right)$ or $\mathrm{NTU}_i = \frac{2}{S}\operatorname{arcoth}\left(\frac{2-P_i(1+R_i)}{SP_i}\right)$ where $S = \sqrt{1 + R_i^2 + 2R_i(2\varepsilon - 1)}$ NTU-ratio ε from Eq. (32) Temperature ϑ_{2z} of tube-side stream between passes Layout I: $\frac{\vartheta'_{2z} - \vartheta'_2}{\vartheta'_1 - \vartheta'_2} = 1 - \frac{SP_1 \exp\left[\frac{\mathrm{NTU}_1}{2}(1 + R_1(2\varepsilon - 1))\right]}{2\sinh\left(\frac{\mathrm{NTU}_1}{2}S\right)}$ Layout II: $\frac{\vartheta''_{2z} - \vartheta'_2}{\vartheta'_1 - \vartheta'_2} = 1 - P_1 - \frac{SP_1 \exp\left[-\frac{\mathrm{NTU}_1}{2}(1 + R_1(2\varepsilon - 1))\right]}{2\sinh\left(\frac{\mathrm{NTU}_1}{2}S\right)}$	$P_{i\infty} = \frac{2}{1 + R_i + S}$
One shell-side and $2m$ tube-side passes, $m = 1, 2, \ldots, \infty$ [1, 11]	$\frac{1}{P_1} = \frac{\sqrt{1 + (R_1/m)^2}}{1 - \exp\left(-\mathrm{NTU}_1\sqrt{1 + (R_1/m)^2}\right)} + \frac{R_1}{1 - e^{-R_1\mathrm{NTU}_1}} - \frac{R_1/m}{1 - e^{-R_1\mathrm{NTU}_1/m}}$ $+ \frac{1}{2}\left(1 + \frac{R_1}{m} - \sqrt{1 + \left(\frac{R_1}{m}\right)^2}\right)$	$P_{1\infty} = \frac{2}{1 + 2R_1 - R_1/m + \sqrt{1 + (R_1/m)^2}}$
One shell-side and three tube-side passes, two countercurrent [12]	$P_1 = \frac{S_1\left(e^{S_1} + e^{S_3}\right)\left(e^{S_2} - 1\right) + S_2\left(e^{S_2} + e^{S_3}\right)\left(1 - e^{S_1}\right) + \ldots}{S_1\left(e^{S_1} + e^{S_3}\right)\left(R_1 e^{S_2} - 1\right) + S_2\left(e^{S_2} + e^{S_3}\right)\left(1 - R_1 e^{S_1}\right) + \ldots}$ $\frac{\ldots + \mathrm{NTU}_1(1 - R_1)\left(e^{S_2} - e^{S_1}\right)\left(1 + e^{S_3}\right)}{\ldots + \mathrm{NTU}_1(1 - R_1)\left(e^{S_2} - e^{S_1}\right)\left(1 + R_1 e^{S_3}\right)}$ $S_{1/2} = \frac{p}{2} \pm \sqrt{\frac{p^2}{4} - q}$ $S_3 = \frac{1}{2}R_1\mathrm{NTU}_1(1 - \varepsilon)$ $p = \mathrm{NTU}_1\left(1 - \frac{1}{2}R_1(1 - 3\varepsilon)\right)$ $q = \frac{1}{2}\varepsilon(1 - \varepsilon)\mathrm{NTU}_1^2 R_1(1 - R_1)$ NTU-ratio ε from Eq. (32) $\frac{P}{1-P} = \mathrm{NTU}\frac{\varepsilon(1-\varepsilon)}{1+3\varepsilon} - 2\left(\frac{1+\varepsilon}{1+3\varepsilon}\right)^2\left[\left(e^{-0.5\mathrm{NTU}(1+3\varepsilon)} - 1\right)^{-1} + \left(e^{0.5\mathrm{NTU}(1-\varepsilon)} + 1\right)^{-1}\right]^{-1}$ for $R_1 = 1$	$P_{1\infty} = \begin{cases} 1; & R_1 \le 1 \\ \frac{1}{R_1}; & R_1 > 1 \end{cases}$
One shell-side and two tube-side passes, both countercurrent [12]	$P_1 = \frac{\left(e^{\mathrm{NTU}_1(0.5R_1 - 1)} - 1\right)\left(e^{0.5R_1\mathrm{NTU}_1} + 1\right)}{(0.5R_1 - 1)\left(e^{\mathrm{NTU}_1(0.5R_1-1)} + e^{0.5R_1\mathrm{NTU}_1}\right) + (R_1 e^{0.5R_1\mathrm{NTU}_1} + 1)\left(e^{\mathrm{NTU}_1(0.5R_1-1)} - 1\right)}$ for $R_1 \neq 2$ $\frac{1}{P_1} = 1 + \frac{1}{\mathrm{NTU}_1} + \frac{1}{1 + \exp(-\mathrm{NTU}_1)}$ for $R_1 = 2$	$P_{1\infty} = \begin{cases} 2/(2 + R_1); R_1 \le 2 \\ 1/R_1; & R_1 > 2 \end{cases}$
Divided flow with one shell-side and one tube-side pass [13]	$P_1 = \frac{1}{R_1} - \frac{(2 - R_1)(2 + R_1\exp[-\mathrm{NTU}_1(1 + R_1/2)])}{R_1(2 + R_1)(2 - R_1\exp[-\mathrm{NTU}_1(1 - R_1/2)])}$ for $R_1 \neq 2$ $P_1 = \frac{1}{2} - \frac{1 + \exp(-2\mathrm{NTU}_1)}{4(1 + \mathrm{NTU}_1)}$ for $R_1 = 2$	$P_{1\infty} = \begin{cases} 2/(2 + R_1); R_1 \le 2 \\ 1/R_1; R_1 > 2 \end{cases}$
Divided flow with one shell-side and two tube-side passes [14]	$\frac{1}{P_1} = 1 + \frac{R_1}{2} + \kappa\frac{e^{\kappa\mathrm{NTU}_1} + 1}{e^{\kappa\mathrm{NTU}_1} - 1} - \frac{2\kappa e^{0.5\,\mathrm{NTU}_1(1+\kappa)} + 1}{\kappa - 1 + (\kappa + 1)e^{\kappa\mathrm{NTU}_1}}\left(1 - \frac{\kappa e^{0.5\,\mathrm{NTU}_1(\kappa-1)}}{1 - e^{\kappa\mathrm{NTU}_1}}\right)$ $\kappa = 0.5\sqrt{R_1^2 + 4}$	$\frac{1}{P_{1\infty}} = 1 + \frac{R_1}{2} + \kappa$
Split flow with longitudinal baffle and two shell-side and two tube-side passes (tube-side outlet and shell-side inlet at the same side) [15, 16]	$P_1 = \frac{1}{R_1} - \frac{(1 - \beta)^2(1 - \gamma)}{R_1 - 2\beta^2(1 - \gamma)}$ for $R_1 \neq 2$ $\beta = \frac{1 - \exp[-\mathrm{NTU}_1(2 + R_1)/4]}{1 + 2/R_1}$ $\gamma = \frac{1 - \exp[-\mathrm{NTU}_1(2 - R_1)/2]}{2/R_1 - \exp[-\mathrm{NTU}_1(2 - R_1)/2]}$ $P_1 = \frac{(1 + 2\mathrm{NTU}_1)e^{\mathrm{NTU}_1} - e^{-\mathrm{NTU}_1}}{2 + (3 + 4\mathrm{NTU}_1)e^{\mathrm{NTU}_1} - e^{-\mathrm{NTU}_1}}$ for $R_1 = 2$	$P_{1\infty} = \begin{cases} \frac{2+R_1}{2+R_1+R_1^2}; & R_1 \le 2 \\ 1/R_1; & R_1 > 2 \end{cases}$



C1. Fig. 5. Layouts of shell-and-tube heat exchangers with one shell-side and two tube-side passes and with baffles on the shell side. Layout A: the adjacent nozzles for stream 1 and 2 are either both inlets or both outlets. Layout B: one of the adjacent nozzles for stream 1 and 2 is an inlet, the other one is an outlet.

countercurrent one. Analysis by the cell method [2, 3] shows that layout B is fundamentally superior to layout A and should therefore be preferred, although the differences are not very pronounced.

4.4 Cross-flow Heat Exchangers

If the flow arrangement is asymmetric, subscript 1 is allotted to the stream inside the tubes and subscript 2 to that outside the tubes. In Sect. 4.3, complete lateral mixing in each pass for all shell-and-tube flow arrangements was assumed. In cross-flow heat exchangers, however, even the limiting case of no lateral mixing is of significance. Thus, there are three fundamental cross-flow arrangements, each with one pass on both sides, as indicated below.

- Both streams are unmixed in the lateral direction (pure cross-flow or unmixed–unmixed cross-flow; Fig. 30).
- Stream 1 (inside the tubes) is laterally mixed, and stream 2 (outside the tubes) is not (cross-flow with one tube row or mixed–unmixed cross-flow; Fig. 31).
- Both streams are laterally mixed (mixed–mixed cross-flow; Fig. 32).

The analytical solutions for these flow arrangements are given in Table 5. Since the thermal efficiency is reduced by lateral mixing, the calculation for the case of complete mixing yields results on the safe side.

The degree of lateral mixing of stream 1 and the thermal efficiency achieved in cross-flow arrangements with n tube rows ($n = 2, 3, \ldots$) in one pass lie between the figures obtained for cross-flow with one tube row and those for pure cross-flow (Figs. 33–35, and the equations in Table 5).

In multipass cross-flow heat exchangers, the thermal efficiency depends not only on the degree of lateral mixing in each pass but also on the overall flow arrangement, i.e., on whether the flow is overall countercurrent or cocurrent, and on the degree of mixing between passes. If the outer stream is not laterally mixed, the thermal efficiency also depends on whether the flow on the tube side is in alternate directions in successive passes (counterdirected countercurrent cross-flow) or in the same direction in each pass (codirected countercurrent cross-flow). Many flow arrangements are feasible, but only a few are of practical significance. If the two streams are adequately mixed between each pass, the coupling equations given in Sect. 5.1 for overall cocurrent or countercurrent flow should be used.

The counterdirected countercurrent cross-flow with stream 2 unmixed is easy to realize in tube bundles of rectangular cross-section. The relevant design charts are shown in Figs. 36–41. Equations are presented in Table 5 for flow arrangements with four or less passes and with stream 1 completely mixed in the lateral direction (one tube row for each pass; Figs. 36–38) and for flow arrangements with two passes and two tube rows in each pass (Fig. 39).

Counterdirected cross-flow heat exchangers with four or more passes and one tube row per pass can be designed with the aid of the following approximate equation [24]:

$$F = \frac{n}{\mathrm{NTU}_1\sqrt{R_1}} \frac{3\sinh\left(\frac{\mathrm{NTU}_1}{n}\sqrt{R_1}\right)}{1 + 2\cosh\left(\frac{\mathrm{NTU}_1}{n}\sqrt{R_1}\right)} \qquad (33)$$

where n is the number of passes. The dimensionless temperature change P_i ($i = 1, 2$) can then be obtained from Eq. (25) or (26). The error in P is at the most 1% for $n \geq 4$.

The charts for flow arrangements in which the number of tube rows in each pass is very large (each pass as in pure cross-flow; Figs. 40 and 41) were calculated numerically. For the numerical calculation each pass was subdivided into 40 × 40 cells. In addition to the given charts and coefficients for Eq. (24), a most powerful approximation [24] can be recommended which is valid for any number of counterdirected pure cross-flow passes.

The codirected countercurrent cross-flow arrangement in which the flow is in the same direction in each pass is the more effective one. It is realized in helical coil heat exchangers (Fig. 6), in which each turn corresponds to one pass with one row of tubes. In Table 5 design equations are given for arbitrary values of n. Alternatively, if mixing between passes or counterdirected pass flow is assumed for the design calculation, the exchanger surface will be overestimated and one is on the safe side.

Countercurrent cross-flow transforms into pure countercurrent flow as the number of passes increases. However, if the NTU is high, i.e., NTU > 5, the equations for countercurrent flow do not apply unless the number of passes is about 20 or more.

4.5 Plate Heat Exchangers

The following is restricted to the thermal analysis of heat exchangers with a large number of plates, i.e., those in which thermal end effects can be ignored (heat is transferred on only one side of the channels at the ends). According to Kandlikar and Shah [25], this end effect can generally be neglected if there are more than 40 plates in the complete heat exchanger. Solutions that have been determined numerically or analytically for equipment with a smaller number of plates and for various flow arrangements can be found in the literature [25, 26].

Plate heat exchangers can be classified regarding the number of passes for the two streams. Subscript 1 is allotted to the stream with the smaller number of passes. Flow arrangements with the same number of passes on each side are symmetrical. Several flow arrangements are feasible with a given number of passes on each side. They are partly identical regarding the

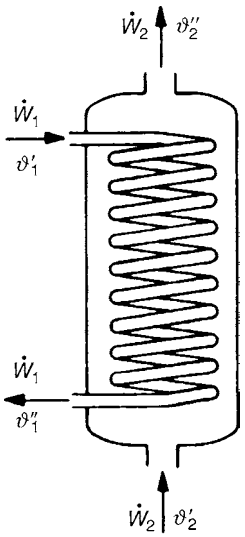
C1. Table 5. Equations for cross-flow heat exchangers, stream 1 inside tubes

Flow arrangement	Equation	Limiting curve
Pure cross-flow [19, 20] $i = 1, 2$	$P_i = \frac{1}{R_i \mathrm{NTU}_i} \sum_{m=0}^{\infty} \left\{ \left[1 - e^{-\mathrm{NTU}_i} \sum_{j=0}^{m} \frac{1}{j!} \mathrm{NTU}_i^j \right] \left[1 - e^{-R_i \mathrm{NTU}_i} \sum_{j=0}^{m} \frac{1}{j!} (R_i \mathrm{NTU}_i)^j \right] \right\}$	$P_{i\infty} = \begin{cases} 1; R_i \le 1 \\ 1/R_i; R_i > 1 \end{cases}$
Cross-flow with one tube row, laterally mixed on one side [21]	$P_1 = 1 - \exp\left[\left(e^{-R_1 \mathrm{NTU}_1} - 1 \right) / R_1 \right]$ or $\mathrm{NTU}_1 = -\frac{1}{R_1} \ln[1 + R_1 \ln(1 - P_1)]$	$P_{1\infty} = 1 - e^{-1/R_1}$
Cross-flow, laterally mixed on both sides [21] $i = 1, 2$	$\frac{1}{P_i} = \frac{1}{1 - e^{-\mathrm{NTU}_i}} + \frac{R_i}{1 - e^{-R_i \mathrm{NTU}_i}} - \frac{1}{\mathrm{NTU}_i}$	$P_{i\infty} = \frac{1}{1 + R_i}$
Cross-flow with n tube rows and one pass[a]	$P_1 = 1 - e^{-nB} \sum_{j=0}^{n-1} \left(1 - \frac{j}{n} \right) (v_j - a v_{j-1})$ where $\nu_{-1} = 0$; $\nu_0 = 1$ $v_{j+1} = \frac{1}{j+1} \left[(nR_1B^2 + 2ja + a) v_j - ja^2 v_{j-1} \right]$; $j = 0, 1, 2, \ldots$ $a = e^{-R_1 \mathrm{NTU}_1 / n}$; $B = (1 - a)/R_1$	$P_{1\infty} = 1 - e^{-n/R_1} \sum_{j=0}^{n-1} \frac{1}{j!} \left(1 - \frac{j}{n} \right) \left(\frac{n}{R_1} \right)^j$
Counterdirected countercurrent cross-flow with two tube rows and two passes [22]	$\frac{1}{1 - P_1} = \frac{\delta}{2} + \left(1 - \frac{\delta}{2} \right) e^{2\delta/R_1}$ where $\delta = 1 - e^{-R_1 \mathrm{NTU}_1 / 2}$	$P_{1\infty} = 1 - \frac{2}{1 + e^{2/R_1}}$
Counterdirected countercurrent cross-flow with three tube rows and three passes [22]	$\frac{1}{1 - P_1} = \left(1 - \frac{\delta}{2} \right)^2 e^{3\delta/R_1} + \left[\delta \left(1 - \frac{\delta}{4} \right) - \frac{\delta^2}{R_1} \left(1 - \frac{\delta}{2} \right) \right] e^{\delta/R_1}$ where $\delta = 1 - e^{-R_1 \mathrm{NTU}_1 / 3}$	$P_{1\infty} = 1 - \frac{4}{\left(3 - \frac{2}{R_1} \right) e^{1/R_1} + e^{3/R_1}}$
Counterdirected countercurrent cross-flow with four tube rows and four passes [23]	$\frac{1}{1 - P_1} = \frac{\delta}{2} \left(1 - \frac{\delta}{2} + \frac{\delta^2}{4} \right) + \delta \left(1 - \frac{\delta}{2} \right) \left[1 - \frac{2\delta}{R_1} \left(1 - \frac{\delta}{2} \right) \right] e^{2\delta/R_1} + \left(1 - \frac{\delta}{2} \right)^3 e^{4\delta/R_1}$ where $\delta = 1 - e^{-R_1 \mathrm{NTU}_1 / 4}$	$\frac{8}{1 - P_{1\infty}} = 3 + 4 \left(1 - \frac{1}{R_1} \right) e^{2/R_1} + e^{4/R_1}$
Counterdirected countercurrent cross-flow with four tube rows and two passes [23]	$\frac{1}{1 - P_1} = \frac{\frac{1}{2R_1} \delta^3 \left(4 - \delta + \frac{2\delta^2}{R_1} \right) + \delta \left(1 - \frac{\delta}{2} + \frac{\delta^2}{8} \right) \left(1 - e^{4\delta/R_1} \right) + e^{4\delta/R_1}}{\left(1 + \frac{\delta^2}{R_1} \right)^2}$ where $\delta = 1 - e^{-R_1 \mathrm{NTU}_1 / 4}$	$\frac{1}{1 - P_{1\infty}} = \frac{\frac{1}{2R_1} \left(3 + \frac{2}{R_1} \right) + \frac{5}{8} \left(1 - e^{4/R_1} \right) + e^{4/R_1}}{\left(1 + \frac{1}{R_1} \right)^2}$
Codirected countercurrent cross-flow with n tube rows and n passes[a]	$\frac{1}{1 - P_1} = e^B \prod_{j=0}^{n-1} \delta_j$ where $\delta_0 = 1$; $\delta_1 = e^B - R_1 B^2$ $\delta_i = \delta_1 - \sum_{j=2}^{i} \frac{\mu_j - a\mu_{j-1}}{\prod_{k=i-j+1}^{i-1} \delta_k}$; $i = 2, 3, 4, \ldots$ $\mu_{-1} = 0$; $\mu_0 = 1$ $\mu_{j+1} = \frac{1}{j+1} \left[(R_1 B^2 + 2ja + a) \mu_j - ja^2 \mu_{j-1} \right]$; $j = 0, 1, 2, \ldots$ $a = e^{-R_1 \mathrm{NTU}_1 / n}$; $B = (1 - a)/R_1$	$\frac{1}{1 - P_{1\infty}} = e^{1/R_1} \prod_{j=0}^{n-1} \delta_{j\infty}$ where $\delta_{0\infty} = 1$; $\delta_{1\infty} = e^{1/R_1} - 1/R_1$ $\delta_{i\infty} = \delta_{1\infty} - \sum_{j=2}^{i} \frac{1}{j! R_1^j \prod_{k=i-j+1}^{i-1} \delta_{k\infty}}$ $i = 2, 3, 4, \ldots$

[a]These equations have been derived by Th. Bes, Institute of Thermodynamics, Helmut Schmidt University/University of the Federal Armed Forces Hamburg, 1993

thermal performance. A method of determining the thermal efficiency is to break down the flow arrangement into a system of cocurrent and countercurrent units connected in series and parallel and to apply the coupling equations (Sect. 5.1).

Design charts showing the most favorable flow configurations in four different arrangements of passes are presented in Figs. 42–45. The equations used for their determination are listed in Table 6. The most advantageous flow arrangement with the same number of passes on both sides is pure countercurrent flow.



C1. Fig. 6. Schematic diagram of a helical coil heat exchanger with $n = 10$ turns (or passes).

4.6 Spiral Heat Exchangers

In spiral heat exchangers with a finite number of turns, the two streams flow in countercurrent, but the thermal efficiency is poorer than that in pure countercurrent flow. A schematic diagram of the flow arrangement is shown in Fig. 7. The stream that enters on the inside is allotted the subscript 1. The following approximation equation [28] applies to the logarithmic mean temperature difference correction factor:

$$F = \frac{1}{\mathrm{NTU}^2} \ln \frac{1 + \mathrm{NTU}^2}{1 + \left(\frac{\mathrm{NTU} r_1}{r_1 + nb}\right)^2} \tag{34}$$

where

$$\mathrm{NTU} = \frac{k\pi d_o H}{\sqrt{\dot{W}_1 \dot{W}_2}} \tag{35}$$

is formed with the geometric mean of both heat capacity flow rates, and with the outside shell surface of diameter d_o and height H. The number of turns is denoted with n, r_i is the radius of the central tube and b the width of the flow channels.

The temperature change P_i ($i = 1, 2$) can be determined from the correction factor F by means of Eqs. (25) or (26) (Sect. 3.4). If $n \geq 4$ and $F > 0.8$, the relative error for P is less than 1%. The approximation equation yields symmetrical results, although the flow arrangement is slightly asymmetric.

Equations (34) and (35) are valid for a constant overall heat transfer coefficient. In a special method [29] the effect of changing radius of channel curvature on the transfer coefficients can also be taken into account.

C1. Table 6. Equations for plate heat exchangers [27]. P_{1c} dimensionless temperature change for pure countercurrent flow (Table 3). P_{1p} dimensionless temperature change for pure cocurrent flow (Table 3)

Flow arrangement	Equation	Limiting curve
One pass for stream 1 and two passes for stream 2	$P_1 = \frac{1}{2}\left(P_{1c} + P_{1p} - \frac{1}{2}R_1 P_{1c} P_{1p}\right)$ where $P_{1c} = P_{1c}(\mathrm{NTU}_1, R_1/2)$ and $P_{1p} = P_{1p}(\mathrm{NTU}_1, R_1/2)$	$P_{1\infty} = \begin{cases} 2/(2+R_1); & R_1 \leq 2 \\ 1/R_1; & R_1 > 2 \end{cases}$
One pass for stream 1 and three passes for stream 2, two in countercurrent	$P_1 = \frac{1}{3}\left(P_{1p} + P_{1c}\left(1 - \frac{1}{3}R_1 P_{1p}\right)\left(2 - \frac{1}{3}R_1 P_{1c}\right)\right)$ where $P_{1c} = P_{1c}(\mathrm{NTU}_1, R_1/3)$ and $P_{1p} = P_{1p}(\mathrm{NTU}_1, R_1/3)$	$P_{1\infty} = \begin{cases} (9-R_1)/(9+3R_1); & R_1 \leq 3 \\ 1/R_1; & R_1 > 3 \end{cases}$
One pass for stream 1 and four passes for stream 2	$P_1 = \delta\left(1 - \frac{1}{4}R_1\delta\right)$ $\delta = \frac{1}{2}\left(P_{1c} + P_{1p} - \frac{1}{4}R_1 P_{1c} P_{1p}\right)$ where $P_{1c} = P_{1c}(\mathrm{NTU}_1, R_1/4)$ and $P_{1p} = P_{1p}(\mathrm{NTU}_1, R_1/4)$	$P_{1\infty} = \begin{cases} (4/(4+R_1))^2; & R_1 \leq 4 \\ 1/R_1; & R_1 > 4 \end{cases}$
Two passes for stream 1 and four passes for stream 2 in overall counterflow	$P_1 = \delta + \frac{\delta(1-\delta)(1-\delta R_1)}{1-\delta^2 R_1}$ $\delta = \frac{1}{2}\left(P_{1c} + P_{1p} - \frac{1}{2}R_1 P_{1c} P_{1p}\right)$ where $P_{1c} = P_{1c}(\mathrm{NTU}_1, R_1/2)$ and $P_{1p} = P_{1p}(\mathrm{NTU}_1, R_1/2)$	$P_{1\infty} = \begin{cases} 4/\left(4+R_1^2\right); & R_1 \leq 2 \\ 1/R_1; & R_1 > 2 \end{cases}$

4.7 Plug-in Double-Pipe Heat Exchangers

The dimensionless temperature change P that occurs within a heating or cooling medium that flows in a double-pipe heat exchanger with closed ends (Fig. 8) can be obtained from the following equation [1]:

$$P = 2\frac{1 - e^{-\mu NTU}}{1 + \mu + (\mu - 1)e^{-\mu NTU}} \qquad (36)$$

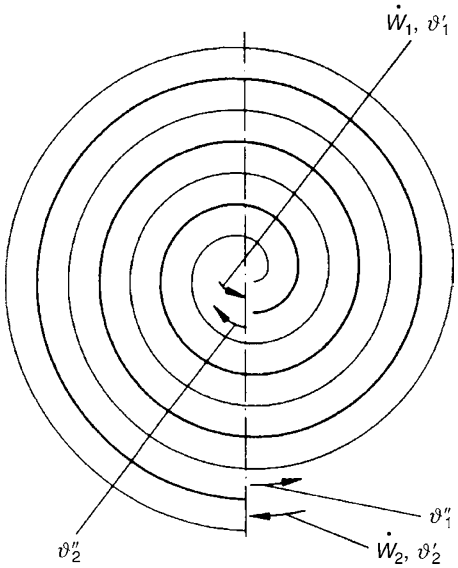
where

$$P = \frac{\vartheta' - \vartheta''}{\vartheta' - \vartheta_s},$$

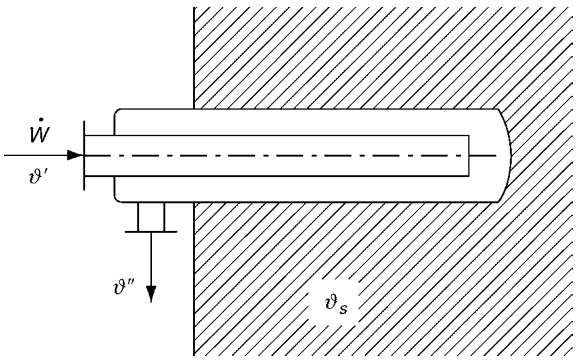
$$NTU = \frac{(kA)_o}{\dot{W}},$$

$$\mu = \sqrt{1 + 4\frac{(kA)_i}{(kA)_o}},$$

ϑ_s is the temperature of the ambient medium to be heated or cooled and is assumed to be constant (complete mixing or phase change),



C1. Fig. 7. Schematic diagram of a spiral heat exchanger with $n = 3$ turns in the double spiral.



C1. Fig. 8. Inserted double-pipe heat exchanger for heating or cooling a medium at a constant temperature.

$\dot{W}$ is the heat capacity flow rate of the heating or cooling medium,

$(kA)_o$ is the product of the overall heat transfer coefficient and the area of the outer pipe,

and

$(kA)_i$ is the corresponding product for the inner pipe.

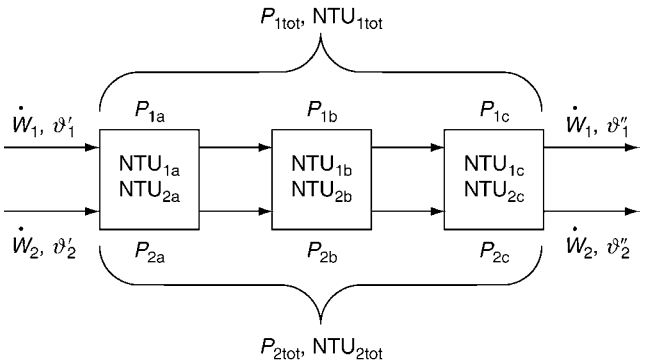
Equation (36) is valid regardless of whether the heating or cooling medium enters the inner or outer pipe.

5 Heat Exchanger Systems

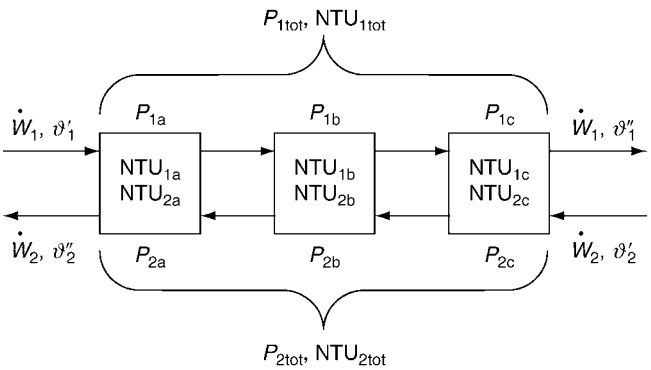
5.1 Coupled Heat Exchangers

A number of heat exchangers of the same or different types may be connected together. The temperature changes that can be achieved by the coupled system depend on the nature of the connections, the behavior of the individual units, and the degree of mixing of the streams between the units.

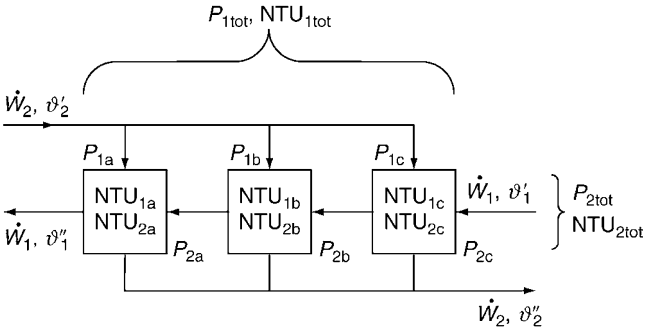
It is assumed here that the streams between the individual exchangers are completely mixed and that the heat capacity rates in the entire system are constant. Exchangers can be connected in series with overall cocurrent (Fig. 9) or countercurrent (Fig. 10) flow, and stream 2 can be readily divided into a number of parallel substreams (Fig. 11). The individual flow arrangements are unaffected by the nature of the series or parallel connections, and the equations and design charts in Sect. 4 still apply.



C1. Fig. 9. Schematic diagram of three heat exchangers in series connection with overall cocurrent flow.



C1. Fig. 10. Schematic diagram of three heat exchangers in series connection with overall countercurrent flow.



C1. Fig. 11. Schematic diagram of three heat exchangers in parallel connection, stream 2 divided into three substreams.

The number of transfer units NTU_{1tot} and the heat transfer area A_{tot} in a coupled system are the sums of the corresponding values NTU_{1i} and A_i for the individual exchangers, regardless of the type of connection. Thus,

$$NTU_{1tot} = \sum_{i=1}^{n} NTU_{1i} \tag{37}$$

If $NTU_{1a} = NTU_{1b} = \ldots = NTU_1$,

$$NTU_{1tot} = nNTU_1 \tag{38}$$

If the exchangers are connected in series (Figs. 9 and 10), the heat capacity rate ratios R_1 and R_2 in each of them are equal and identical to the corresponding ratios for the entire system. If they are connected in parallel (Fig. 11), the following applies:

$$\frac{1}{R_{1tot}} = \sum_{i=1}^{n} \frac{1}{R_{1i}} \tag{39}$$

If $R_{1a} = R_{1b} = \ldots = R_1$,

$$\frac{1}{R_{1tot}} = \frac{n}{R_1} \tag{40}$$

The relationship between the dimensionless temperature change in each of the exchangers P_{1i} and that in the entire system P_{1tot} differs for the types of connection.

(a) Series connection with overall cocurrent flow

The following equation applies [30]:

$$1 - P_{1tot}(1 + R_1) = \prod_{i=1}^{n} [1 - P_{1i}(1 + R_1)] \tag{41}$$

Groups of exchangers within a system may be considered as single units. The total effect is independent of the sequence in which the individual elements are connected.

In the special case that the dimensionless temperature change is the same in each exchanger, i.e., $P_{1a} = P_{1b} = \ldots = P_1$, Eq. (41) can be simplified to give

$$1 - P_{1tot}(1 + R_1) = [1 - P_1(1 + R_1)]^n \tag{42}$$

It could be closely approximated if, for example, the individual exchangers are all identical.

A possible adverse effect of the series connection in overall cocurrent flow should be mentioned: If in the first exchanger the temperatures cross, i.e., if $P_{11}(1 + R_1) > 1$, the following exchangers will partially or totally reduce the overall temperature changes P_{1tot} and P_{2tot}. This effect is particularly pronounced for two exchangers with crossing temperatures. If, for example, for $n = 2$ identical exchangers $R_1 = 1$ and $P_1 = 1$ (counterflow, $NTU_1 = NTU_2 = \infty$), the total temperature change $P_{1tot} = 0$, according to Eq. (42).

Similar effects may also occur in single heat exchangers, e.g., in multipass shell-and-tube exchangers (Fig. 5, layout A) or in the mixed–mixed cross-flow.

(b) Series connection with overall countercurrent flow

In principle, series connections with overall countercurrent flow are more effective than those in cocurrent flow [30]. The equation that applies in this case is

$$\frac{1 - P_{1tot}}{1 - R_1 P_{1tot}} = \prod_{i=1}^{n} \left(\frac{1 - P_{1i}}{1 - R_1 P_{1i}} \right) \text{for } R_1 \neq 1 \tag{43}$$

$$\text{or } \frac{P_{tot}}{1 - P_{tot}} = \sum_{i=1}^{n} \frac{P_i}{1 - P_i} \tag{44}$$

for $R_1 = 1$ ($P_i = P_{1i} = P_{2i}$ and $P_{tot} = P_{1tot} = P_{2tot}$).

From Eq. (43) one can derive for the correction factor

$$F_{tot} NTU_{1tot} = F_{tot} \sum_{i=1}^{n} NTU_{1i} = \sum_{i=1}^{n} F_i NTU_i \tag{45}$$

In the special case of equal dimensionless temperature changes, i.e., $P_i = P$, Eqs. (43) and (44) become

$$\frac{1 - P_{1tot}}{1 - R_1 P_{1tot}} = \left(\frac{1 - P_1}{1 - R_1 P_1} \right)^n \quad \text{for } R_1 \neq 1 \tag{46}$$

$$\text{and } \frac{P_{tot}}{1 - P_{tot}} = \frac{nP}{1 - P} \quad \text{for } R_1 = 1 \tag{47}$$

In this particular case, $F_{tot} = F_i = F$, where F_i is the correction factor for the individual exchanger and F_{tot} is the value for the whole system.

(c) Stream 2 split up into parallel substreams

The equation that applies in this case is [31]

$$1 - P_{1tot} = \prod_{i=1}^{n} (1 - P_{1i}) \tag{48}$$

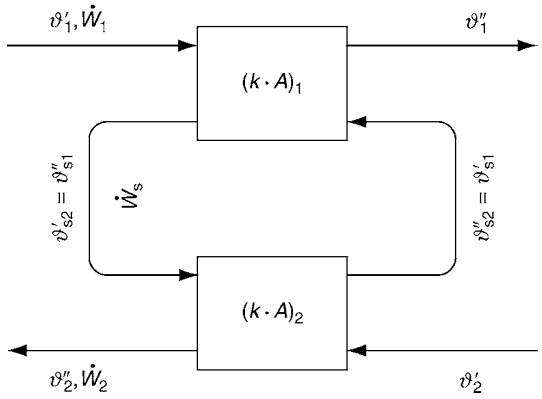
For the special case in which the dimensionless temperature change is the same in each exchanger, i.e., $P_{1i} = P_1$, Eq. (48) can be simplified to give

$$1 - P_{1tot} = (1 - P_1)^n \tag{49}$$

Many types of connections other than those dealt with above are feasible. They are described and discussed in detail in Chap. C5. In the cell method, as described in Sect. 2, a single exchanger is regarded as a system of individual elements.

5.2 Two Heat Exchangers Coupled by a Circulating Thermal Fluid

For heat transfer between two gases, space considerations or safety aspects sometimes require systems that consist of two



C1. Fig. 12. Schematic diagram of a system of two heat exchangers coupled by a circulating stream.

single heat exchangers coupled by a circulating thermal fluid. Such a system is shown in Fig. 12.

The following equations apply to the individual exchangers. When the subscripts consist of two digits, the first refers to the fluid, and the second to the exchanger.

Heat exchanger 1 Heat exchanger 2

$$\mathrm{NTU}_{11} = \frac{(kA)_1}{\dot{W}_1} \qquad \mathrm{NTU}_{22} = \frac{(kA)_2}{\dot{W}_2}$$

$$R_{11} = \frac{\dot{W}_1}{\dot{W}_s} \qquad R_{22} = \frac{\dot{W}_2}{\dot{W}_s}$$

$$P_{11} = \frac{\vartheta'_1 - \vartheta''_1}{\vartheta'_1 - \vartheta'_{s1}} \qquad P_{22} = \frac{\vartheta''_2 - \vartheta'_2}{\vartheta'_{s2} - \vartheta'_2}$$

The following apply to the entire system.

$$P_{1\mathrm{tot}} = \frac{\vartheta'_1 - \vartheta''_1}{\vartheta'_1 - \vartheta'_2}$$

$$R_{1\mathrm{tot}} = \frac{\dot{W}_1}{\dot{W}_2} = \frac{1}{R_{2\mathrm{tot}}}$$

$$\mathrm{NTU}_{1\mathrm{tot}} = \frac{(kA)_{\mathrm{eff}}}{\dot{W}_1}$$

The first step in rating a system is to determine the dimensionless temperature changes $P_{11}(\mathrm{NTU}_{11}; R_{11})$ and $P_{22}(\mathrm{NTU}_{22}; R_{22})$ for the individual exchangers and their flow arrangements using the equations and design charts in Sect. 4. The dimensionless temperature change within the whole system can then be determined from the following equation [1, 32]:

$$\frac{1}{P_{1\mathrm{tot}}} = \frac{1}{P_{11}} + \frac{1}{P_{22}} R_{1\mathrm{tot}} - R_{11} \tag{50}$$

Concerning the total temperature change $P_{1\mathrm{tot}}$, there exists an optimum value of the circulating heat capacity flow rate $\dot{W}_{s,\mathrm{opt}}$ [1] if the overall heat transfer coefficients do not depend on the circulating flow rate. For two counterflow heat exchangers [33]

$$\frac{1}{\dot{W}_{s,\mathrm{opt}}} = \frac{\kappa_1}{\dot{W}_1} + \frac{\kappa_2}{\dot{W}_2} \tag{51}$$

with

$$\kappa_1 = \frac{(kA)_1}{(kA)_1 + (kA)_2} \text{ and } \kappa_2 = \frac{(kA)_2}{(kA)_1 + (kA)_2} \tag{52}$$

Under this optimum condition, the exchanger system can be regarded as one single counterflow heat exchanger with the effective overall heat transfer resistance

$$\frac{1}{(kA)_{\mathrm{eff}}} = \frac{1}{(kA)_1} + \frac{1}{(kA)_2} \tag{53}$$

The required value of $(kA)_{\mathrm{eff}}$ is determined from the given data $(P_{1\mathrm{tot}}, \dot{W}_1, \dot{W}_2)$ in the known manner for the hypothetical single counterflow heat exchanger.

The individual values of the real counterflow exchangers $(kA)_1$ and $(kA)_2$ have to be designed such that Eq. (53) is fulfilled. For individual flow arrangements other than counterflow one can, as an approximation, simply replace in Eqs. (52) and (53) $(kA)_1$ and $(kA)_2$ by $(kA)_1 F_1$ and $(kA)_2 F_2$, respectively.

Many designs are possible which fulfill Eq. (53). The economically optimal values of both heat transfer surface areas A_1 and A_2 depend on the ratio of the prices per unit area π_1/π_2 as well as the ratios of both the overall heat transfer coefficients k_1/k_2 and the correction factors F_1/F_2 [33]. The optimum surfaces can be estimated as follows [33].

With guessed values of the above-mentioned ratios one can first calculate optimal values of κ_1 and κ_2 according to

$$\frac{1}{\kappa_1} = 1 + \sqrt{\frac{k_2 F_2 \pi_1}{k_1 F_1 \pi_2}}; \quad \kappa_2 = 1 - \kappa_1 \tag{54}$$

and the optimum flow rate $\dot{W}_{s,\mathrm{opt}}$ from Eq. (51). Then, the unknown inlet and outlet temperatures of the circulating flow stream can be determined from

$$\begin{aligned} \vartheta''_{s1} &= \vartheta'_{s2} = \kappa_1 \vartheta'_1 + \kappa_2 \vartheta''_2 \\ \vartheta'_{s1} &= \vartheta''_{s2} = \kappa_1 \vartheta''_1 + \kappa_2 \vartheta'_2 \end{aligned} \tag{55}$$

Using the charts or equations for the individual flow arrangements one can determine for both exchangers the required values of $(kA)_1$ and $(kA)_2$ as well as F_1 and F_2.

The heat transfer calculations yield κ_1 and κ_2, and the guessed values in Eq. (54) can be improved. This way the required heat transfer surfaces A_1 and A_2 can iteratively be determined.

A detailed investigation of the thermal behavior of such systems was carried out by NaRanong [34, 35]. In his work, various individual flow arrangements are considered and the effect of transfer coefficients varying with the circulating flow rate are taken into account. Not only the steady state but also the transient behaviour is investigated.

The coupled system can also be regarded as a heat exchanger network (see Chap. C5).

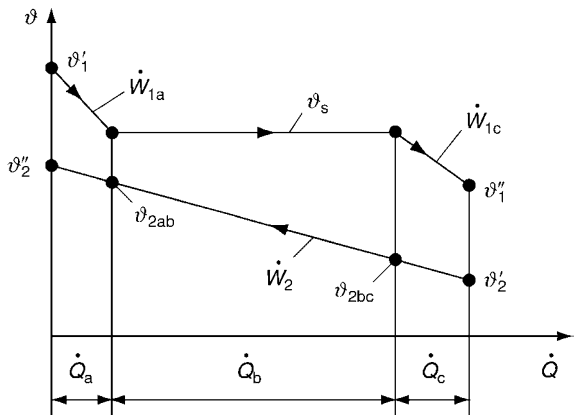
5.3 Phase Change with Superheating and Subcooling

Normally, heat exchangers in which superheated vapor is cooled and completely condensed and the condensate is subcooled are also regarded as coupled systems. The same applies to the reverse case of evaporation. The three unit operations are designed as if they were to take place in separate exchangers and the individual areas are added together to obtain the area of the entire system.

In Fig. 13, the average temperatures over the cross-sections have been plotted against the heat flow rate $\dot{Q}$ transferred from the vapor in the heat exchanger (on the assumption of constant specific heat capacities and constant pressure during condensation). Since it is unknown how the entire heat transfer area has to be divided over the three unit operations, assumptions must be made on the flow arrangement in the desuperheating section *a* and the subcooling section *c*. These assumptions must be checked in the light of the results obtained, and the calculation must then be repeated when necessary.

If the inlet and outlet temperatures for the complete heat exchanger and the boiling point ϑ_{bp} are known, the temperatures ϑ_{2ab} and ϑ_{2bc} can be derived from the energy balances for the desuperheating and subcooling sections. The dimensionless temperature changes P_{1j} and P_{2j} (j = *a*, *b*, *c*) can thus be determined for the three parts of the exchanger. The values obtained for P_{1j} and P_{2j} can then be taken to calculate the number of transfer units NTU_{2j} (j = *a*, *b*, *c*) for the flow arrangements in each part. The method to be adopted is that described in Sect. 4. Regardless of the flow arrangement, Eq. (29) with $i = 2$ always applies for the condensation section *b*. The mean overall heat transfer coefficient in the condensation section can be calculated by the three-point method described in Chap. C2, Sect. 6. The single-phase coefficients at the ends *ab* and *bc* may be used for this purpose. The values for $(kA)_j$ and A_j (j = *a*, *b*, *c*) can be obtained directly from NTU_{2j}, and the partial areas can be added to the total area.

This simple mathematical treatment actually applies only to evaporation and condensation in the tubes of a countercurrent heat exchanger. In other cases, the results must be regarded merely as a rough guide. More accurate results can be obtained only by step-by-step numerical calculations [36].



C1. Fig. 13. Temperature as a function of the heat transferred in a countercurrent condenser with vapor desuperheating and condensate subcooling.

6 Examples of Application

The two principal aims in heat exchanger design are

- Rating existing designs
- Designing or dimensioning heat exchangers from scratch

Each aim requires different means of applying the equations and charts given above. This is demonstrated with some characteristic examples.

6.1 Rating of Existing Designs

For this problem the design of the heat exchanger, the mass flow rates (and hence the heat capacity rates $\dot{W}_1$ and $\dot{W}_2$), and the inlet temperatures ϑ'_1 and ϑ'_2 are known. The aim is to determine the outlet temperatures ϑ''_1 and ϑ''_2 and the transferred heat flow rate $\dot{Q}$. The product (kA) can be obtained from the design data, the mass flow rates, and by means of estimated reference temperatures for the thermophysical properties (Chap. C2). The estimated values of the reference temperatures must be checked with the results and the calculation must be repeated with improved estimates if necessary.

Example 1

Ambient air (volumetric flow rate at the inlet 2 m^3/s, inlet temperature ϑ'_2 = 20°C, pressure 1 bar) shall be heated in an existing heat exchanger using hot water (mass flow rate 1 kg/s, inlet temperature ϑ'_1= 120°C, pressure 10 bar). The heat exchanger consists of a rectangular tube bundle with 120 finned tubes (material aluminium) in staggered arrangement. The tubes are arranged in six tube rows and six counterdirected passes. The air on the outside flows perpendicular to the tubes, the water inside the tubes. The dimensions of the finned tubes are as follows:

Outside tube diameter = 16 mm
Inside tube diameter = 12 mm
Tube length = 1 m
Circular fins with outside diameter = 42 mm
Fin pitch = 400 fins/m
Fin thickness = 0.4 mm
Tube pitch in the bundle = 45 mm

The outlet temperatures and the thermal performance shall be calculated. Additional heat transfer resistances due to fouling are to be neglected.

Solution

In this case, the usual mean value of the overall heat transfer coefficient shall approximately be used: $k \approx \bar{k}$ (cf. Chap. C2). In Example 2 of Chap. C2, it is shown that in this case the

usual mean value is a very good approximation for the true mean overall heat transfer coefficient.

The reference temperatures (arithmetic mean of inlet and outlet temperatures) must be estimated: tube side $\vartheta_1 = 100°C$, on the outside $\vartheta_2 = 60°C$. At these reference temperatures the properties of water and air, respectively, are determined (Chap. D2). For the tube-side heat transfer, the correlations from Chap. G1 yield

$Re_1 = 1.88 \cdot 10^4$ and $\alpha_1 = 4{,}625$ W/m^2 K,

where the correction for temperature-dependent properties has been neglected. For the outside heat transfer, the correlations from Chap. M1 yield

$Re_2 = 3.78 \cdot 10^3$ and $\alpha_2 = 48.7$ W/m^2 K.

Following Chap. C2 it is

$k \cdot A = 4{,}495$ W/K.

With the heat capacity flow rates

$\dot{W}_1 = 4{,}220$ W/K and $\dot{W}_2 = 2{,}404$ W/K

the dimensionless parameters NTU_2 and R_2 can be determined:

$NTU_2 = 1.87$ ($NTU_1 = 1.06$)

$R_2 = 0.57$ ($R_1 = 1.76$).

From the chart Fig. 38, for counterdirected countercurrent cross-flow with six tube rows and six passes one obtains

$P_1 = 0.42$ ($P_2 = 0.74$).

The outlet temperatures can then be calculated from Eqs. (9) and (10):

$\vartheta_1'' = 78°C$ and $\vartheta_2'' = 94°C$.

From Eq. (7) the transferred heat flow rate is

$\dot{Q} = 177$ kW.

Note

From the chart Fig. 38, one can see that in this case the correction factor F exceeds 0.99. Generally, for small NTU-values the flow arrangement has little impact on the thermal performance. The equations for pure countercurrent flow (or the chart Fig. 17) yield nearly the same results. However, there is no general limit where the impact of the flow arrangement can be neglected (see for example the flow arrangement "two-sided stirred tank" in Fig. 15 with the NTU-values and heat capacity rate ratios of this example). It is recommended to use always the equations or the chart for the flow arrangement under consideration because this requires no significant additional work.

Example 2

In this example, the cell method (Sect. 3.1) is applied.

The design data of a shell-and-tube heat exchanger are given. The flow arrangement consists of two tube-side and one shell-side pass with one shell-side baffle.

Heat transfer: $k \cdot A = 4{,}749$ W/K

Stream 1 on the shell side: $\dot{W}_1 = 3{,}500$ W/K, $\vartheta_1' = 100°C$

Stream 2 inside the tubes: $\dot{W}_2 = 3{,}500$ W/K, $\vartheta_2' = 20°C$

The outlet temperatures ϑ_1'' and ϑ_2'' shall be determined. The (unrealistic) assumption of only one shell-side baffle has been made in order to facilitate the calculation required to follow this numerical example.

Solution

The heat exchanger is considered to be a system of four single and identical units (Fig. 14).

It is assumed that stream 2 (inside the tubes) is not laterally mixed in the individual units and that stream 1 (on the shell side) is completely laterally mixed. Thus the flow arrangement selected for each unit is mixed–unmixed cross-flow or cross-flow with one tube row (Fig. 31, equation in Table 5).

For the whole exchanger, Eqs. (11) and (12) yield

$$NTU_{1tot} = NTU_{2tot} = 1.357 (R_1 = R_2 = 1).$$

For the individual cells, Eq. (17) yields

$$NTU_{1,2} = \frac{1}{4} NTU_{1,2tot} = 0.3392$$

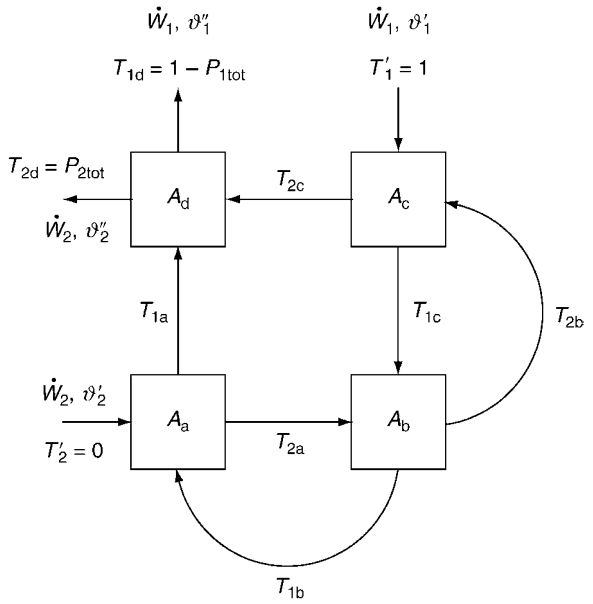
The equation for cross-flow with one tube row or mixed–unmixed cross-flow, stream 1 mixed (Table 5) yields

$$P_1 = P_2 = 0.25$$

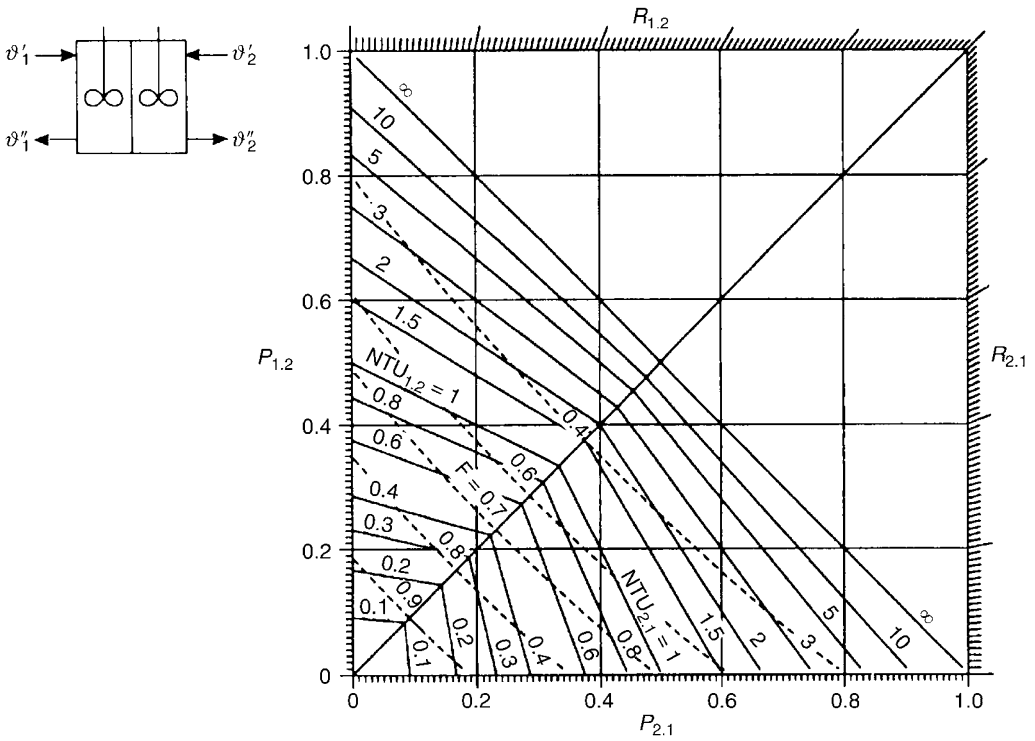
Dimensionless temperatures according to Eq. (18) are introduced to simplify the further calculations.

At the inlet $T_1' = 1$ and $T_2' = 0$. The unknown outlet temperatures in the individual units are designated as T_{1a}, T_{1b}, T_{1c}, and $T_{1d} = 1 - P_{1tot}$ as well as T_{2a}, T_{2b}, T_{2c}, and $T_{2d} = P_{2tot}$ (see Fig. 14). If the dimensionless temperature changes in each unit are expressed as defined in Eqs. (9) and (10), eight equations are obtained for these eight unknown temperatures. Following stream 2 through the units, one gets

$$P_{2a} = \frac{T_{2a} - 0}{T_{1b} - 0}, \quad P_{2b} = \frac{T_{2b} - T_{2a}}{T_{1c} - T_{2a}},$$
$$P_{2c} = \frac{T_{2c} - T_{2b}}{1 - T_{2b}}, \quad P_{2d} = \frac{T_{2d} - T_{2c}}{T_{1a} - T_{2c}}.$$



C1. Fig. 14. System of four coupled heat exchangers as a model for a shell-and-tube design with two tube-side passes and one shell-side pass with one shell-side baffle in layout A (Example 2).



C1. Fig. 15. Two-sided stirred tank.

C1. Table 7. Results for the calculation of the dimensionless outlet temperatures of the individual units with $P_1 = P_2 = 0.25$

T_{2a}	T_{2b}	T_{2c}	T_{2d}	T_{1c}	T_{1b}	T_{1a}	T_{1d}
0.167	0.333	0.5	0.5	0.833	0.667	0.5	0.5

With identical individual units it is $P_{2a} = P_{2b} = P_{2c} = P_{2d} = P_2$. Following stream 1 through the units yields

$$P_{1c} = \frac{1 - T_{1c}}{1 - T_{2b}},\ P_{1b} = \frac{T_{1c} - T_{1b}}{T_{1c} - T_{2a}},$$

$$P_{1a} = \frac{T_{1b} - T_{1a}}{T_{1b} - 0},\ P_{1d} = \frac{T_{1a} - T_{1d}}{T_{1a} - T_{2c}}.$$

In this case, too, $P_{1a} = P_{1b} = P_{1c} = P_{1d} = P_1$.

This system of linear equations can be solved iteratively by known numerical methods. The results are listed in Table 7.

The dimensionless temperature changes for the complete heat exchanger are obtained from the dimensionless outlet temperatures T_{1d} and T_{2d}, i.e.,

$$P_{1tot} = P_{2tot} = 0.5$$

and the real outlet temperatures from Eqs. (9) and (10), i.e.,

$$\vartheta''_1 = \vartheta''_2 = 60^\circ\mathrm{C}$$

6.2 Design and Dimensioning of Heat Exchangers

In this case a heat exchanger has to be designed to solve a given heat transfer problem. Designing and dimensioning of a heat exchanger is much more difficult than rating an existing exchanger and requires a lot of experience. The procedure depends on the problem to be solved, and in particular, on the specified heat transfer conditions.

Example 3

The following heat capacity flow rates and inlet temperatures are given:

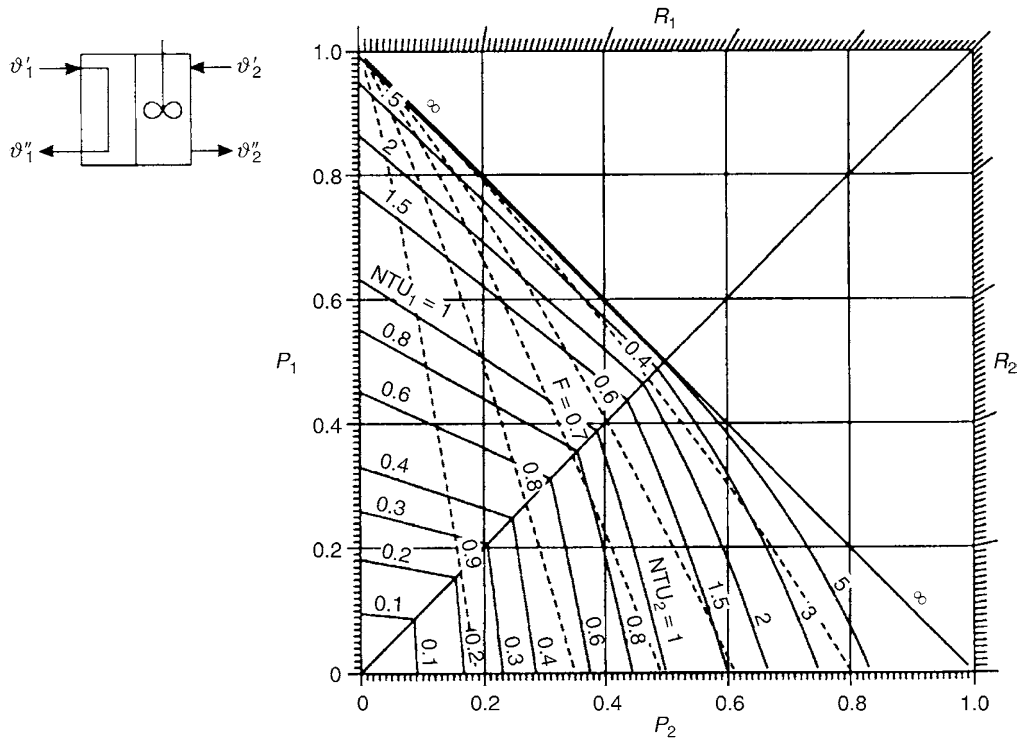
$$\dot{W}_1 = 8{,}500\,\mathrm{W/K},\ \dot{W}_2 = 7{,}000\,\mathrm{W/K},$$
$$\vartheta'_1 = 300^\circ\mathrm{C},\ \vartheta'_2 = 100^\circ\mathrm{C}.$$

For stream 1 an outlet temperature of $\vartheta''_1 = 160^\circ\mathrm{C}$ is prescribed. The outlet temperature for stream 2 follows from the energy balance for the complete exchanger according to Eq. (7) as $\vartheta''_2 = 270^\circ\mathrm{C}$.

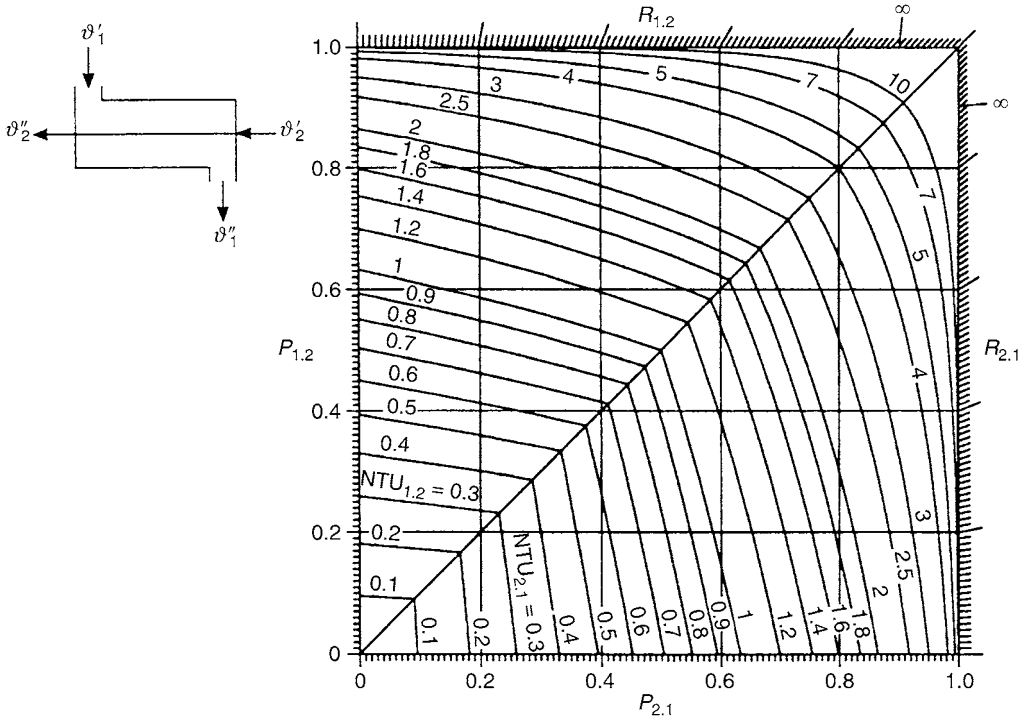
A shell-and-tube heat exchanger with several shell-side passes and two tube-side passes per shell-side pass shall be used. How many shell-side passes and which heat transfer area are required?

Solution

The flow arrangement corresponds to the coupling of several identical shell-and-tube heat exchangers, each with one



C1. Fig. 16. One-sided stirred tank.



C1. Fig. 17. Pure countercurrent flow.

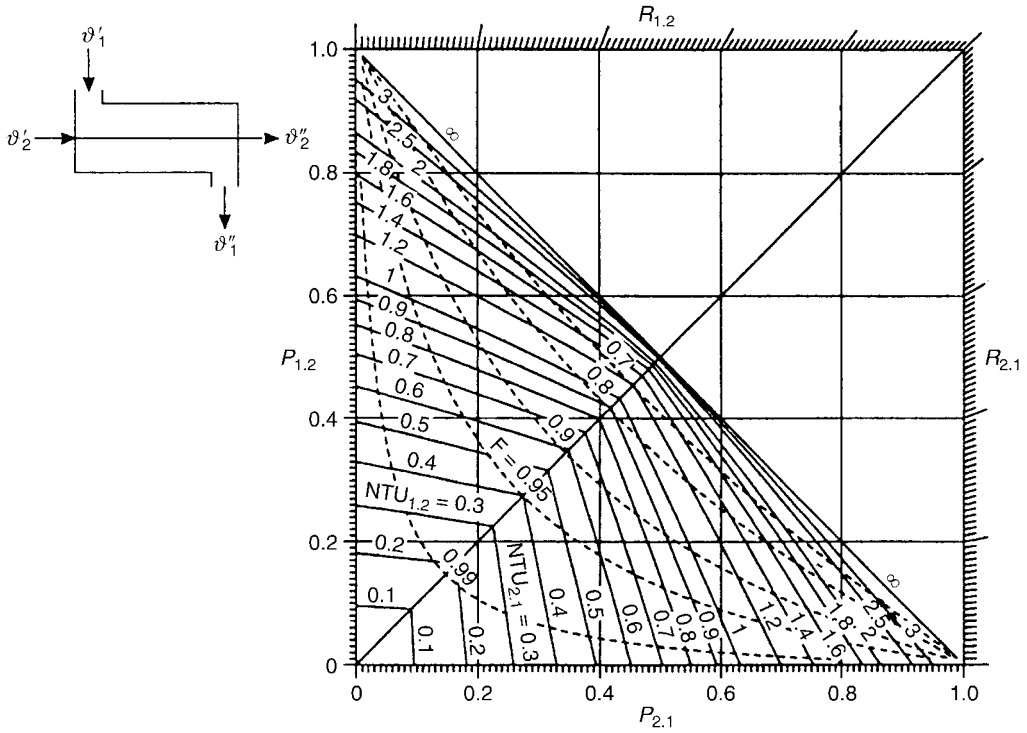
shell-side and two tube-side passes in overall countercurrent flow. The dimensionless temperature changes for the complete heat exchanger are

$$P_{1\text{tot}} = \frac{300 - 160}{300 - 100} = 0.7 \text{ and } P_{2\text{tot}} = \frac{270 - 100}{300 - 100} = 0.85.$$

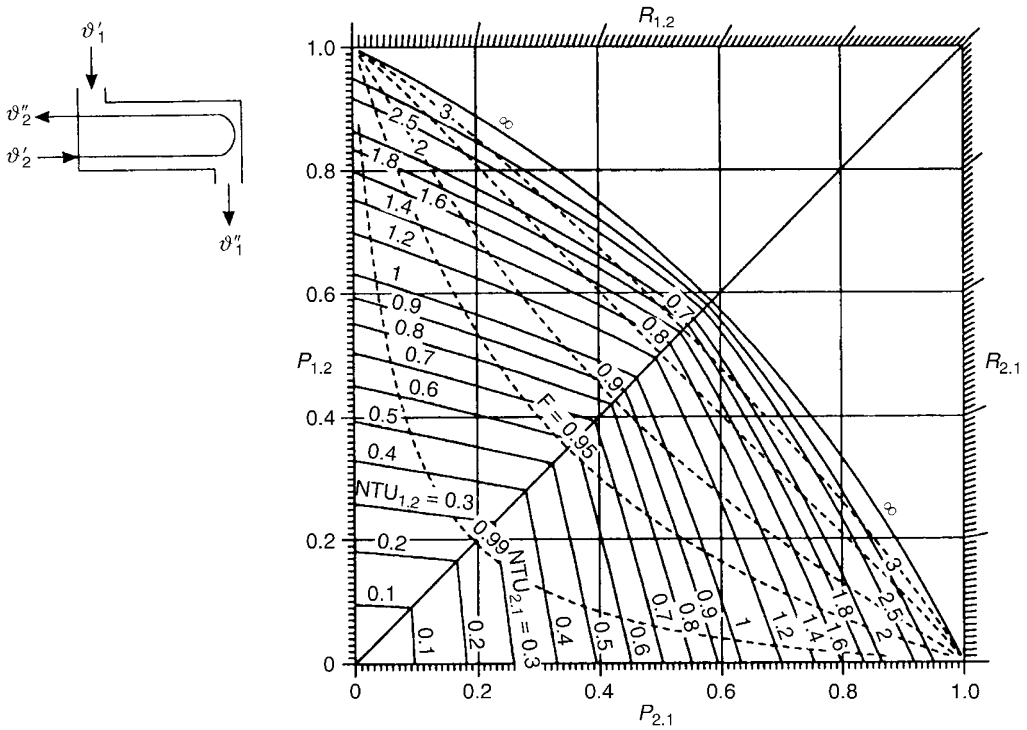
The heat capacity rate ratio is

$$R_1 = \frac{8{,}500}{7{,}000} = 1.214 \ (R_2 = 0.8235).$$

From Eq. (46) for the countercurrent series connection of identical individual exchangers together with the equation

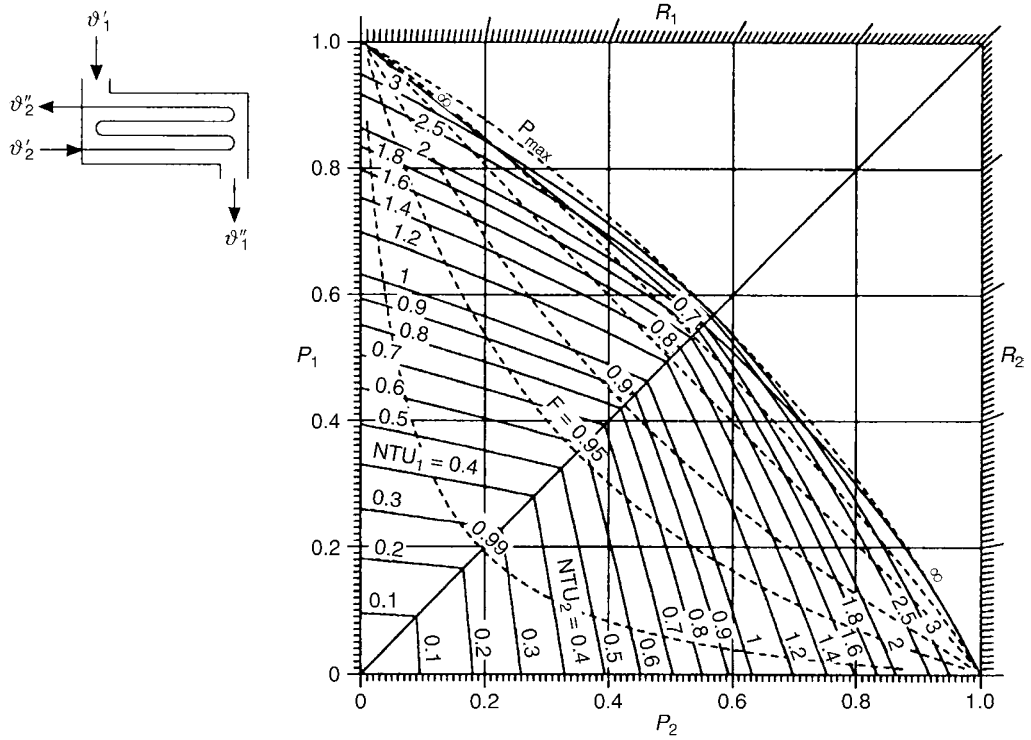


C1. Fig. 18. Pure cocurrent flow.

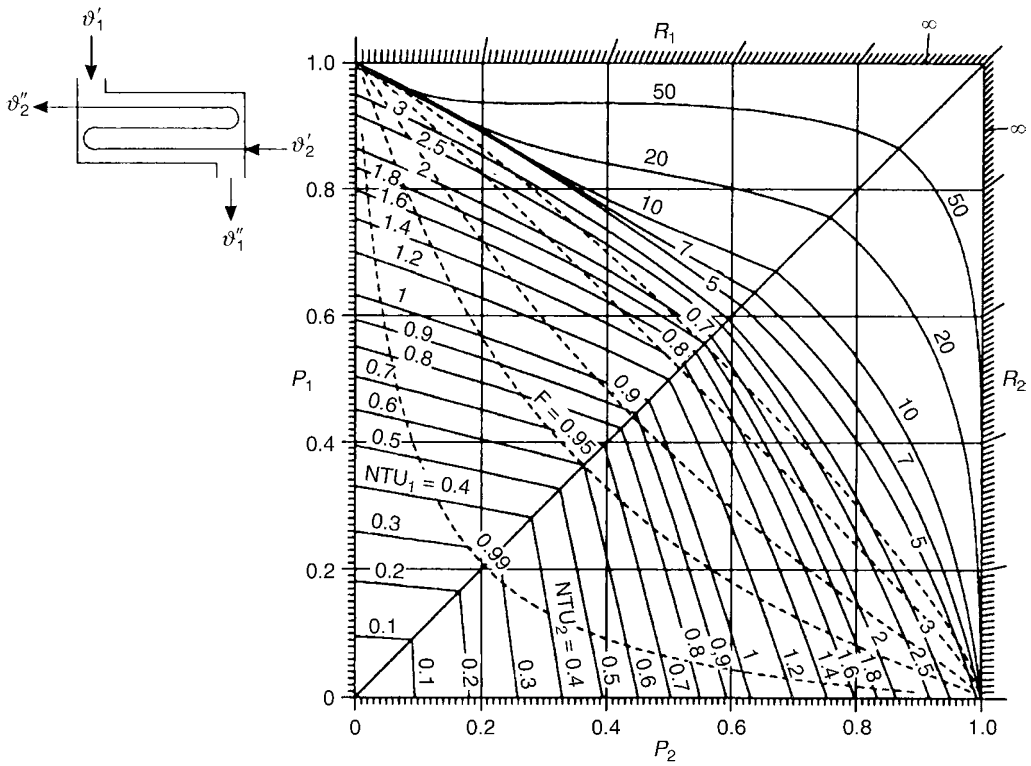


C1. Fig. 19. Shell-and-tube heat exchanger with one shell-side and two tube-side passes; $\varepsilon = 1/2$.

for the shell-and-tube exchanger with one shell-side and two tube-side passes (Table 4) it can be calculated that at least three shell-side passes for the complete exchanger are necessary to reach the required thermal performance. For three shell-side passes the logarithmic mean temperature difference correction factor F is marginally smaller than 0.7. A rule of thumb in heat exchanger design says that the correction factor should be $F > 0.7 - 0.8$ (see also [37]). For smaller



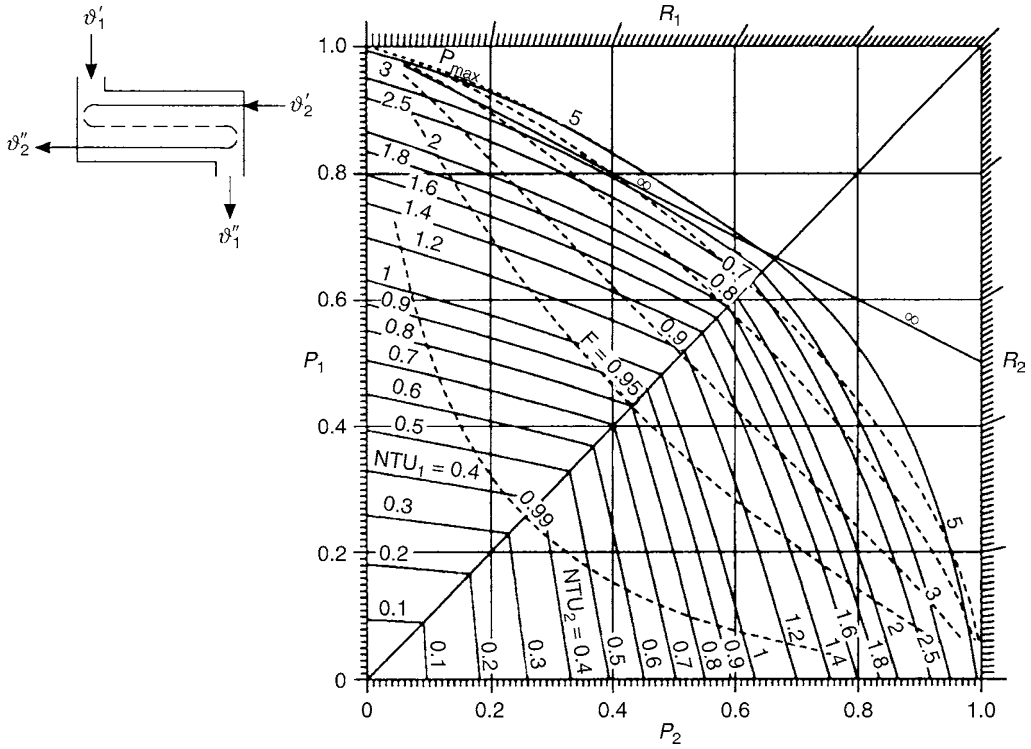
C1. Fig. 20. Shell-and-tube heat exchanger with one shell-side and four tube-side passes.



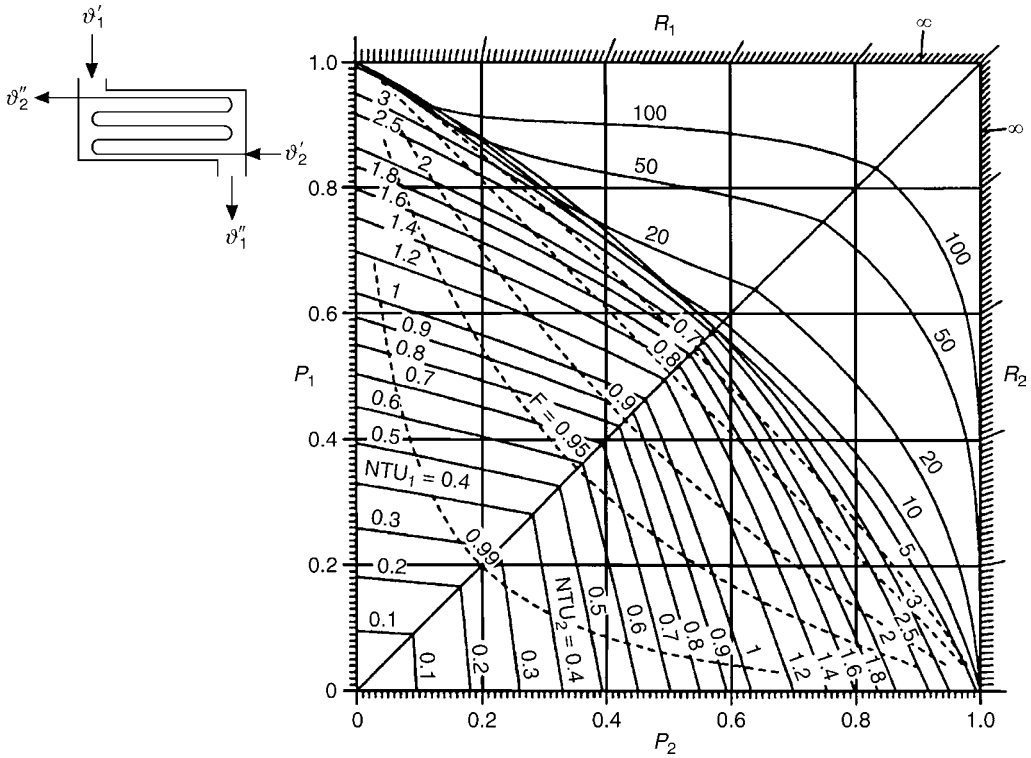
C1. Fig. 21. Shell-and-tube heat exchanger with one shell-side and three tube-side passes, two of it in countercurrent flow; $\varepsilon = 1/3$.

values of F the operating point falls within a range where small changes in P cause pronounced changes in F, with the result that the thermal performance is very sensitive to fluctuations. Therefore, in practice at least four shell-side passes are necessary to reach the required temperature changes. For four shell-side passes it is $P_1 = 0.426$, $NTU_1 = 0.95$ and $NTU_{1tot} = 4 \cdot 0.95 = 3.8$.

As the design details are not yet fixed, resort must be taken to typical values of the overall heat transfer coefficient (Chap. C3) for estimating the heat transfer area. With



C1. Fig. 22. Shell-and-tube heat exchanger with one shell-side and two countercurrent tube-side passes.

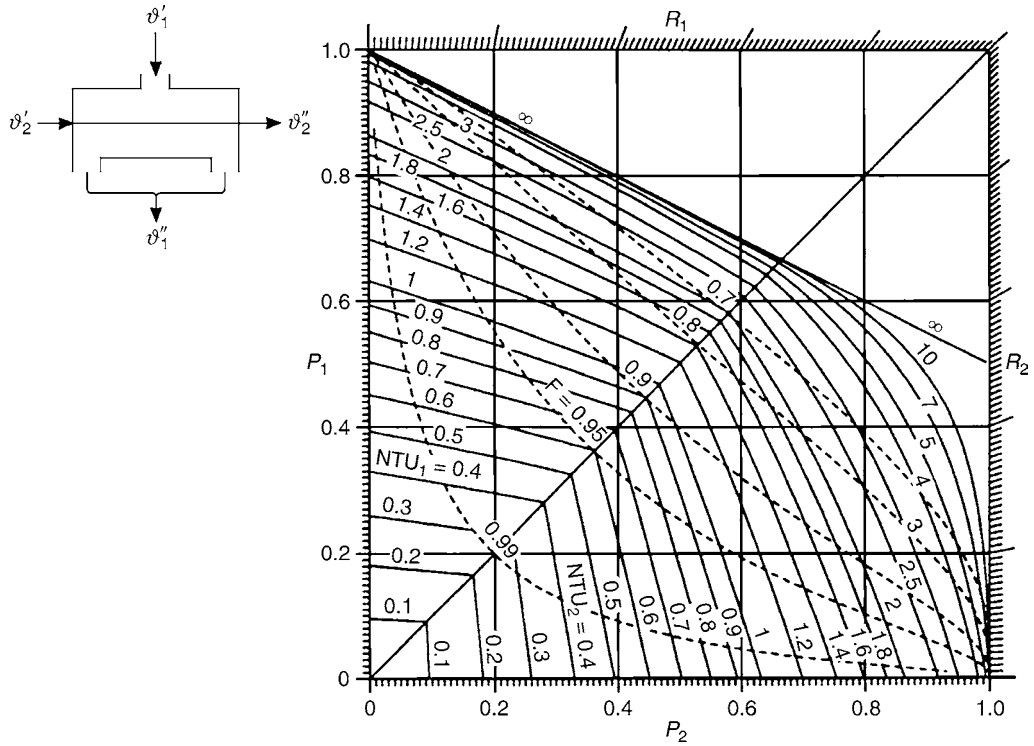


C1. Fig. 23. Shell-and-tube heat exchanger with one shell-side and five tube-side passes, three of it in countercurrent flow.

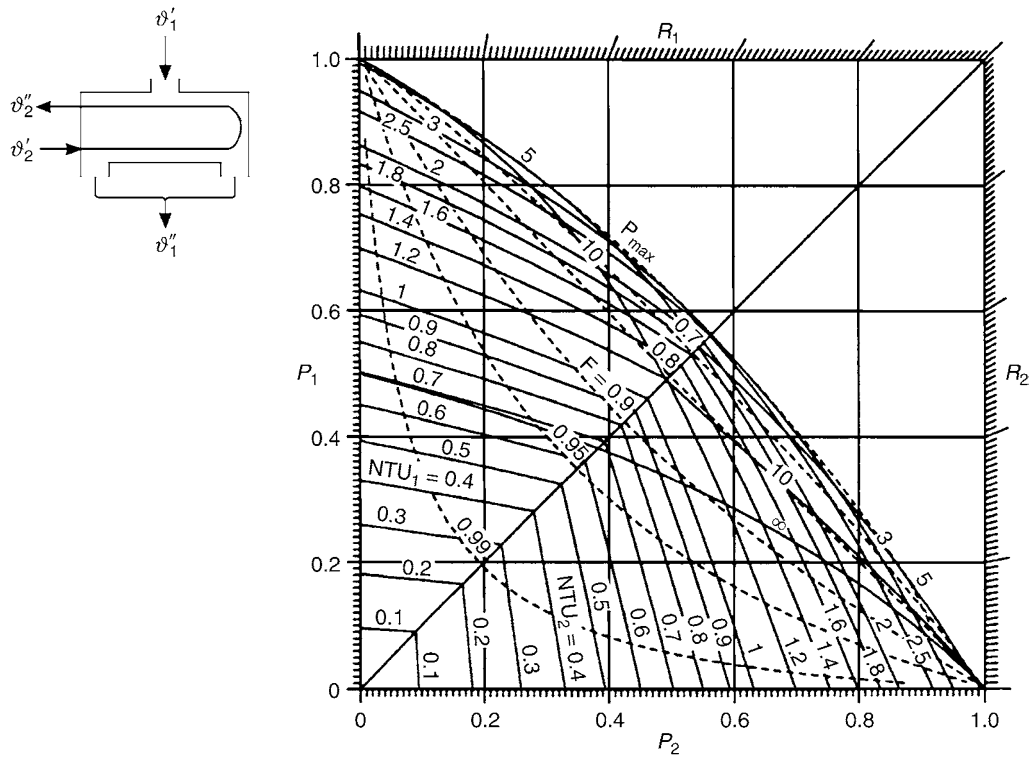
k = 500 W/m^2 K (liquid inside and outside the tubes) the required total area is

$$(A_{tot})_{req} = \frac{R_1 NTU_{1tot} \dot{W}_2}{k} \approx 65\,m^2$$

After the design details have been fixed, the overall heat transfer coefficient can be determined and it can be checked by rating (Sect. 6.1), whether the required thermal performance is actually attained.



C1. Fig. 24. Shell-and-tube heat exchanger; divided flow with one shell-side and one tube-side pass.

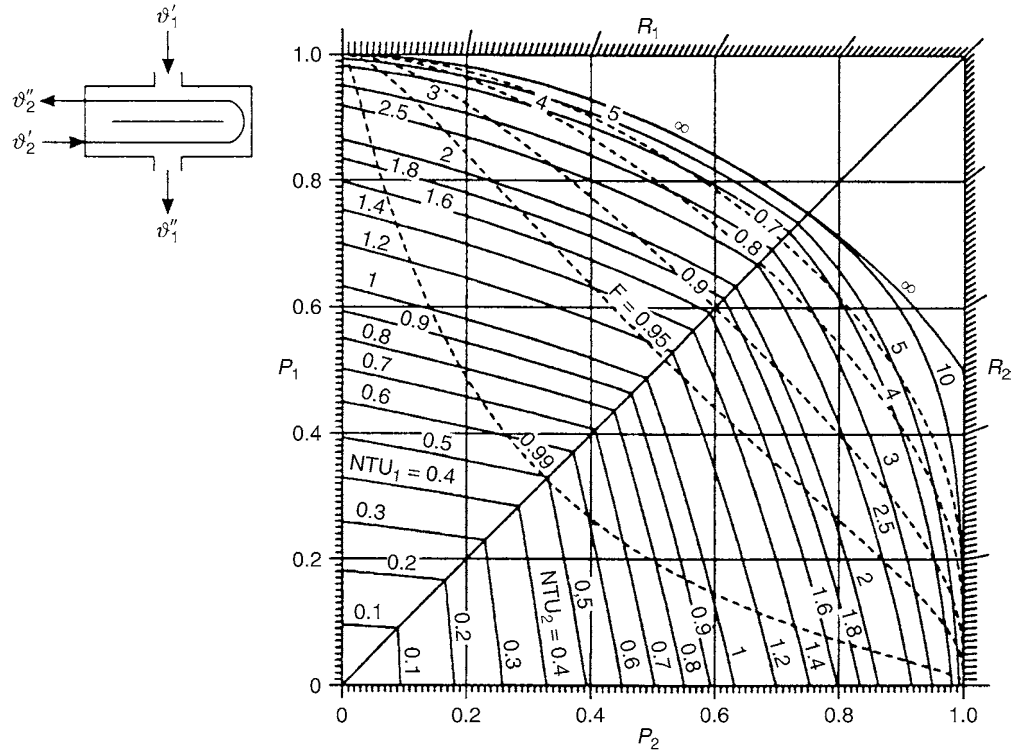


C1. Fig. 25. Shell-and-tube heat exchanger; divided flow with one shell-side and two tube-side passes.

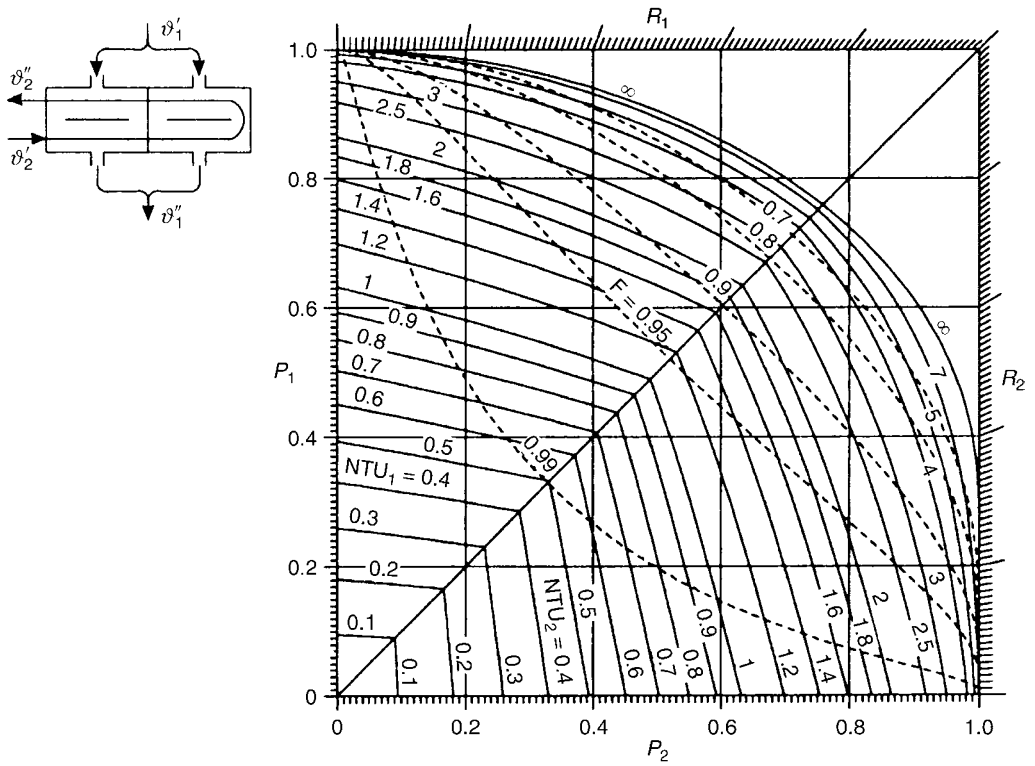
In this case the NTU-value of the individual exchanger could be calculated from an explicit equation NTU = $f(P, R)$. For most flow arrangements this is not possible, and the equation $P = f(\text{NTU}, R)$ must be solved iteratively for NTU if P and R are given.

Example 4

For air-cooled cross-flow heat exchangers usually the inlet and outlet temperature and the heat capacity rate of the process stream 1 are given, whereas for the air (stream 2) only the

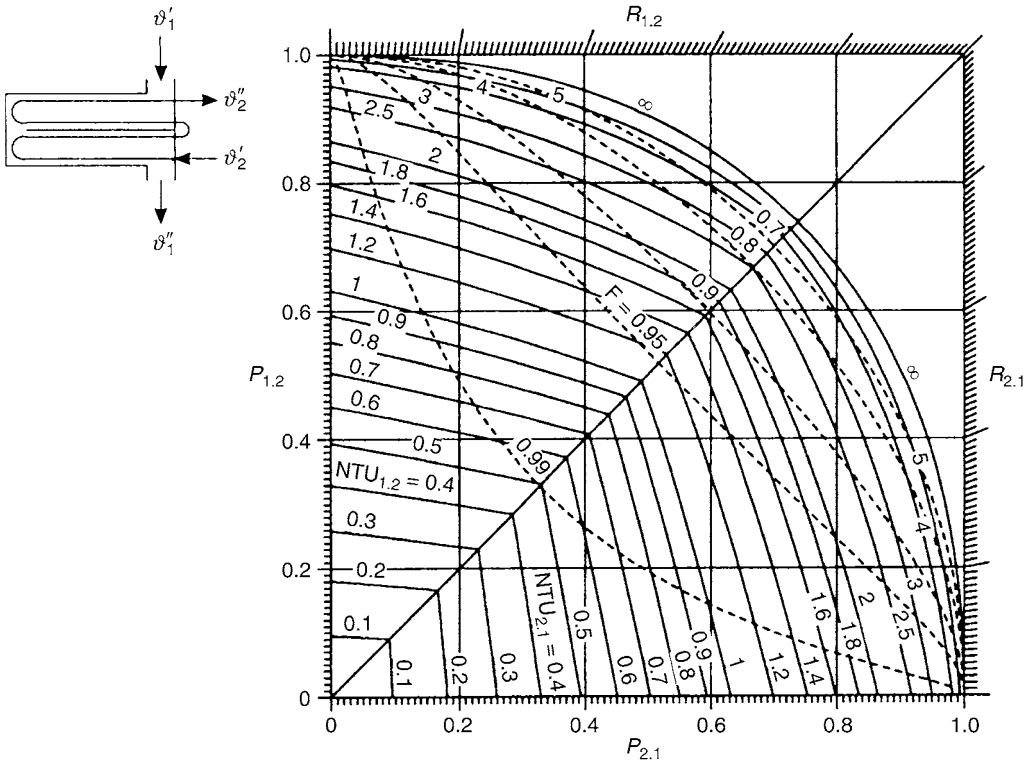


C1. Fig. 26. Shell-and-tube heat exchanger; split flow with longitudinal baffle and two shell-side and two tube-side passes.

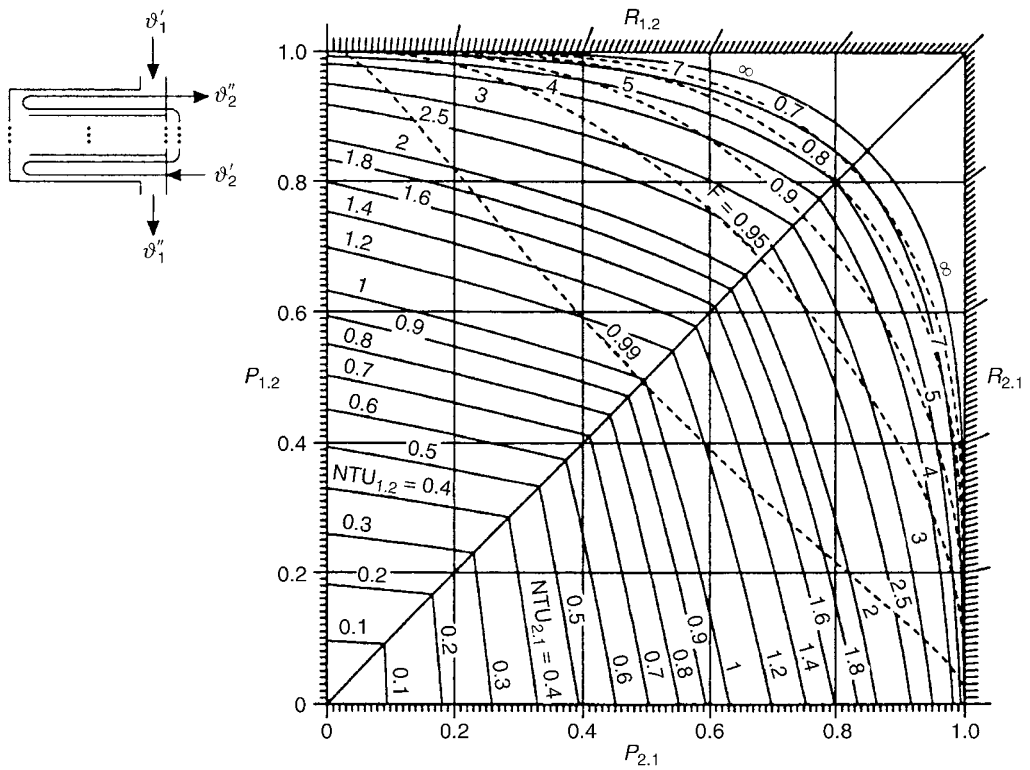


C1. Fig. 27. Shell-and-tube heat exchanger; double split flow with two longitudinal baffles and two shell-side passes on each side; two tube-side passes.

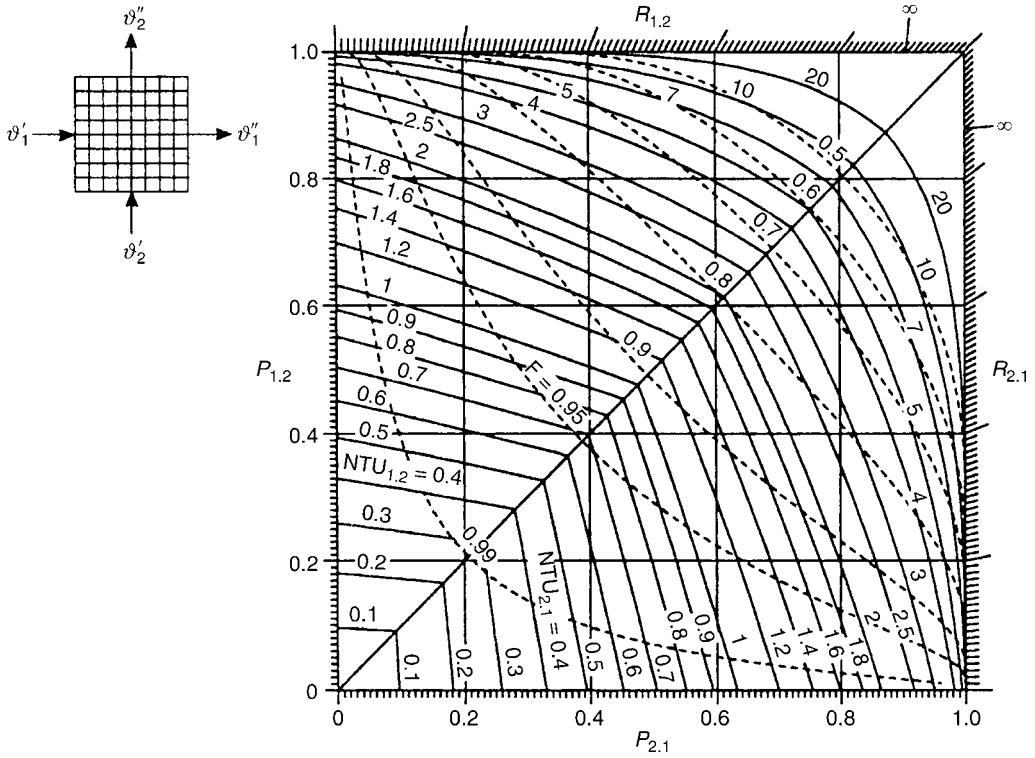
inlet temperature is known. However, empirical values for preferred approach velocities w_2 in certain finned tube bundles are also known. With these values the overall heat transfer coefficient and the number of transfer units NTU_2 can be estimated. For this purpose, only the ratio of total heat transfer area A and the cross-sectional area f for the air flow has to be known, but not their individual values, as shown by the following relationship:



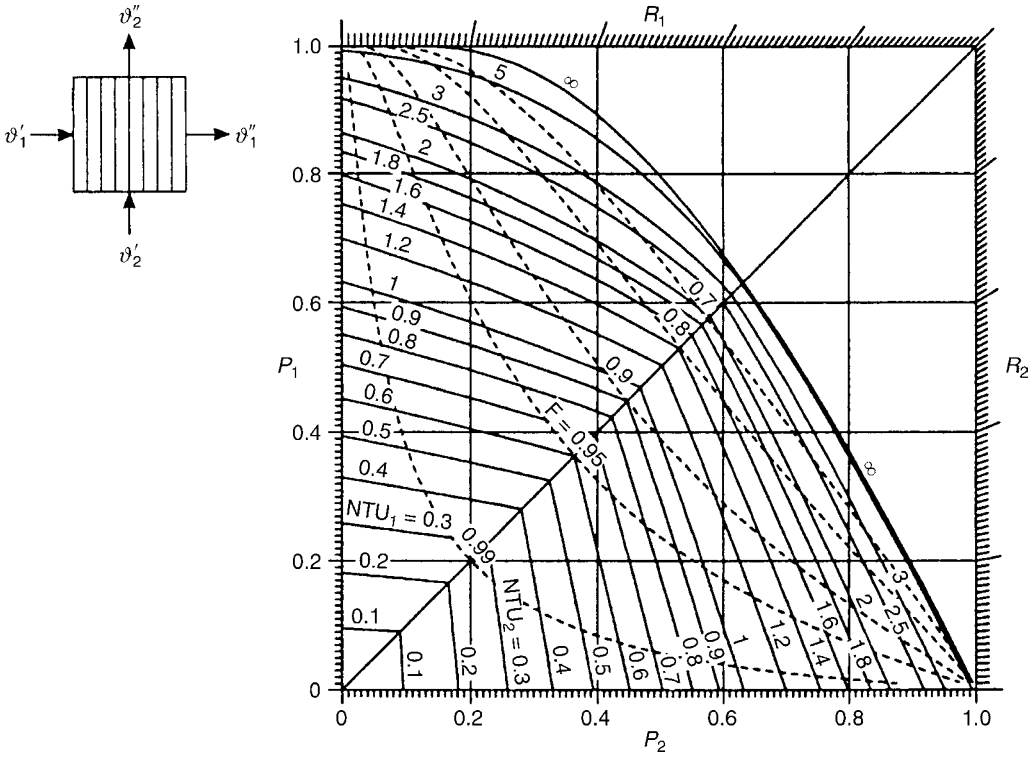
C1. Fig. 28. Shell-and-tube heat exchanger with two shell-side and four tube-side passes.



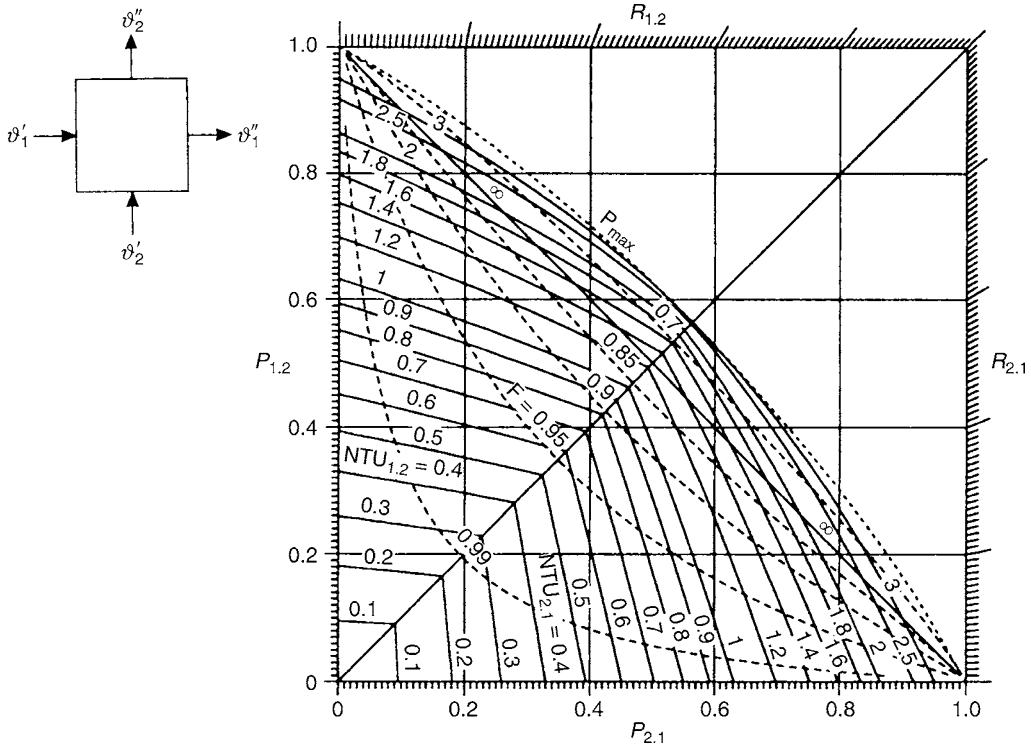
C1. Fig. 29. Shell-and-tube heat exchanger with four shell-side and eight tube-side passes.



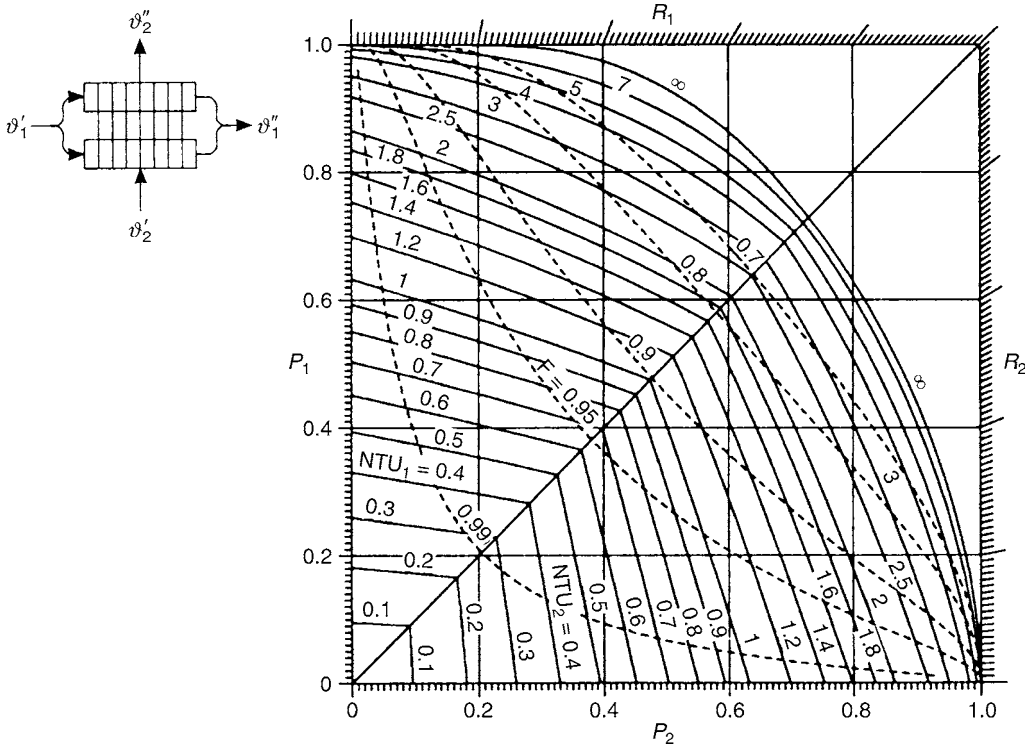
C1. Fig. 30. Pure cross-flow.



C1. Fig. 31. Cross-flow with one tube row; laterally mixed on one side.



C1. Fig. 32. Cross-flow, laterally mixed on both sides.



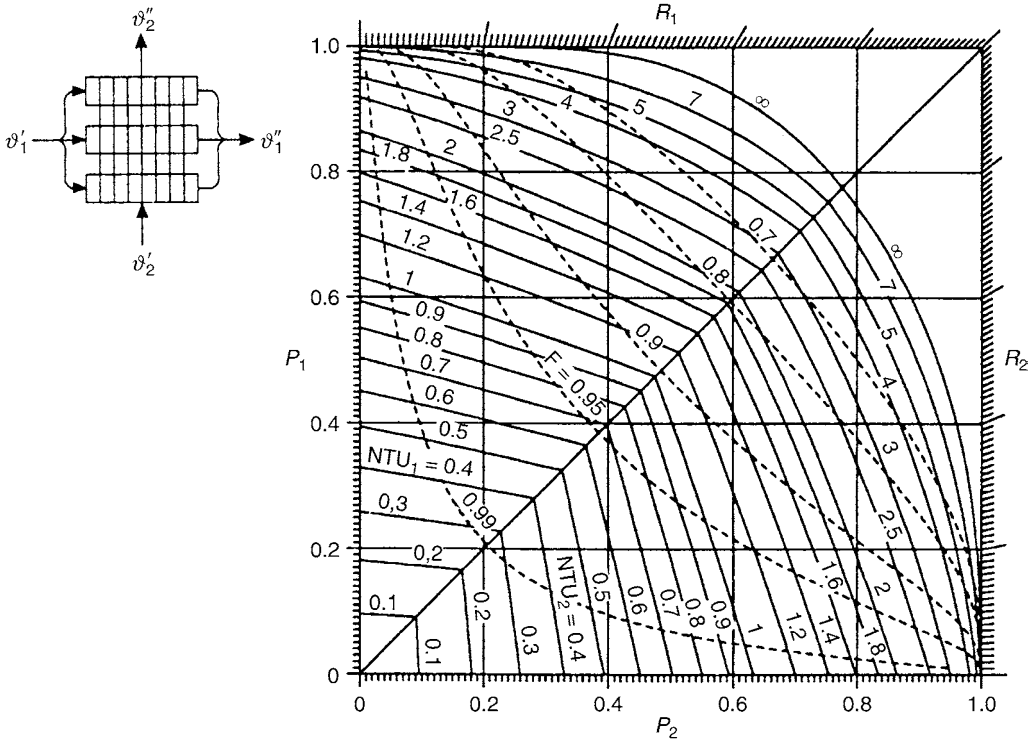
C1. Fig. 33. Cross-flow with two tube rows and one pass.

$$\mathrm{NTU}_2 = \frac{kA}{w_2 f \rho_2 c_{p2}} \tag{56}$$

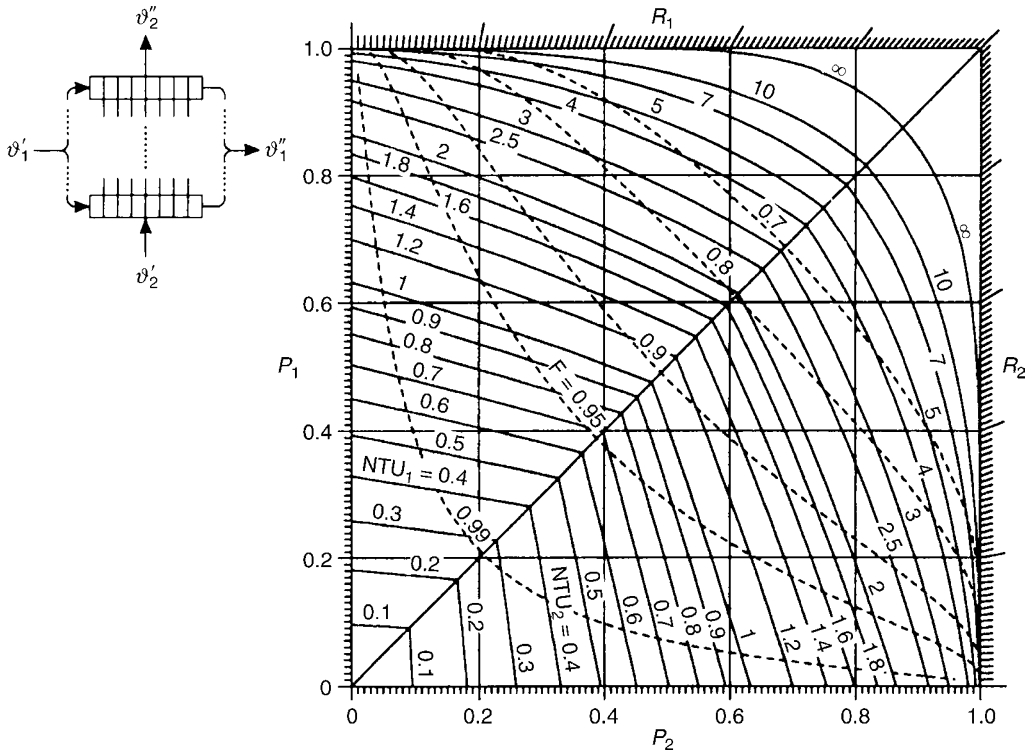
One can also introduce the overall heat transfer coefficient relating to the cross-sectional area f

$$k_f = \frac{(kA)_{req}}{f} \tag{57}$$

which subsequently allows the immediate calculation of the required cross-sectional area



C1. Fig. 34. Cross-flow with three tube rows and one pass.



C1. Fig. 35. Cross-flow with ten tube rows and one pass.

$$f_{\text{req}} = \frac{(kA)_{\text{req}}}{k_{\text{f}}} \tag{58}$$

In the following the flow arrangement and the heat transfer data from Example 1 are taken. Thus, the flow arrangement is a counterdirected countercurrent cross-flow with six tube rows and six passes and the design data of the finned tube bundle from Example 1 except for the tube length. The process stream (water, $\dot{W}_1$ = 4,220 W/K) is to be cooled from ϑ_1' = 120°C to

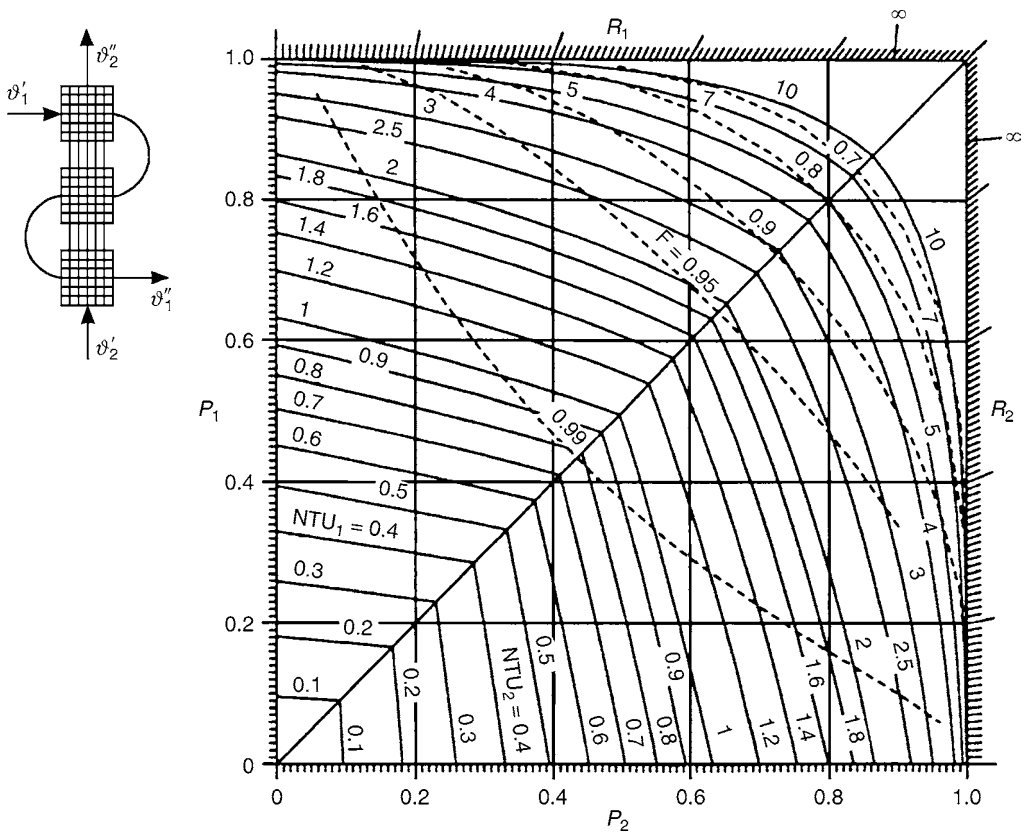
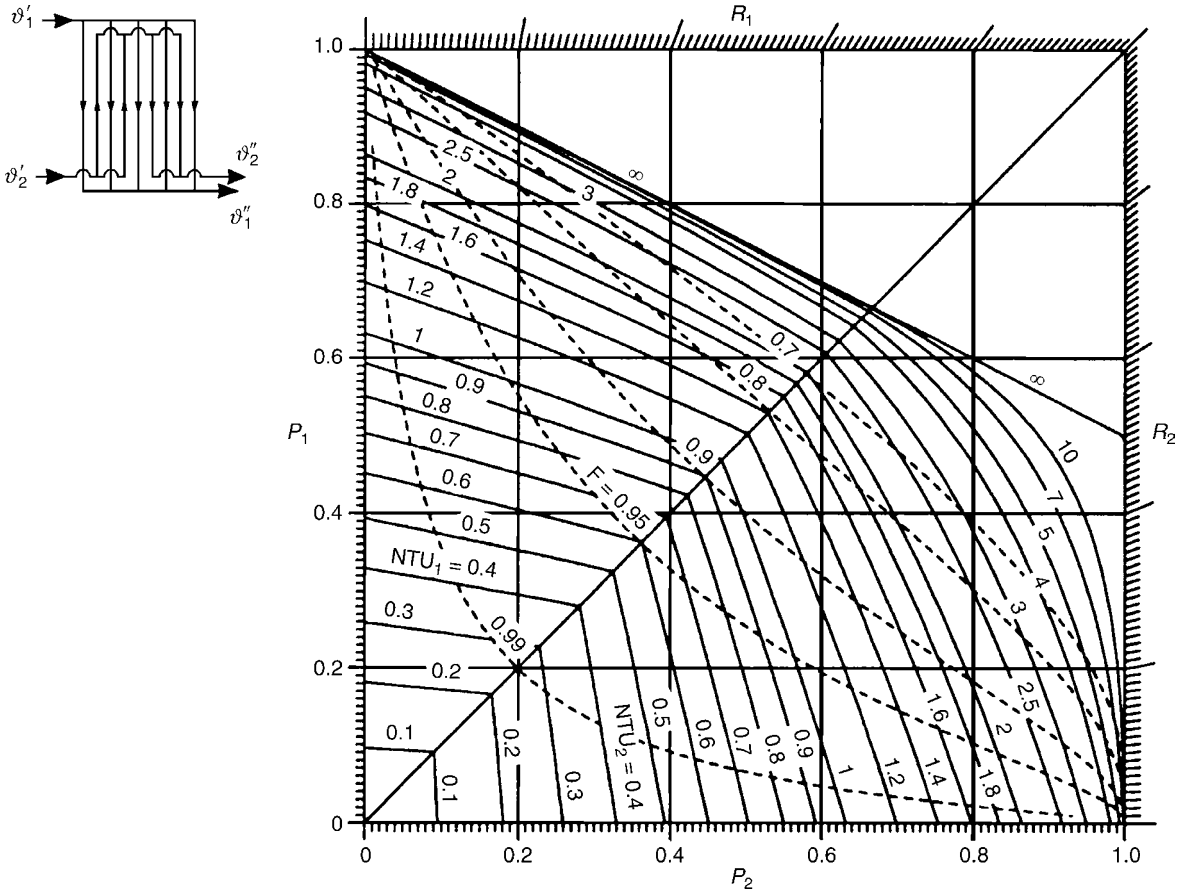
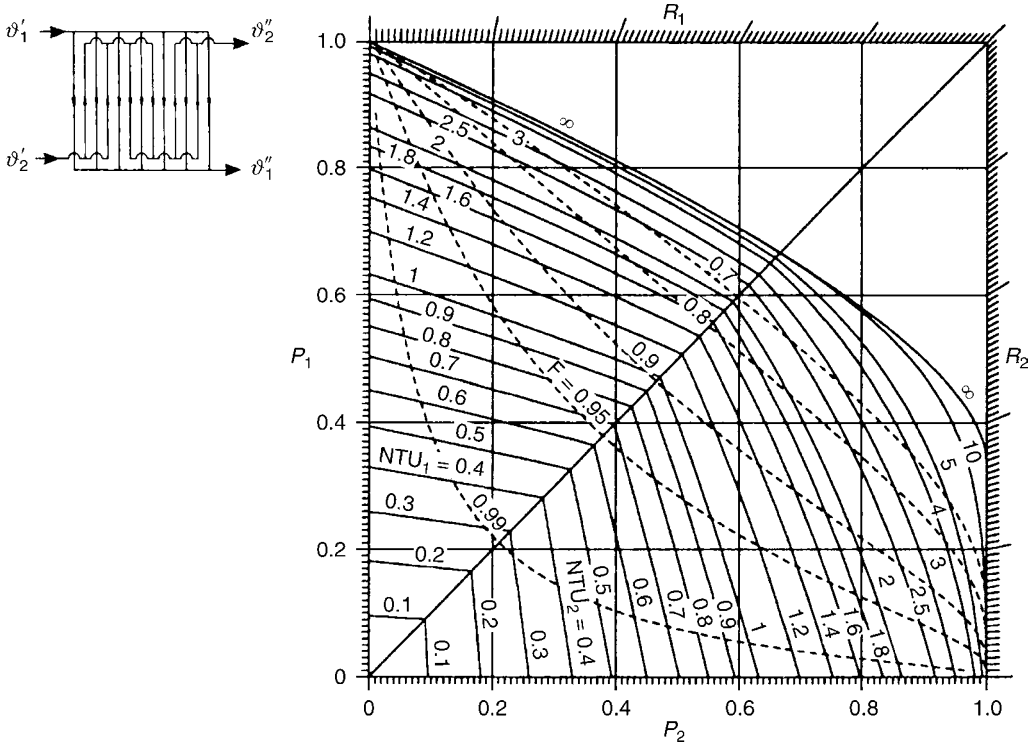
C1. Fig. 40. Counterdirected countercurrent cross-flow with two passes; stream 2 unmixed, stream 1 mixed only between passes.



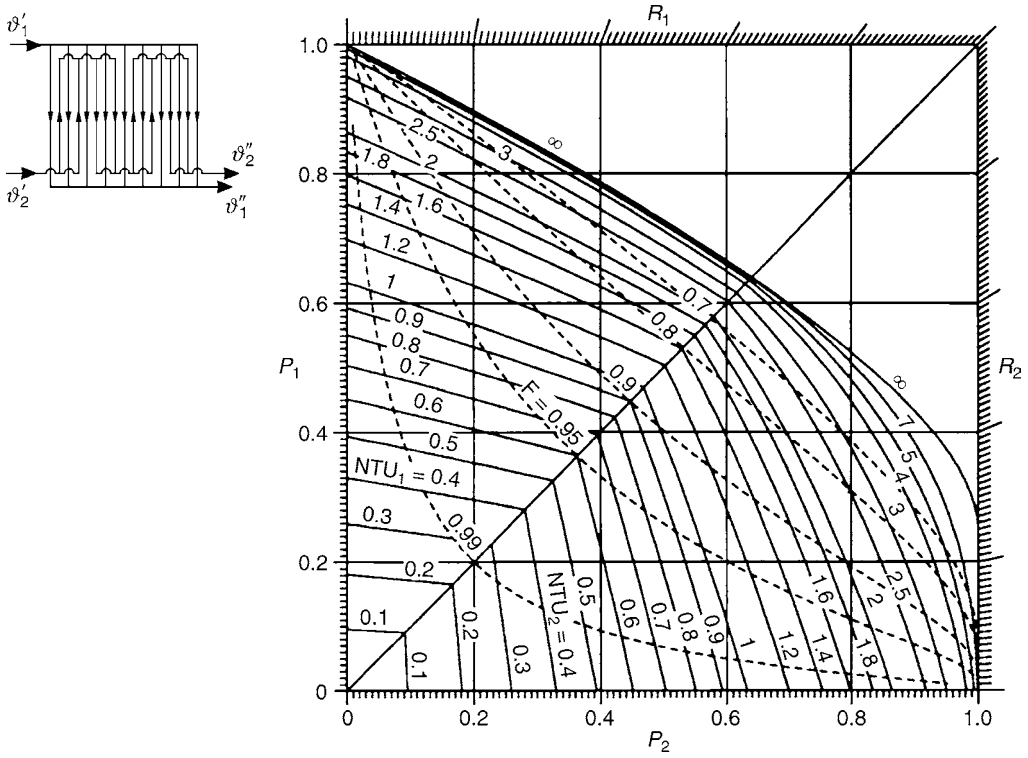
C1. Fig. 41. Counterdirected countercurrent cross-flow with three passes; stream 2 unmixed, stream 1 mixed only between passes.



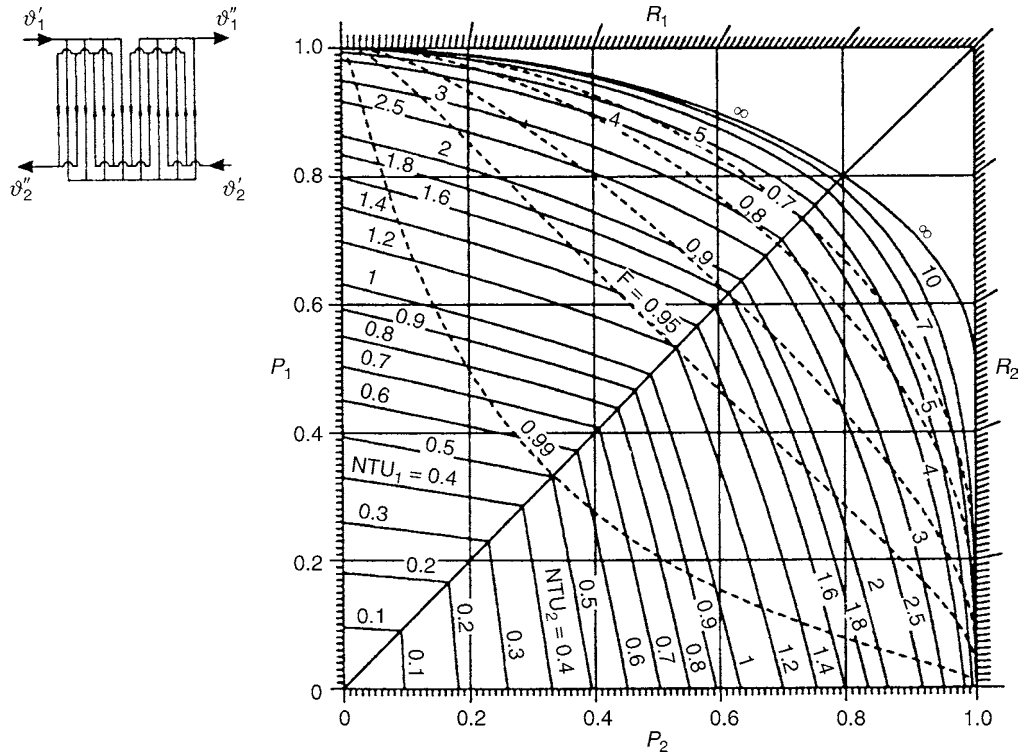
C1. Fig. 42. Plate heat exchanger with one pass for stream 1 and two passes for stream 2.



C1. Fig. 43. Plate heat exchanger with one pass for stream 1 and three passes for stream 2, two of it in countercurrent flow.



C1. Fig. 44. Plate heat exchanger with one pass for stream 1 and four passes for stream 2.



C1. Fig. 45. Plate heat exchanger with two passes for stream 1 and four passes for stream 2 in overall countercurrent flow arrangement.

$\vartheta_1'' = 70°C$. The inlet temperature of the air is $\vartheta_2' = 20°C$. The required cross-sectional area of the tube bundle and the tube length shall be calculated.

Solution

The ratio of the heat transfer area A and the cross-sectional area f follows from the design data of the finned tube bundle:

$$\frac{A}{f} = 132.$$

In Chap. C3 typical values of the overall heat transfer coefficient (related to the outside surface area) for gas heaters with finned tubes of 12–50 W/m^2 K are given. With $k = 20$ W/m^2 K

$$k_f = 2,640 \text{ W/m}^2 \text{ K}.$$

The air approach velocities are usually in the range of 2–5 m/s. With $w_2 = 2$ m/s Eq. (56) yields $\text{NTU}_2 = 1.25$.

From Eq. (9) it follows $P_1 = 0.5$

From the chart in Fig. 38 it is $P_2 = 0.57$ and $R_2 = 0.88$. It follows

$$\text{NTU}_1 = R_2\text{NTU}_2 = 1.10 \text{ and}$$
$$(kA)_{\text{req}} = 4,640 \text{ W/K}$$

Equation (58) yields $f_{\text{req}} = 1.76$ m^2. With the design data of the tube bundle the required tube length is 1.96 m $\approx$ 2 m.

7 Additional Symbols

Symbol	Description	Unit
F	Logarithmic mean temperature difference correction factor (Eq. (23))	–
m	Number of shell-side passes	–
n	Number of tube-side passes, tube rows, turns, or items of equipment	–
NTU	Number of transfer units (Eqs. (11), (12))	–
P	Dimensionless temperature change (Eqs. (9) and (10))	–
R	Heat capacity rate ratio (Eqs. (13) and (14))	–
T	Dimensionless temperature (Eq. (18))	–
$\dot{W}$	Heat capacity flow rate (Eq. (6))	W/K
z	Number of baffles	–
ε	NTU-ratio for cocurrent pass (Eq. (32))	–
Θ	Dimensionless mean temperature difference (Eq. (8))	–
ϑ	Temperature	K
Subscripts

C2 Overall Heat Transfer

Wilfried Roetzel[1] · *Bernhard Spang*[2]
[1]Helmut-Schmidt-Universität, Universität der Bundeswehr Hamburg, Hamburg, Germany
[2]BUCO Wärmeaustauscher International GmbH, Geesthacht, Germany

1 Introduction

In a heat exchanger hot and cold fluids are separated by a wall of one or more layers. The process of steady state heat transport from the hot fluid to the cold fluid through the separating wall is denoted with overall heat transfer and characterized by the overall heat transfer coefficient. This overall coefficient varies together with the two local heat transfer coefficients, and suitable mean values have to be introduced for the thermal design and rating of heat exchangers.

2 Local and Mean Heat Transfer Coefficient

If heat transfer is convective, the local heat transfer coefficient at a surface is directly related to the length of the flow path x, the local temperature of the fluid ϑ, and the temperature of the wall surface ϑ_w over which the fluid flows. In other words, it is given by

$$\alpha_{loc} = \alpha_{loc}(x, \vartheta, \vartheta_w).$$

The direct dependence of heat transfer on the length of the flow path is caused by the development of the velocity and temperature profiles, and is referred to as the flow length effect. The relationship to temperature is brought about by the temperature-dependent properties of the fluid or by radiation, and is referred to as the temperature effect.

The mean coefficient of heat transfer at a surface is obtained directly from the correlation for convective heat transfer (cf. Part G). Thus

$$\alpha = \frac{1}{L}\int_{x=0}^{L} \alpha_{loc}\, dx = \frac{1}{A}\int_{A} \alpha_{loc}\, dA \qquad (1)$$

is valid for constant temperatures ϑ and ϑ_w (or for constant fluid properties) and is averaged over the length of flow path or area of contact.

The average applies only for the length effect and depends on the local temperatures ϑ and ϑ_w, i.e.,

$$\alpha = \alpha(\vartheta, \vartheta_w).$$

3 Local Overall Heat Transfer Coefficient

The local overall heat transfer coefficient is the reciprocal of the total heat transfer resistance, consisting of the two heat transfer resistances at surfaces A_1 and A_2, and the conductive wall resistance R_w:

$$\frac{1}{k_{loc}A} = \frac{1}{\alpha_{1,loc}A_1} + R_w + \frac{1}{\alpha_{2,loc}A_2}. \qquad (2)$$

The left-hand side of Eq. (2) applies to an area A of any given size.

The resistance offered by the wall is calculated from its thickness δ and the material's thermal conductivity λ, i.e.,

$$R_w = \frac{\delta}{\lambda A_m}, \qquad (3)$$

where A_m is the mean area that governs the thermal conductivity.

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_5,

For a cylindrical tube of circular cross-section,

$$A_m = \frac{A_1 - A_2}{\ln \frac{A_1}{A_2}} = \frac{d_1 - d_2}{\ln \frac{d_1}{d_2}} \pi L. \quad (4)$$

For a spherical shell,

$$A_m = \sqrt{A_1 A_2} = d_1 d_2 \pi. \quad (5)$$

The local temperatures at the surfaces ϑ_{w1} and ϑ_{w2} on which heat is transferred are obtained from the following equation:

$$\alpha_{1,\mathrm{loc}} A_1 (\vartheta_1 - \vartheta_{w1}) = \alpha_{2,\mathrm{loc}} A_2 (\vartheta_{w2} - \vartheta_2) = k_{\mathrm{loc}} A (\vartheta_1 - \vartheta_2). \quad (6)$$

If the wall consists of n layers, its total resistance to heat transfer is the sum of those offered by the individual layers, i.e.,

$$R_w = \sum_{j=1}^{n} R_{wj} = \sum_{j=1}^{n} \left(\frac{\delta}{\lambda A_m} \right)_j. \quad (7)$$

The intermediate temperature $\vartheta_{z,p}$ behind the pth layer, as counted from the temperature ϑ_{w1}, can be derived from the equation

$$(\vartheta_{w1} - \vartheta_{z,p}) \sum_{j=1}^{n} R_{wj} = (\vartheta_{w1} - \vartheta_{w2}) \sum_{j=1}^{p} R_{wj}. \quad (8)$$

The local overall heat transfer coefficient, as defined by Eq. (2), depends on the temperatures of the two fluids, the two wall surface temperatures, and the lengths of both flow paths, i.e.,

$$k_{\mathrm{loc}} = k_{\mathrm{loc}}(\vartheta_1, \vartheta_2, \vartheta_{w1}, \vartheta_{w2}, x_1, x_2).$$

4 Mean Overall Heat Transfer Coefficient

The local overall heat transfer coefficient k_{loc} varies with the length of the flow path and the local fluid and wall temperatures over the area available for heat transfer. A mean value k must be found that can be used in the equations and charts given in Chap. C1. A figure that is frequently taken for this purpose is the value $\tilde{k}$ obtained by substituting the mean for the local heat transfer coefficients in Eqs. (2) and (6), i.e.,

$$\frac{1}{\tilde{k}A} = \frac{1}{\alpha_1 A_1} + R_w + \frac{1}{\alpha_2 A_2}. \quad (9)$$

This value depends only on the local fluid and wall temperatures, i.e.,

$$\tilde{k} = \tilde{k}(\vartheta_1, \vartheta_2, \vartheta_{w1}, \vartheta_{w2}).$$

As a rule, iteration must be resorted to for determining either the overall coefficient from Eq. (9) or the wall temperatures, because they are interdependent. Of practical importance are a few cases where the heat transfer coefficient can be calculated without iteration [1]. The mean value $\tilde{k}$ determined from Eq. (9) is merely an approximation for the true mean value of the overall heat transfer coefficient k.

The true mean value can be derived as follows from Eqs. (1)–(4) in Chap. C1, but only if the temperature difference remains unchanged over the entire heat transfer area ($\triangle\vartheta = \vartheta_1 - \vartheta_2 = \mathrm{const.}$):

$$k = k_A = \frac{1}{A} \int_A k_{loc} dA. \quad (10)$$

In this case, the local overall heat transfer coefficient may be an arbitrary function of location and temperature. In addition, it can be demonstrated that the area-average overall coefficient, as defined by Eq. (10), is the true mean value in cocurrent and countercurrent flow without restrictions if the heat capacity rates are constant.

Equation (10) does not apply in most other cases. However, the better the P_1,P_2-chart in the operating range agrees with that for pure countercurrent or pure cocurrent flow, the less the difference between k_A and k, provided the heat capacity rates are constant.

The difference is particularly small for arrangements in countercurrent cross-flow and in countercurrent coupling of individual units, because they closely agree with pure countercurrent flow. Likewise, cocurrent cross-flow, cocurrent coupling of individual units, and cross-flow with lateral mixing on both sides agree well with pure cocurrent flow, and again very small differences are obtained. Larger differences may arise in pure cross-flow and in cross-flow equipment with few passes [2].

Reservations must also be made for mixed flow arrangements in which so-called true cocurrent and countercurrent passes occur. Examples are multipass plate (true cocurrent and countercurrent flow) and shell-and-tube heat exchangers. In these cases, the (area-average) overall heat transfer coefficient must be determined separately for each pass in order to ensure accuracy, because the sizes of the countercurrent and cocurrent passes relative to one another, i.e., the NTUs, affect the quality of the flow arrangement. A simplifiation can be made by determining a common mean coefficient for all the cocurrent passes and another one for all the countercurrent passes [3].

If the overall heat transfer coefficient depends on temperature and the flow differs greatly from pure countercurrent or cocurrent flow arrangement, an approximate value for k can be obtained by correcting the reference temperatures in the methods described below [2]. If the specific heat capacity varies with temperature, an apparent mean value must be taken [4] that differs from the mean value k, as determined from Eq. (10), even in pure cocurrent and countercurrent flow.

For the determination of the mean value k the temperature and the flow length effect have to be taken into account. This can be done separately as shown in the following.

5 Allowance for the Flow Length Effect

The frequently adopted mean value $\tilde{k}$ that is obtained from Eq. (9) makes only a rough allowance for the flow length effect, because it is determined from heat transfer coefficients that have already been integrated. However, in analogy to Eq. (1), which corresponds to Eq. (10), the values for k_{loc} ought to be integrated over the whole area at constant temperatures (or properties).

Therefore, a distinction is drawn between $\tilde{k}$ and a mean value $\bar{k}$ that makes due allowance for the flow length effect. In common with the usual approximation $\tilde{k}$, $\bar{k}$ still depends on the local fluid and wall temperatures, i.e.,

$$\bar{k} = \bar{k}(\vartheta_1, \vartheta_2, \vartheta_{w1}, \vartheta_{w2}).$$

In most cases of practical importance, e.g., turbulent flow on both sides, the flow length effect is so slight that the normal, simplified approach according to Eq. (9) yields sufficient accuracy ($\tilde{k} \approx \bar{k}$ [5]).

However, if flow is laminar, unacceptable errors on the unsafe side with an uncertainty of more than 10% may occur ($\tilde{k} > \bar{k}$). In such cases, the approximate value must be corrected by a factor $V \leq 1$, i.e.,

$$\bar{k} = \tilde{k}V. \tag{11}$$

Equations for the determination of V in various cases are given below [6, 7].

5.1 Flow Length Effect on One Side Only

It is assumed that the flow length effect of one stream can be expressed as

$$\alpha_{L,loc} = \alpha_L \left(1 - \frac{1}{p}\right) \left(\frac{x}{L}\right)^{-1/p} \tag{12}$$

with integer values $p \geq 2$. For laminar flow in channels of uniform cross-section $p = 3$ [5, 6]. The heat transfer coefficient of the other stream does not directly depend on the flow length $0 \leq x/L \leq 1$ (no length effect). The correction factor is

$$V = (1+u)(p-1)\left[\left(-u\frac{p-1}{p}\right)^{p-1} \ln\left(1 + \frac{p}{u(p-1)}\right) + \sum_{j=0}^{p-2} \frac{\left(-u\frac{p-1}{p}\right)^j}{p-1-j}\right] \tag{13}$$

with $u = \dfrac{\alpha_L A_L}{\tilde{k}A} - 1$.

The coefficient α_L is the mean heat transfer coefficient determined from the correlation under consideration and A_L is the corresponing surface area. Although Eq. (13) is valid for all integer values $p \geq 2$ and arbitrary values of u, the numerical evaluation becomes difficult for $p > 5$ and $u > 1$. In such cases the following equation is recommended which has been found by a series development:

$$V = (1+u)(p-1)\sum_{j=1}^{\infty} \frac{1}{\left(-u\frac{p-1}{p}\right)^j (1-p-j)}. \tag{14}$$

The equation is valid for $u(p–1)/p > 1$ and arbitrary values of p. The truncation error of the sum is smaller than the following summand.

Equations (13) and (14) can be applied to all flow arrangements in which no axial dispersion takes place.

5.2 Laminar Flow in Both Streams

For both laminar streams the flow length effect is expressed by Eq. (12) with $p = 3$. Regarding the mean value α_L for laminar flow (Part G), one should keep in mind that the boundary conditions for heat transfer depend on the flow arrangement. For countercurrent flow and $R \approx 1$ the boundary condition "uniform heat flux, $\dot{q}$ = const." is more appropriate than the condition "uniform wall temperature, ϑ_w = const." The reverse is valid for cocurrent flow.

Using the abbreviations

$$a_1 = \alpha_{L1} A_1;\ a_2 = \alpha_{L2} A_2 \tag{15}$$

V is given by the following equations:

For countercurrent flow

$$V = 1 + \frac{0.65 + 0.23R_w(a_1 + a_2)}{4.1 + \frac{a_1}{a_2} + \frac{a_2}{a_1} + 3R_w(a_1 + a_2) + 2R_w^2 a_1 a_2}. \tag{16}$$

For cross-flow

$$V = 1 + \frac{0.44 + 0.23R_w(a_1 + a_2)}{4.1 + \frac{a_1}{a_2} + \frac{a_2}{a_1} + 3R_w(a_1 + a_2) + 2R_w^2 a_1 a_2}. \tag{17}$$

If both fluids are transversally mixed at the inlets to each pass, Eq. (17) is valid for all kinds of cross-flow.

For cocurrent flow, with the simplifying abbreviation

$$Z = \frac{R_w}{\frac{1}{a_1} + \frac{1}{a_2}} \tag{18}$$

V is given by [6, 7]

$$V = (1+Z)\left[1 - \frac{4}{3}Z + \frac{8}{9}Z^2 \ln\left(1 + \frac{3}{2Z}\right)\right] \tag{19}$$

The correction equations, Eqs. (13)–(19), are valid for laminar flow in channels of constant cross-section.

An additional effect of the flow path length that occurs in spiral heat exchangers is that the heat transfer coefficients depend on the radius of curvature of the channel wall, which varies with the length of the flow path. The relationship is linear for an Archimedes' spiral. The normal methods of calculation with mean heat transfer coefficients allow quite accurately for this effect, because the coefficients on both sides of the curved wall change in the same manner. The allowance for laminar length effects is as discussed above.

Other definite relationships between local heat transfer coefficients and the flow length exist for flow channels of changing cross-section, e.g., in conical tubes. In these cases, the mean value $\bar{k}$ is calculated from Eq. (10) by determining the values of k_{loc} with constant temperature at several points and integrating these values over the surface A. In the case of conical tubes, it is advisable to integrate the product $k_{loc}d$ over the length of the channels.

6 Allowance for the Temperature Effect

6.1 Usual Method

The simplest method of allowing for the temperature effect is to determine the temperature-dependent mean coefficient $\bar{k}$ at one reference temperature for each fluid – usually the arithmetic mean of the temperatures at the inlet and outlet, i.e.,

$$\vartheta_i = \frac{1}{2}(\vartheta_i' + \vartheta_i'')$$

where $i = 1, 2$.

The same simple method is usually adopted for the calculation of pressure drop (cf. Chap. L1). It can give rise to unacceptable errors if the fluid properties depend strongly on temperature or if heat is transferred by radiation or free convection. If this is the case, a more accurate method of calculating the overall heat transfer coefficients at several points in the heat exchanger is recommended [5, 8]. The pressure drop can also be determined more accurately by a similar procedure [9].

6.2 Multi-Point Method

This method applies to cocurrent and countercurrent flow, including the limiting cases of $\dot{W}_1 = \infty$ or $\dot{W}_2 = \infty$ for any given flow arrangement with the exception of the stirred tank. It allows for the temperature dependence of heat transfer coefficients and heat capacities.

If the effects of length and temperature are pronounced and occur simultaneously, it is assumed that the local overall heat transfer coefficient k_{loc} can be approximated (in the same way as a heat transfer coefficient) by the product of a pure flow length function and a pure temperature function in the range considered [5].

The desired mean value k can be determined from the equation

$$\frac{1}{k} = \frac{\dfrac{1}{\dot{M}_1 c_{pm1}} \pm \dfrac{1}{\dot{M}_2 c_{pm2}}}{\ln \dfrac{\Delta\vartheta_b}{\Delta\vartheta_a}} \int_{\ln\Delta\vartheta_a}^{\ln\Delta\vartheta_b} \frac{d(\ln\Delta\vartheta)}{\bar{k}\left(\dfrac{1}{\dot{M}_1 c_{p1}} \pm \dfrac{1}{\dot{M}_2 c_{p2}}\right)}, \qquad (20)$$

where the indices "a" and "b" designate the ends of the exchanger. The positive sign is valid for parallel flow and the negative sign for counterflow. The integral is approximated according to Gauss [5, 8] or Simpson [8, 11] using $n = 2$ or $n = 3$ (or more) reference points j at which the mean (with respect to laminar length effect) overall heat transfer coefficient $\bar{k}_j$ has to be determined. First two simple special cases are considered.

6.2.1 One Constant Fluid Temperature

The fluid temperature ϑ_k remains constant if the heat capacity rate ratio $R_i = \dot{M}_i c_{pmi} / \dot{M}_k c_{pmk} = 0$ ($i = 1, 2$; $k = 2, 1$). The Gauss or Simpson integration yields

$$\frac{1}{k} = \frac{1}{c_{pmi}} \sum_{j=1}^{n} a_j \frac{c_{pi,j}}{\bar{k}_j} \qquad (21)$$

with the local values $\bar{k}_j(\vartheta_{i,j}, \vartheta_k, \vartheta_{w,i,j}, \vartheta_{w,k,j}, R_w)$ and $c_{pi,j}(\vartheta_{i,j})$, determined for the reference temperatures

$$\vartheta_{i,j} = \vartheta_k + \Delta\vartheta_b \left(\frac{\Delta\vartheta_a}{\Delta\vartheta_b}\right)^{s_j}. \qquad (22)$$

The coefficients a_j and s_j are given in Table 1.

6.2.2 Constant Heat Capacities

In the special case of constant heat capacities, which often can be assumed as an approximation, the mean overall heat transfer coefficient

$$\frac{1}{k} = \sum_{j=1}^{n} a_j \frac{1}{\bar{k}_j} \qquad (23)$$

and the reference temperatures

$$\vartheta_{i,j} = \vartheta_{i,b} + (\vartheta_{i,a} - \vartheta_{i,b}) \frac{\left(\frac{\Delta\vartheta_a}{\Delta\vartheta_b}\right)^{s_j} - 1}{\frac{\Delta\vartheta_a}{\Delta\vartheta_b} - 1} \qquad (24)$$

for the calculation of $\bar{k}_j(\vartheta_{1,j}, \vartheta_{2,j}, \vartheta_{w1,j}, \vartheta_{w2,j}, R_w)$.

In the limiting case $\Delta\vartheta_a = \Delta\vartheta_b$ which occurs in a balanced counterflow exchanger, the fraction on the right hand side in Eq. (24) turns to the value s_j.

6.2.3 Temperature-Dependent Heat Capacities

In the general case of temperature-dependent heat transfer coefficients and heat capacities the integral in Eq. (20) cannot be calculated directly [5, 8]. For the simple integration as in the case of constant heat capacities the hypothetical temperatures have been introduced which are linear functions of the related enthalpies and coincide with the true fluid temperatures at the inlets and outlets of the exchanger [4, 8]. If the heat capacities are constant, the hypothetical temperatures and the true temperatures are identical. The concept of hypothetical temperatures leads to the following equations, in which the hypothetical

C2. Table 1. Coefficients for Gauss and Simpson integration with n points

	n	j	a_j	s_j
Gauss	2	1	$\frac{1}{2}$	$\frac{1}{2}+\frac{1}{6}\sqrt{3}$
		2	$\frac{1}{2}$	$\frac{1}{2}-\frac{1}{6}\sqrt{3}$
	3	1	$\frac{5}{18}$	$\frac{1}{2}+\frac{1}{2}\sqrt{\frac{3}{5}}$
		2	$\frac{4}{9}$	$\frac{1}{2}$
		3	$\frac{5}{18}$	$\frac{1}{2}-\frac{1}{2}\sqrt{\frac{3}{5}}$
Simpson	3	1 = a	$\frac{1}{6}$	1
		2	$\frac{2}{3}$	$\frac{1}{2}$
		3 = b	$\frac{1}{6}$	0

temperatures are eliminated. All temperatures are true fluid temperatures.

With the factor

$$\Psi_j = \frac{\Delta\vartheta_b}{\Delta\vartheta_j}\left(\frac{\Delta\vartheta_a}{\Delta\vartheta_b}\right)^{s_j}$$

it is

$$\frac{1}{k} = \sum_{j=1}^{n} a_j \frac{1}{\bar{k}_j}\Psi_j. \tag{25}$$

The factor Ψ_j represents a correction for variable heat capacities. For the determination of the local temperatures $\vartheta_{i,j}$ and their difference $\Delta\vartheta_j = \vartheta_{1,j} - \vartheta_{2,j}$ the local specific enthalpies $h_{i,j}$ have to be calculated from

$$h_{i,j} = h_{i,b} + \left(h_{i,a} - h_{i,b}\right)\frac{\left(\frac{\Delta\vartheta_a}{\Delta\vartheta_b}\right)^{s_j} - 1}{\frac{\Delta\vartheta_a}{\Delta\vartheta_b} - 1}. \tag{26}$$

The local temperatures $\vartheta_{i,j}\left(h_{i,j}\right)$ are then determined from the enthalpies $h_{i,j}$ with the help of equations of state, tables or diagrams. With the temperatures $\vartheta_{i,j}$ the local mean coefficient $\bar{k}_j\left(\vartheta_{1,j}, \vartheta_{2,j}, \vartheta_{w1,j}, \vartheta_{w2,j}, R_w\right)$ and $\Delta\vartheta_j$ can be calculated.

If the heat capacities are constant $h = c_p\vartheta + h_0$ and Eq. (26) turns to Eq. (24). With the temperatures from Eq. (24) the correction factor in Eq. (25) $\Psi_j = 1$. So for $c_{pi} = \text{const}(i = 1, 2)$ all three methods described in 6.2.1, 6.2.2, and 6.2.3 are identical.

For variable heat capacities and one constant fluid temperature the Eqs. (25) and (26) and the Eqs. (21) and (22) do not yield identical results, but their accuracy is about the same. The Eqs. (21) and (22) are more convenient for the special case of one constant fluid temperature.

Concerning the appropriate integration method: Basically the Gauss integrations achieve the highest accuracy for a given number of reference points. With two points a polynomial of third degree is exactly integrated, a polynomial of fifth degree requires three points. In normal cases of industrial application the two-point-Gauss method is sufficiently accurate. However, extreme cases may arise in which the three-point-Gauss integration is required [10, 8]. This may occur when high viscous oils are heated up by condensing steam or when a transition takes place between laminar and turbulent flow. However, the main problem in such extreme cases is not the proper integration but the accurate prediction of the local heat transfer coefficients.

The Simpson method is nearly as accurate as the two-point-Gauss integration, although three reference points are used. The method has been recommended [11] because the Reynolds numbers are frequently determined anyhow at the inlet and outlet in order to check whether or not the flow is turbulent or laminar throughout the exchanger. Another advantage is that at the terminal reference points $j = 1 = a$ and $j = 3 = b$ the reference temperatures are the given inlet and outlet temperatures and the correction factors in Eq. (25) $\Psi_1 = \Psi_a = \Psi_3 = \Psi_b = 1$. So, only at the central reference point $j = 2$ the enthalpies are needed for the determination of the reference temperatures if the heat capacities vary with temperature.

If the heat capacities vary, this mean value of k must be regarded as an apparent coefficient that differs from the area-average value obtained from Eq. (10) and even from a value that remains unchanged over the heat transfer area, i.e., $\bar{k} = \bar{k}_j$. In other words, $k \neq \bar{k}$.

Unsuitable cases may arise if the specific heat capacities depend considerably on temperature or if other pronounced nonlinear relationships exist between enthalpy and temperature, e.g., in the $h(\vartheta)$ condensing curve for mixtures. Thus, in countercurrent flow with high values of $\text{NTU}_1 \approx \text{NTU}_2$, the temperature curves for both fluids may theoretically intersect at a point ($\vartheta_1 = \vartheta_2$). This would entail that the process concerned would be impracticable. A case of this nature would occur if the values for $\Delta\vartheta_a$ and $\Delta\vartheta_b$ were positive and a temperature difference $\Delta\vartheta_j$ were negative or zero.

Example 1

An example given by Colburn [12] is calculated with the three-point-Simpson method.

Aniline ($\dot{W}_1 = 5.4\text{kW/K}$) is to be cooled down from $\vartheta_1' = 125°\text{C}$ to $\vartheta_1'' = 25°\text{C}$ in a countercurrent heat exchanger. The coolant is water ($\dot{W}_2 = 12\text{kW/K}$) at an inlet temperature of $\vartheta_2' = 20°\text{C}$. From the energy balance it follows $\vartheta_2'' = 65°\text{C}$. The wall resistance is $1.76 \times 10^{-4}\ \text{m}^2\,\text{K/W}$. It can be assumed as a close approximation that the heat capacities in this case (two liquids) are constant. Since flow is turbulent on both sides, there are no length effects to be taken into account.

For the data used by Colburn the temperature dependence of the heat transfer coefficients can be expressed by the following numerical equations [12] (converted into SI units):

$$\alpha_1 = 829 + 8.3\vartheta_1 + 0.0834\vartheta_1^2,$$

$$\alpha_2 = 6,092(1 + 0.0127\vartheta_2),$$

ϑ in °C, α in $\text{W/(m}^2\,\text{K)}$.

The usual method (calculation of the heat transfer coefficients at the arithmetic mean fluid temperatures $\vartheta_{1m} = 75°\text{C}$ and $\vartheta_{2m} = 42.5°\text{C}$, respectively) yields with $A_1 = A_2 = A$ the approximate value $k = 1{,}245\ \text{W/(m}^2\,\text{K)}$.

For the three-point-Simpson method the mean overall heat transfer coefficients $\bar{k}_a$ and $\bar{k}_b$ at both ends ($j = 1, 3$) must be calculated. They are

$$\bar{k}_a(\vartheta_1 = 125°\text{C}, \vartheta_2 = 65°\text{C}) = 1,720\,\text{W/(m}^2\,\text{K)},$$
$$\bar{k}_b(\vartheta_1 = 25°\text{C}, \vartheta_2 = 20°\text{C}) = 816\,\text{W/(m}^2\,\text{K)}.$$

According to Eq. (24) the fluid temperatures at the central reference point $j = 2$ are

$$\vartheta_{1,2} = 47.4°\,\text{C} \text{ and } \vartheta_{2,2} = 30.1°\,\text{C}$$

and hence the central mean overall heat transfer coefficient

$$\bar{k}_2 = 996\,\text{W/(m}^2\text{K)}$$

From Eq. (23) the approximation for the desired mean value is $k = 1{,}030\ \text{W/(m}^2\,\text{K)}$. A numerical finite-difference calculation yields the exact value $k = 1{,}034\ \text{W/(m}^2\,\text{K)}$.

The two-point-Gauss method yields $k = 1{,}037\ \text{W/(m}^2\,\text{K)}$ and the three-point-Gauss method the exact value $k = 1{,}034\ \text{W/(m}^2\,\text{K)}$.

6.2.4 Averaging the Resistances to Heat Transfer

Since the resistances to heat transfer in Eqs. (9) and (20) are additive, Eqs. (20)–(25) can also be applied separately to $1/\alpha_1$, R_w and $1/\alpha_2$ by substituting α and $1/R_w$ for k in Eqs. (21), (23), and (25). The triple application then yields the proper (for variable heat capacities) apparent mean values (with respect to temperature effects) of both heat transfer coefficients and the wall resistance.

Subsequently the mean value $\tilde{k}$ with respect to temperature effects according to Eq. (9) and, if flow is laminar, the desired mean value $k = \tilde{k}V$ using the correction equations Eqs. (11)–(19) can be determined.

6.2.5 Other Flow Arrangements

Although, strictly speaking, the multi-point method is valid only for pure cocurrent or countercurrent flow, it can be applied as an approximation to other flow arrangements in which the thermal behaviour is similar.

Similarity to countercurrent flow can be found in countercurrent spiral heat exchangers, all counter-crossflow configurations, and systems coupled in overall countercurrent flow. For a system of identical heat exchangers, a combined mean overall heat transfer coefficient common to all individual units can be determined analogous to that for a single countercurrent flow exchanger. Thus the total effect is correctly described but intermediate temperatures cannot be correctly calculated with the common mean coefficient. If the arrangement deviates more from pure countercurrent flow, an additional correction to the reference temperatures for calculating the true overall coefficient is recommended [7]. The logarithmic mean temperature difference correction factor F is used to express the degree of deviation from pure countercurrent flow. No correction is needed if $F = 1$.

The correction equations for $i = 1, 2$ and the reference point j are

$$\vartheta_{i,j,corr} = \vartheta_{i,j} + (-1)^i \left(\vartheta_{1,j} - \vartheta_{2,j}\right) \frac{1 - F}{1 + R_i^{2/3}}. \qquad (27)$$

The two corrected reference temperatures are used solely for calculating the true heat transfer coefficients at the reference point. The remaining equations for countercurrent flow are unaffected.

If the three-point-Simpson method is used, for simplicity the correction is only applied to the central reference point ($j = 2$), but has to be weighted with the factor 3/2 in front of $(-1)^i$ for compensation [2].

Considerations corresponing to those for countercurrent flow apply to cocurrent spiral exchangers, all cocurrent cross-flow configurations, and systems coupled in overall cocurrent flow. For the purpose of calculating the common mean coefficient k, the cocurrent system can be regarded as one single cocurrent heat exchanger, provided that $P_{1tot} + P_{2tot} < 1$.

A comparison of the P_1, P_2-charts for other flow arrangements with those for cocurrent or countercurrent flow allows an estimation on whether the flow arrangement concerned conforms more to the one or to the other. For instance, pure crossflow corresponds more to countercurrent flow, mixed-mixed cross-flow more to cocurrent flow.

As mentioned above the cocurrent method can only be used as a model for the calculation of the mean overall heat transfer coefficient $\tilde{k}$ if $P_1 + P_2 < 1$. However, the mixed-mixed crossflow can reach values $P_1 + P_2 > 1$. In such cases either the general method, i.e., counterflow with correction Eq. (27) or preferably a special method [8], derived for mixed-mixed crossflow ($\alpha(\vartheta)$ and $c_p(\vartheta)$), has to be applied. This method [8] is also applicable to multipass shell-and-tube heat exchangers with one shell-side and a high even number of tube-side passes (1,2m-HEX; $m \geq 2$; see Chap. C1).

For other types of multipass 1,n-HEX the most general analytical method [3] can be used, in which for each pass an individual tubeside heat transfer coefficient is calculated, using the arithmetic mean of the terminal pass temperatures as reference temperature. One mean shellside coefficient (for all passes) could be determined as discussed before, e.g., as for the counterflow with correction Eq. (27).

For the mixed-unmixed cross-flow (one tube row) a special method ($\alpha(\vartheta)$ and $c_p(\vartheta)$) can be recommended for the calculation of $\tilde{k}$ [8].

Example 2

It shall be checked with the three-point-Simpson method if the usual mean value of the overall heat transfer coefficient used in the calculation of Example 1 in Chap. C1 is sufficiently accurate.

Solution

As the flow on both sides is turbulent, only the temperature effect has to be taken into account: $\bar{k} = \tilde{k}$. The heat capacities of water and air at the present temperatures and pressures are nearly constant, so that Eqs. (23) and (24) can be applied.

At first the outlet temperatures have to be estimated. The outlet temperatures calculated in Example 1 of Chap. C1 are taken. Hence the temperatures at both ends of the heat exchanger are

$$\vartheta_{1,a} = \vartheta_1' = 120°C,\ \vartheta_{2,a} = \vartheta_2'' = 94°C \text{ and}$$

$$\vartheta_{1,b} = \vartheta_1'' = 78°C,\ \vartheta_{2,b} = \vartheta_2' = 20°C$$

The fluid temperatures at the point $j = 2$ follow from Eq. (24) (constant heat capacities) $\vartheta_{1,2} = 103°C$, $\vartheta_{2,2} = 64°C$. The correction from Eq. (27) is negligible because the correction factor F is greater than 0.99 (Chap. C1, Example 1).

The fluid property values of water at a pressure of 10 bar and of air at 1 bar can be taken from the tables in Chap. D2 at the fluid temperatures at both ends and at the central reference point "2". With these property values the tubeside heat transfer coefficients follow from correlations given in Chap. G1:

at point a: $\alpha_{1,a} = 4{,}912$ W/(m^2 K),
at point b: $\alpha_{1,b} = 4{,}129$ W/(m^2 K),
at point "2": $\alpha_{1,2} = 4{,}668$ W/(m^2 K).

On the shellside it follows from Chap. M1:

at point a: $\alpha_{2,a} = 50.3$ W/(m^2 K),

at point b: $\alpha_{2,b} = 46.8$ W/(m^2 K),
at point "2": $\alpha_{2,2} = 49.0$ W/(m^2 K).

Equation (9) yields the mean overall heat transfer coefficient $\bar{k} = \tilde{k}$:

at point a: $\bar{k}_a A = 4,679$ W/K,
at point b: $\bar{k}_b A = 4,253$ W/K,
at point "2": $\bar{k}_2 A = 4,528$ W/K

where area A is arbitrary. From Eq. (23) the desired mean value is kA = 4,504 W/K. In this case the usual mean value kA = 4,495 W/K deviates only slightly from the actual mean value.

7 Reduction in Heat Transfer Caused by Protective Layers and Fouling

Heat transfer surfaces often have to be coated to provide protection against corrosion. Other coats, e.g., oxides, may also be formed if the heat transfer surfaces react with the flowing substance; or deposits that are difficult to remove may accumulate on the heating and cooling surfaces.

All these layers impede the heat flow through the wall of an exchanger. Their effect depends on their thickness and thermal conductivity and, in particular, on the heat flow through the wall. While, for example, a lead coating on the heat transfer surface of a gas cooler would have practically no effect on overall heat transfer, the same lead layer may considerably reduce the thermal performance of an evaporator with its usually very high heat flux.

The reduction of overall heat transfer can be expressed by a correction factor φ, i.e.,

$$k = \varphi\, k_0, \tag{28}$$

where k_0 is the overall heat transfer coefficient if no layers were present and k is the actual heat transfer coefficient. With the thickness δ_j of layer j and its thermal conductivity λ_j it is

$$\frac{1}{\varphi} = 1 + k_0 A \sum_{j=1}^{n} \left(\frac{\delta}{\lambda A_m} \right)_j . \tag{29}$$

The thermal conductivities of some protective coatings and fouling layers are listed in Table 2. The corresponding figures for materials of construction and insulation are presented in Chap. D6, and for various forms of fouling in Chap. C4.

C2. Table 2. Thermal conductivity in W/m K at room temperature

Protective coatings		Fouling
Tin 65	Oppanol (polyisobutylene) 0.2–0.35	Scale, high-gypsum 0.6–2.3
Lead 35		Scale, high-silicate 0.08–0.18
Glass 0.76–0.84	Acid-resistant bricks ≈ 1.2	Soot, dry 0.035–0.07
Vitreous silica 1.34		Coal dust, dry 0.11
Enamel 0.9–1.2	Carbon bricks 1.6–4.7	Ice 1.75–2.3
Rubber 0.15–0.17	Porcelain 1.7–3.5	Slime from cooling water ≈ 0.35
Asphalt 0.76	Salting ≈ 0.6	
Igelit (PVC film) 0.16		Slime from brine ≈ 0.46

8 Symbols

Symbol	Description	Unit
F	logarithmic mean temperature difference correction factor (C1 Eq. (23))	-
n	number of layers or of reference points	-
NTU	number of transfer units (C1 Eqs. (11) and (12))	-
P	dimensionless temperature change (C1 Eqs. (9) and (10))	-
R	heat capacity rate ratio (C1 Eqs. (13) and (14))	-
R_w	wall resistance	m^2 K/W
$\dot{W}$	heat capacity flow rate (C1 Eq. (6))	W/K
δ	thickness	m
ϑ	temperature	K
Subscripts		
1, 2	stream 1 or 2 in the heat exchanger or j = 1, 2, 3 for reference points	
a, b	ends of the heat exchanger	
L	on the laminar flow or length effect side	
w	wall	
z	intermediate value	
Superscripts		
$'$	at the inlet	
$''$	at the outlet

1 Introduction

The empirical values listed below are intended for the preliminary design of heat exchangers. The lower values apply to comparatively adverse conditions, e.g., low flow velocities, viscous liquids, free convection, and fouling. The higher values are valid for particularly favorable conditions, e.g., high flow velocities, thin fluid layers, optimum mass flow ratios, and clean surfaces. In special cases, values may fall below or exceed the given range. Therefore, the figures must be regarded critically and with the necessary caution. The given k values do not take additional heat conduction resistances of insulation and protective coatings into account.

Type of exchanger	Conditions of heat transfer	Typical k value (W/m^2 K)
Shell-and-tube heat exchanger 	Gas (≈1 bar) on tube side and gas (≈1 bar) on shell side	5–35
	High-pressure gas (200–300 bar) on shell side and high-pressure gas (200–300 bar) on tube side	150–500
	Liquid on shell side (tube side) and gas (≈1 bar) on tube side (shell side)	15–70
	High-pressure gas (200–300 bar) on tube side and liquid on shell side	200–400
	Liquid on shell and tube sides	150–1,200
	Heating steam on shell side and liquid on tube side	300–1,200
	See below for use as evaporator or condenser	
Evaporator 	Heating steam outside the tubes	
	1. With natural circulation	
	(a) Viscous liquids	300–900
	(b) Low viscosity liquids	600–1,700
	2. With forced circulation	900–3,000
	Brine-heated ammonia evaporator	200–800

Type of exchanger	Conditions of heat transfer	Typical k value (W/m^2 K)
Condenser 	Cooling water on tube side and organic vapors or ammonia on shell side	300–1,200
	Steam-turbine condenser (pure steam; thin brass tubes) k decreases with an increase in the inert gas fraction	1,500–4,000
Waste-heat boiler 	Hot gas on tube side and boiling water on shell side	15–50
Gas heater 	Steam or hot water on (finned) tube side and gas outside finned tubes	
	(a) Free convection (heater)	5–12
	(b) Forced flow	12–50
Double-pipe heat exchanger 	Gas (≈1 bar) on tube side and gas (≈1 bar) on shell side	10–35
	High-pressure gas (200–300 bar) on tube side and gas (≈1 bar) on shell side	20–60
	High-pressure gas (200–300 bar) on tube side and high-pressure gas (200–300 bar) on shell side	150–500
	High-pressure gas (200–300 bar) on tube side and liquid on shell side	200–600
	Liquid on shell and tube sides	300–1,400

continued

Type of exchanger	Conditions of heat transfer	Typical k value (W/m^2 K)
Falling-film cooler  	Cooling water on shell side and gas (≈1 bar) on tube side	20–60
	Cooling water on shell side and high-pressure gas (200–300 bar) on tube side	150–350
	Cooling water on shell side and liquid on tube side	300–900
	Falling-film condenser, e.g., for refrigerants: cooling water outside and condensing vapor inside tubes	300–1,200
Helical coil heat exchanger  	Cooling water or brine outside and gas (≈1 bar) inside the coils	20–60
	Cooling water outside and high-pressure gas (200–300 bar) inside the coils	150–500
	Cooling water or brine outside and liquid inside the coils	200–700
	Cooling water or brine outside and condensing vapor inside the coils	350–900
Plate heat exchanger  	Flat channels, gas to water	20–60
	Flat channels, liquid to water	350–1,200
	Corrugated plates, liquid to liquid	1,000–4,000

continued

Type of exchanger	Conditions of heat transfer	Typical k value (W/m^2 K)
Compartmental heat exchanger Compartmental heat exchanger 	Gas to gas (≈1 bar)	10–35
	Gas to liquid	20–60
Spiral plate heat exchanger Spiral heat exchanger 	Liquid to liquid	700–2,500
	Condensing vapor to liquid	900–3,500
Stirred tank 	(A) Outer shell	
	Condensing vapor outside and liquid inside the tank	500–1,500
	Condensing vapor outside and boiling liquid inside the tank	700–1,700
	Cooling water or brine outside and liquid inside the tank	150–350
	(B) Inner coil	
	Condensing vapor inside the coils and liquid inside the tank	700–2,500
	Condensing vapor inside the coils and boiling liquid inside the tank	1,200–3,500
	Cooling water or brine inside the coils and liquid inside the tank	500–1,200
	(C) Outer tube welded onto shell	
	Condensing vapor inside the heating channels and liquid inside the tank	500–1,700
	Condensing vapor inside the heating channels and boiling liquid inside the tank	700–2,300
	Cooling water or brine inside the cooling channels and liquid inside the tank	350–900

C4 Fouling of Heat Exchanger Surfaces

Hans Müller-Steinhagen
Universität Stuttgart, Stuttgart, Germany

1 Introduction

In most industrial processes, heat exchanging fluids contain certain amounts of dissolved or suspended material or provide conditions favorable for the growth of biological organisms. Design and operation of heat exchangers are still to a major extent determined by the process-related formation of deposits on the heat transfer surfaces, i.e., fouling. Since the thermal conductivity of such deposits is low, see Table 1, their resistance to heat transfer may well exceed that of the clean fluids, resulting in significantly reduced heat exchanger performance.

As a result, substantial safety margins in the design, pretreatment of hot/cold fluids and regular cleaning of equipment may be required.

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_7,

C4. Table 1. Thermal conductivity of various deposits

Sodium aluminum silicate	0.2–0.4 W/mK
Milk components	0.5–0.7 W/mK
Hematite (boiler deposit)	0.6 W/mK
Biofilm	0.7 W/mK
Calcium sulfate (boiler)	0.8–2.2 W/mK
Calcite (boiler deposit)	0.9 W/mK
Serpentine (boiler deposit)	1.0 W/mK
Gypsum (boiler deposit)	1.3 W/mK
Calcium sulfate	2.3 W/mK
Magnesium phosphate	2.3 W/mK
Calcium phosphate	2.6 W/mK
Calcium carbonate	2.9 W/mK
Magnetite iron oxide	2.9 W/mK

Surveys [1–3] have indicated that more than 90% of heat exchangers suffer from fouling problems. Table 2 identifies the kind and typical extent of fouling for fluids from various industries [39]. More information about research and industrial fouling problems may be found under www.heatexchanger-fouling.com.

1.1 The Fouling Resistance

The possibility of deposition on heat transfer surfaces is generally considered in the design of heat exchangers by using the so-called fouling resistances in the calculation of the overall heat transfer coefficient k.

$$\frac{1}{k} = \left(\frac{1}{\alpha_1} + R_{f,1}\right)\frac{A_2}{A_1} + R_{wall} + \frac{1}{\alpha_2} + R_{f,2} \qquad (1)$$

In Eq. (1), α, A, and R_f are the heat transfer coefficients, the heat transfer areas and the fouling resistances, respectively, for the two heat exchanging fluids; R_{wall} is the thermal resistance of the separating wall. It is obvious that the frequently used expression "fouling factor" is incorrect, as the effect of fouling is to create an additional thermal resistance. The fouling resistance reduces the overall heat transfer coefficient k, and hence leads to the reduction of heat duty of an existing heat exchanger or to additional surface requirement in the design of new heat exchangers.

In the utility industry, it is common to use the cleanliness factor CF

$$CF = \frac{k_f}{k_c} \qquad (2)$$

instead of the fouling resistance R_f, where CF is a function of tube material, flow velocity, and fouling propensity of the cooling water. Typically, cleanliness factors are adding less excess surface and are, hence, more realistic than fouling resistances. However, this purely empirical ratio of overall heat transfer coefficients for fouled and dirty conditions does not provide any access to the understanding of the mechanisms of deposit formation and hence the potential effects of operating conditions.

The main source of publicly available fouling resistances are the approximately 100 values suggested by the Tubular Exchanger Manufacturers Association (TEMA) [4], which are reproduced in Tables 3–5. Although the TEMA tables were originally considered to be only a rough guideline for shell-and-tube heat exchanger design, they are unfortunately often treated as accurate values. This may cause considerable errors because

1. The values were developed in 1949 and were based on hand calculation procedures for heat exchanger design in use at the time. Even though calculation methods have evolved, the values presented by TEMA have not been altered since its publication.
2. Fouling resistances are included for a number of fluids that are known not to foul, such as refrigerants, demineralized water, liquefied natural gas (LNG) and non-polymerizing (diolefin-free) condensing gases, or any other streams which do not foul within the operating conditions of the heat exchanger.
3. R_f values in the tables tend to be used without adequate engineering, resulting in exchangers that are much larger

C4. Table 2. Fouling of heat exchangers in various industries [3]

Industry group	Type of fouling	Extent of problem
Food and kindred products	Chemical reaction	Major

C4. Table 3. TEMA fouling resistances for water (m^2K/kW) [4]

Temperature of heating medium	Up to 115 °C		115–200 °C	
Temperature of water	50 °C		Over 50 °C	
	Water velocity m/s		Water velocity m/s	
	1.0 and less	Over 1.0	1.0 and less	Over 1.0
Cooling tower and artificial spray pond				
Treated make up	0.088	0.088	0.17	0.17
Untreated	0.35	0.17	0.53	0.35
City or well water	0.17	0.17	0.35	0.35
River water				
Minimum	0.35	0.17	0.53	0.35
Average	0.53	0.35	0.70	0.53
Muddy or silty	0.53	0.35	0.70	0.53
Hard (over 250 ppm)	0.53	0.53	0.88	0.88
Engine jacket	0.17	0.17	0.17	0.17
Distilled or closed cycle				
Condensate	0.088	0.088	0.088	0.088
Treated boiler feedwater	0.17	0.088	0.17	0.17
Boiler blowdown	0.35	0.35	0.35	0.35
Seawater	0.09	0.09	0.18	0.18
Brakish water	0.35	0.18	0.54	0.35

than required. For example, Fig. 1 includes a summary of the percent overdesign of all cases submitted to HTRI in 2006. As can be seen from the figure, most exchangers are 50–500% too large, based primarily on the assumed fouling resistances. This results in unnecessary capital expense and exchangers that foul due to poor design.

4. R_f values are only available for a limited number of process fluids and process conditions.
5. Tabulated R_f values provide only limited information about the influence of process parameters such as flow velocity, fluid, and wall temperature on the fouling resistance. These parameters have a considerable influence on the deposition of foulants matter onto the heat transfer surface.
6. Using constant fouling resistances, the transient character of the fouling process is ignored. Conditions in the initially overdesigned heat exchanger often promote deposition, thus making fouling a self-fulfilling prophecy.
7. The TEMA values do not apply for heat exchanger types other than conventional shell and tube heat exchangers, e.g., plate heat exchangers, compact heat exchangers or finned tubes. Some fouling resistances for other heat exchanger types are given in Tables 6–8.

To demonstrate the significance of the selected fouling resistance on the sizing of heat exchangers, Table 9 shows the excess heat transfer surface required for several heat exchanger types, if a typical TEMA fouling resistance of 0.18 m^2K/kW is used for each of the two heat exchanging fluids. As shown in the following

C4. Table 4. TEMA fouling resistances for oil refinery streams in shell-and-tube exchangers, (m^2K/kW) [4]

Crude and vacuum unit gases and vapors						
Atmospheric tower overhead vapors	0.18					
Light naphthas	0.18					
Vacuum overhead vapors	0.35

Atmosphere tower bottoms	1.2					

equation, the percentage excess surface area for a fixed heat duty increases with increasing clean heat transfer coefficient.

$$\frac{A_f}{A_c} = 1 + k_c R_f \tag{3}$$

Obviously, the impact of the fouling resistance is more severe for heat exchangers with high overall heat transfer coefficients.

To account for unreliable design procedures and operational problems, heat exchangers are typically overdesigned by 70–80%, from which 30–50% is attributed to fouling [8]. While the installation of excess heat transfer surface may extend the operation time of heat exchangers, it provides no remedy against the deposition of dirt. Fluid pretreatment, antifouling installations, and regular cleaning will still be required in most cases. Industrial practice and state of the art of such fouling mitigation and of heat exchanger cleaning are outlined in this chapter.

1.2 Mechanisms of Heat Exchanger Fouling

Because of the great variety of fouling mechanisms it is useful to divide fouling according to the key physical/chemical processes into five major categories:

1. Crystallization Fouling
   - Precipitation and deposition of dissolved salts, which at process conditions become supersaturated at the heat

C4. Table 5. Fouling resistances for various processing streams in shell-and-tube exchangers, (m^2K/kW)

Hydrocarbons	Fuel oil no.2	0.35
	Fuel oil no.6	0.88
	Transformer oil	0.18
	Lube oil	0.18
	Hydraulic oil	0.18
	Quench oil	0.7
	Pitch	0.8
	Tar	0.9
	Vegetable oil	0.53
Gases and vapors	Steam (oil free)	0.0
	Steam (oil contaminated)	0.18
	Refrigerant vapor (oil contaminated)	0.35 0.0
	Alcohol vapor	0.09
	Organic vapor	0.18
	Ammonia	0.35

	Stable column bottom stream	0.18–0.35
	Caustic solutions	0.35
	Black liquor	0.7–1.4

transfer surface. Supersaturation may be caused by the following processes:

(a) Evaporation of solvent
(b) Cooling below solubility limit for solution with normal solubility, e.g., increasing solubility with increasing temperature
(c) Heating above the solubility limit for solutions with inverse solubility such as $CaCO_3$, $CaSO_4$, $Ca_3(PO_4)_2$, $CaSiO_3$, $Ca(OH)_2$, $Mg(OH)_2$, $MgSiO_3$, Na_2SO_4, Li_2SO_4, and Li_2CO_3 in water
(d) Mixing of streams with different composition
(e) Variation of pH which affects the solubility of CO_2 in water
(f) Solidification fouling due to cooling below the solidification temperature of a dissolved component (e.g., solidification of wax from crude oil streams)

2. Particulate Fouling
   - Deposition of small suspended particles such as clay, silt, or iron oxide on heat transfer surfaces of any orientation
   - Gravitational settling of relatively large particles onto horizontal surfaces
3. Chemical Reaction Fouling

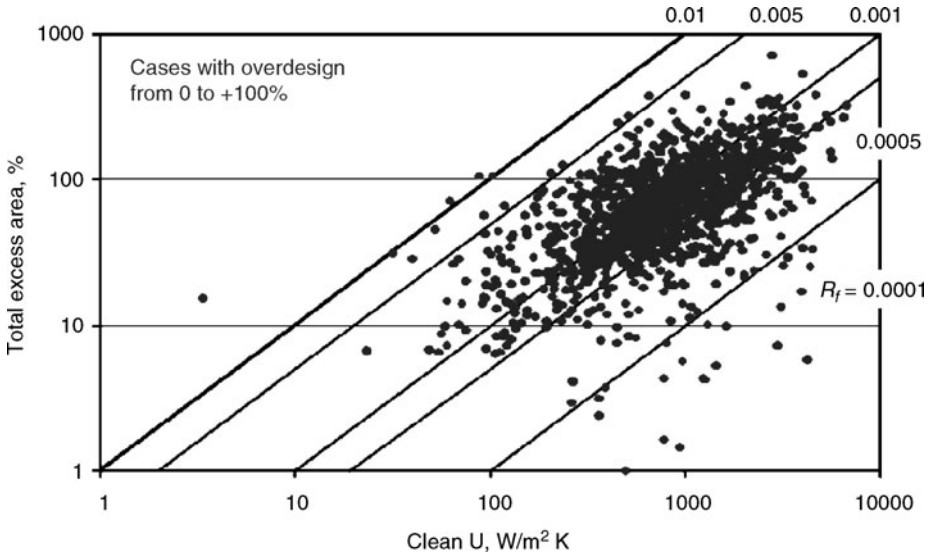
   Deposit formation at the heat transfer surface by a chemical reaction in which the surface material itself does not participate (polymerization, food processing).
4. Corrosion Fouling

   The thermal resistance of corrosion layers is usually low because of the relatively high thermal conductivity of oxides. However, the increased surface roughness may promote fouling due to other fouling mechanisms.
5. Biological Fouling

   Biological fouling refers to the development and deposition of organic films consisting of microorganisms and their products such as bacteria (microbial or micro-biofouling) and the attachment and growth of macro-organisms such as mussels, algae, etc. (macro-biofouling) on the heat transfer surfaces. Microbial fouling always precedes fouling by macro-organisms, with the microorganisms acting as the nutrient source for the macro-organisms. Suspensions of seaweed and other organic fibres often cause fouling. Many types of bacteria will deposit slime on the heat transfer surfaces and other types of foulants can adhere to these deposits. Larger growth restricts the fluid flow and often causes pitting of the metal. This type of fouling is common in untreated water such as sea, river, or lake water. Microbiological fouling is a particularly serious problem as the microbes may be introduced into the water cycle not only by the fluid, but also from the ambient air in the cooling tower. Temperatures between 15°C and 50°C in cooling towers are ideal for microbial growth. Both dead and alive microorganisms adhere to the heat transfer surfaces and form a layer of slime with a thermal conductivity similar to that of water. As a consequence of the filtering effect of biological layers, more suspended particles amass in the deposit.
6. Mixed Fouling

   Fouling mechanisms within each category may be described with similar models. Generally, several fouling mechanisms occur at the same time, nearly always being mutually reinforcing. Exceptions are the combination of crystallization and particulate fouling, where particles of the crystallizing matter accelerate fouling, whereas particles from other material may lead to reduced fouling due to a weakening of the deposit structure [9].

Figures 2 and 3 show typical effects of surface temperature and flow velocity on most of the above fouling mechanisms.



C4. Fig. 1. Impact of fouling resistance on 2000 shell and tube heat exchangers designed from 2003–2008

1.3 Sequential Events of Fouling

The above fouling mechanisms generally occur in five consecutive steps:

(i) *Initiation Period or Delay Period*

When the new or cleaned heat exchanger has been taken into operation, the initially high heat transfer coefficients may remain unchanged for a certain time. During this time, nuclei for crystallization are formed or nutrients for biological growth are deposited. This delay period may last anytime from few seconds to several days. According to [10], no delay period occurs for particulate fouling. For crystallization fouling and for chemical reaction fouling, the initiation period decreases with increasing surface temperature, as supersaturation and/or reaction rate increase [11]. Generally, it is reported that the delay time, before deposition starts, decreases with increasing roughness of the heat transfer surface.

(ii) *Mass Transport*

To form a deposit at the heat transfer surface it is necessary that at least one key component is transported from the fluid bulk to the heat transfer surface. In most cases, this occurs by diffusion. For the transport of particles to the wall, inertia effects and thermophoretic forces have to be considered, as well.

(iii) *Formation of Deposit*

After the foulant has been transported to the heat transfer surface, it must stick to the surface (for particulate fouling) or react to the deposit forming substance (e.g., $CaCO_3$).

(iv) *Removal or Auto-Retardation*

Depending on the strength of the deposit, erosion occurs immediately after the first deposit has been laid down. Furthermore, several mechanisms exist, which cause auto-retardation of the deposition process. For the thermal boundary condition of constant temperature difference between heated and cooled fluid, the growth of deposit causes a reduction of the driving temperature difference between heat transfer surface and fluid.

C4. Table 6. Fouling resistances in plate and frame heat exchangers, (m^2K/W) [5]

Fluid	Fouling resistance (m^2K/kW)
Water	
Demineralized or distilled	0.009
Soft	0.017
Hard	0.043
Treated cooling tower water	0.034
Coastal sea water	0.043
Ocean sea water	0.026
River water	0.043
Engine jacket	0.052
Lube oil	0.017–0.043
Vegetable oil	0.017–0.052
Organic solvents	0.009–0.026
Steam	0.009
General process fluids	0.009–0.052

(v) *Aging*

Every deposit is subjected to aging. Aging may increase the strength of the deposit by polymerization, recrystallization, dehydration, etc. Biological deposits get poisoned by metal ions and may be washed away by the bulk flow. Aging is the least investigated and understood step and is usually ignored in modelling attempts.

Depending on the process parameters and the dominant fouling mechanism, the fouling rate can be either constant or decreasing with time (see Fig. 4).

For hard, adherent deposits such as silicates and some polymerization products, steps iv and v may be ignored and the growth rate of deposits is constant or continuously decreasing with time. For weaker deposits (e.g., particles >1 μm), the fouling resistance approaches a constant (or asymptotic) value which may or may not allow acceptable operation of the process.

C4. Table 7. Fouling resistances for combustion gases on finned surfaces (m^2K/W) [6]

Fuel	Fouling resistance (m^2K/kW)	Flow velocity m/s
Natural gas	0.09–0.53	30–40
Propane	0.18–0.53	25–30
Butane	0.18–0.53	18–24

1.4 Approximate Influence of Operating Conditions on Fouling in Industrial Heat Exchangers

Many correlations have been recommended for the prediction of individual fouling mechanisms [12]. However, these correlations are generally not applicable to industrial conditions where a combination of fouling mechanisms and foulants occurs. Comparing fouling data from a range of industries, the following approximate influence of process parameters on industrial fouling has been found:

(a) Fouling usually increases linearly with increasing foulant concentration in the fluid bulk.
(b) The fouling resistance nearly always decreases with increasing wall shear stress due to increased removal forces. As an average, it was found that the fouling resistance is proportional to the flow velocity to the power of −1.5. Figure 5 shows the effect of dirt content and of flow velocity on the fouling resistance for cooling water [13].
(c) For many fouling mechanisms, the fouling resistance increases with increasing surface temperature (see e.g., Fig. 3). For crystallization and chemical reaction fouling, this trend frequently follows an Arrhenius relationship

$$\frac{dR_f}{dt} = Ke^{-E/RT_S} \quad (4)$$

For biological fouling, a maximum is observed for temperatures around 35°C.
(d) Fouling was found to increase with increasing roughness of the heat transfer surface.

To date, not even these simple rules are considered in the design of heat exchangers, even though they could significantly improve some heat exchanger optimization procedures. This is demonstrated in Fig. 6, which shows the sum of annual operating and capital service costs of an arrangement of multiple double pipe heat exchangers as a function of the flow velocity in the pipes. One curve has been calculated according to Martin [14] for a constant fouling resistance, the second is for the case where the fouling resistance is velocity dependent as suggested above. The optimum flow velocity shifts from 0.8 to about 1.3 m/s and the total annual costs are reduced by 10% despite the higher friction losses.

1.5 Costs due to Heat Exchanger Fouling

Despite the enormous costs associated with heat exchanger fouling, only very limited research has been done to determine accurately the economic penalties due to fouling and to attribute these costs to the various aspects of heat exchanger design and operation. However, reliable knowledge of fouling economics is desirable to evaluate the cost-efficiency of various mitigation strategies. The total fouling related costs consist of

1.5.1 Capital Expenditure

According to Thackery [15], total capital cost due to fouling in England added up to £100 million in 1978, which corresponds to US$190 million. For the United States, Garrett-Price et al. found that capital costs excluding costs for antifouling equipment were US$960–280 million in 1982 [3].

(a) Excess Heat Transfer Surface Area

Thackery [15] found that design excess surface area for fouling varies between 10–500%, with an average around 30%. This result was confirmed by Garrett-Price et al. [3], who obtained a similar value for the USA and by Steinhagen et al. for New Zealand [2]. Investigations by Heat Transfer Research Inc. and TEMA among the major North American heat exchanger manufacturers showed excess surface areas between 11% and 67% [8].

Excess area of 30–40% may correspond to 25% additional capital cost. To estimate the absolute costs of excess heat transfer area in the United Kingdom, Pritchard [16] took the value of

the process plant built in the UK. As much as 6.5% of the process plant hardware consisted of heat exchangers. If each heat exchanger has 30–40% extra surface area to allow for fouling, he concluded that additional costs were £5 million in 1968 and £20 million in 1977. The corresponding American figure is $US320 million per year for 1982 [3].

(b) Transport and Installation Costs

As a result of additional surface area, heat exchangers become bigger and heavier. Therefore costs for stronger foundations, provisions for extra space, increased transport and installation costs must be considered. Woods et al. [17] assume that installation costs tend to increase with the size of the heat exchanger and are usually 2–3 times the delivered costs. Adding these extra costs to the costs for excess heat transfer surface may increase the costs for oversized equipment to $640–960 million per year [3].

(c) Capital Costs for Antifouling Equipment

These costs include expenses for online and off-line cleaning equipment, extra cost for providing non-fouling heat exchangers such as scraped surface or fluidized bed heat exchangers, pretreatment plants, cleaning-in-place equipment, dosing pumps and tanks for antifouling chemicals.

1.5.2 Fuel Costs

Costs for extra fuel only occur if fouling leads to extra fuel burning in furnaces or boilers or if more secondary energy such as electricity or process steam is needed to overcome the effects of fouling. Thackery [15] estimated additional UK fuel costs in 1978 as £100–200 million ($US290–480 million). Garrett-Price et al. [3] calculate that 1–5% of the energy consumed by the industrial sector is used to overcome fouling. The result leads to fouling related fuel costs between $US700 and $US3,500 million.

1.5.3 Maintenance Costs

Maintenance costs are costs for removing fouling deposits and costs for chemicals or other operating costs of antifouling devices. According to Pritchard [16] and Thackery [15], about 15% of the maintenance costs of process plant could be attributed to heat exchangers and boilers and of that 50% was probably due to fouling. Garrett-Price et al. [3] quote a figure of $US2,000 million for annual sales of companies supplying heat exchanger online and off-line cleaning equipment, chemicals, and cleaning services in the USA for 1982.

1.5.4 Costs due to Production Loss

Because of planned and unplanned plant shutdowns due to fouling in heat exchangers, large production losses are possible. These costs are often considered to be the main cost of fouling. For example: Sart and Eimer [18] state that the loss of production for 1 day shutdown of a 1300 MW power plant is about $US500,000; Taborek [13] estimates that shutdown losses of a large oil refinery are about $US1.5 million per day. In addition to production losses during plant shutdown and start-up, penalties for not keeping to a deadline and the loss of customers must be considered. Garrett-Price et al. [3] suggested that an upper limit for loss of production costs may be estimated by assuming that the loss of production has to be less than the cost of providing redundant exchangers. For the US in 1984, this would be $US200 million. According to Thackery, [15] 1978 costs due to production losses in the UK are about £100 million ($US190 million).

The above fouling-related costs will have to be inflated to current prizes. For crude oil heat exchangers, more recent information is available in [19].

2 Consideration of Fouling in the Design of Heat Exchangers

2.1 Preliminary Remarks

Not all heat exchangers have serious problems with fouling; many of them operate satisfactorily for long periods of time without being cleaned. If fouling is anticipated, however, some allowance must be provided in the design of a heat exchanger. Regardless of the approach, the selection of appropriate values still relies more on engineering judgement from past experience than on the application of results from experimental and theoretical research. It is important to keep in mind that heat exchanger fouling can be effectively mitigated at the design stage of the heat exchanger. To design for reliable operation,

(i) Select a suitable heat exchanger type
(ii) Try to avoid operating conditions which promote fouling
(iii) Attempt an optimum design with adequate velocities in the heat exchanger and which avoids hot spots, bypass flow or dead zones
(iv) Design for easy cleaning

Additional guidance is included in Sect. 3. Due to their frequent occurrence and economic importance, detailed best practice guidelines have been prepared by ESDU [19–21] for fouling in crude oil preheat exchangers, and for seawater and fresh water as

C4. Table 10. Reboiler selection guide [8]

Anticipated fouling	Kettle or internal boiler	Horizontal shell-side thermosyphon	Vertical tube-side thermosyphon	Forced flow
No fouling	Good	Good	Good	Expensive
Moderate	Risky	Good	Best	Expensive
Heavy	Poor	Risky	Best	Good
Very heavy	Poor	Poor	Risky	Best

cooling media. These reports present the state-of-the-art of fundamental aspects and industrial practice.

2.2 Selection of Heat Exchanger Type

If fouling will be significant, it may well control the selection of the type of heat exchanger and its size. This is very clearly demonstrated in Table 10, which recommends different reboiler types depending on the severity of fouling [7]. Other examples are:

- Shell and tube heat exchangers are not particularly suitable for fouling conditions; however, good design practices [22–26] and special baffle and tube design may be applied to reduce fouling.
- Plate and frame heat exchangers may be attractive as they can be disassembled for cleaning and sterilizing.
- Since there are no local low velocity regions in spiral plate heat exchangers, these heat exchangers perform well for fluids with a high concentration of suspended solids.
- Scraped heat exchangers improve the heat transfer by continuously removing deposit from the heat transfer surfaces with rotating blades.
- Fluidized bed heat exchangers can be used where the fluidized particles remove deposit from the embedded tubes.
- Direct contact heat transfer may be a suitable alternative.
- Highly compact heat exchangers are normally avoided for severe fouling conditions, as they are difficult to clean.

2.3 Material Selection

The second most important point is the proper selection of the heat exchanger material, as already minor corrosion may considerably increase other fouling mechanisms. In addition, the pipe material itself can also have an effect on fouling. For example, biofouling is reduced in brass tubing, as shown in Fig. 7 for seawater fouling [27], and crude oil fouling can be minimized by careful material selection [26].

Surface roughness increases the contact surface area such that the true contact area is much larger than the apparent surface area. As a result of this difference, stronger adhesion should occur on rough surfaces. This is confirmed by measurements with Kraft black liquor in electropolished tubes shown in Fig. 8 [28].

Surface coatings for reducing the adhesion of deposits on heat transfer surfaces have attracted increased interest in recent years. For example, organic materials such as PTFE and Säkaphen have indeed been shown to reduce fouling from various fluids, for example during seawater evaporation and heat transfer to Kraft black liquor. The main reason why such materials/coatings are not more widely used is that they are poor heat conductors and form an additional resistance to heat transfer which is comparable to the TEMA fouling resistance for cooling water. If very thin coatings were used, the resistance against erosion or other mechanical stress would be greatly diminished. These problems may be avoided with several novel coating methods, such as Ion Beam Implantation, Magnetron Sputtering, Multi-Arc Ion Plating, Filtered Cathodic Vacuum Arc Plating or electroless Ni-P-PTFE plating which have been investigated in recent years [29–33]. These thin and stable coatings have been found to reduce scale formation during convective and boiling heat transfer as well as the adhesion of bacteria.

2.4 Shell and Tube Heat Exchangers

Experience has shown that higher flow velocities and lower tube surface temperatures generally tend to reduce fouling. Therefore, arrangements that eliminate stagnant or low velocity regions have less overall fouling. As a general rule, the more fouling and more corroding fluid should be placed on the tube-side. The inside of tubes can be cleaned much easier than the outside and the tubes can be made from exotic alloys at lower cost than the shell.

The orientation of a heat exchanger influences the ease by which it can be cleaned and can effect particulate fouling. If particulate fouling is anticipated, a vertical down-flow orientation will permit the solids to move through the exchanger. If a horizontal orientation is unavoidable, place the slurry on the

C4. Fig. 11. Twisted Tubes (courtesy Brown Fintube Company)

tube-side and ensure down-flow for multiple tube pass designs. While placing a slurry on the shell-side of a horizontal heat exchanger is not recommended, some success has been reported for vertical-cut double-segmental baffles because they allow the sediment to travel through the exchanger.

While heat exchangers used to be designed for tube-side flow velocities around 1 m/s, modern design velocities are about 2.0 m/s. Table 11 shows optimum and minimum cooling water velocities for condensers of various pipe materials [34].

Based on 20 years of experience in the design of heat exchangers, Gilmour [35] states that "for most applications, only negligible fouling occurs if the heat exchanger is well designed. It is obvious that the majority of poorly performing shell and tube heat exchangers were caused by mistakes in the design of the shell-side flow path." He especially emphasizes that zones with low flow velocity and bypass flows should be avoided under any circumstances. If half-moon baffles are used, the baffle cut should not exceed 20% of the shell inside diameter. Vertical baffles should only be used for condensation or evaporation duties but not for sensible heat transfer situations, because they allow a stratification of flow and hence a sedimentation of suspended particles. Figure 9 [8] shows qualitatively the deposit formation in two shell and tube heat exchangers for identical heat duty. The smaller heat exchanger is designed with appropriate baffle spacing and baffle cut, and hence has higher heat transfer coefficients and less fouling.

Helical flow baffles, as shown in Fig. 10, have been used successfully because they avoid both, flow stratification and stagnant flow zones [36]. Reduced fouling has also been reported for the EM-baffle design developed by Shell Global Solutions [37].

Successful installations of heat exchangers with twisted tubes (Fig. 11) have been reported which may reduce deposit formation both, on the shell and on the tube-side [38].

It is often assumed that finned tubes tend more to fouling because of low flow velocity zones at the base of the fins. While these problems may occur for fouling mechanisms which depend strongly on the flow velocity (such as biological fouling and particulate fouling), there are a number of applications where fouling was even reduced by the use of finned tubes. This effect is explained by the nonuniform thermal expansion of finned tubes due do the temperature profile along the fins, which may reduce the strength of hard and adherent deposits. In [39] numerous investigations on fouling on finned tubes are compared with respect to the effects of fin geometry on deposit formation. When selecting finned tubes for fouling duties it should always be considered that mechanical cleaning of finned surfaces may be difficult or even impossible.

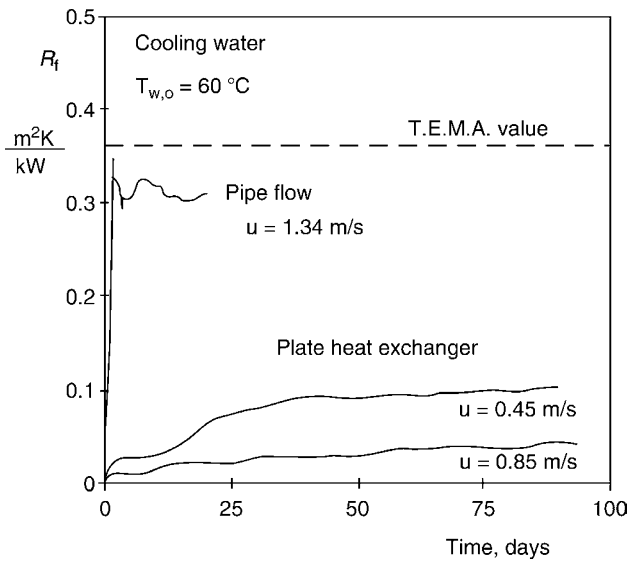
A fairly recent solution for heat transfer involving severely fouling liquids is the fluid bed heat exchanger, which has been described by Klaren [40]. Small solid particles (glass, ceramic, metal) are fluidized inside parallel tubes by the upward flow of liquid. The solid particles regularly break through the viscous boundary layer, so that good heat transfer is achieved in spite of relatively low flow velocities. More importantly, the solid particles have a slightly abrasive effect on the wall of the heat exchanger tubes, thus removing most deposits at an early stage. Fluid bed heat exchangers have been installed in water

treatment plants, paper mills, food and dairy plants, geothermal plants and in various chemical plants. In all cases, a substantial reduction in fouling has been achieved.

2.5 Other Heat Exchanger Types

The widespread installation of compact heat exchangers has been hindered by the perception that the small passages are stronger affected by the formation of deposits. Obviously, compact heat exchangers are unsuitable for fluids containing large particulate material or debris. However, several investigations demonstrated that the high shear forces, low wall superheat and homogeneous flow distribution typical for compact heat exchangers reduce the formation and adhesion of deposits on the heat transfer surfaces. The use of more corrosion resistant materials with smoother heat transfer surfaces further reduces the formation of deposits. Most compact heat exchangers have to be cleaned chemically. Unfortunately, there is very little published information about fouling and cleaning of compact heat exchanger types.

As indicated by Eq. (3), the excess heat transfer surface area increases with increasing clean heat transfer coefficient for a constant heat duty. This places a heavy penalty on compact heat exchanger types, such as plate and frame heat exchangers, if, because of ignorance or because of cautiousness, the TEMA fouling resistances for shell and tube heat exchangers are used. Typical clean overall heat transfer coefficients for plate and frame heat exchangers are about 3000 W/m^{2}K, for shell and tube heat exchangers about 1000 W/m^{2}K. A design fouling resistances of 0.3 m^{2}K/kW then corresponds to 30% overdesign for a shell and tube heat exchanger and to 90% overdesign for a plate and frame heat exchanger.



C4. Fig. 12. Comparison of fouling in plate and frame, and in shell and tube heat exchangers [41]

2.5.1 Plate and Frame Heat Exchangers

The application of plate heat exchangers in the chemical process industry is increasing rapidly, where they begin to replace tubular heat exchangers in several traditional applications. Cooper [36] investigated cooling water fouling using an APV model R405 plate heat exchanger. The water was chemically treated before entering the heat exchangers. As shown in Fig. 12, the fouling resistance in the plate and frame heat exchanger is significantly lower than in the shell and tube heat exchanger, despite the typically lower flow velocities. If the flow velocity is increased, the fouling resistance decreases similarly as it is found for shell and tube heat exchangers. Novak [42] studied the fouling behavior of Rhine River water near Mannheim (Germany), and of Öresund seawater in Sweden. For both waters, mainly biological fouling was observed. The fouling resistances increased almost linearly over the observed period of time. Table 12 summarizes the measured effect of flow velocity on the fouling rate.

Typical values for fouling resistances in plate heat exchangers are given in Table 6. Most manufacturers of plate and frame heat exchangers recommend that the excess surface should not exceed 25% of the heat transfer surface area calculated for the clean duty. Due to the nonuniformity of flow distribution and deposit formation, measured pressure drop increases are significantly higher than values predicted using an average deposit thickness calculated from the fouling resistance.

The actual plate geometry (angle, amplitude, and wavelength of corrugations) affects the formation of deposits [43]. Delplace et al. found that deposition from whey protein solutions on chevron plates is only half of that of straight corrugations, for otherwise identical conditions [44].

2.5.2 Plate-Fin Heat Exchangers

Plate-fin heat exchangers are brazed/welded compact heat exchangers with a heat transfer surface density of about ten times that of tubular heat exchangers. Typical applications are cryogenic, chemical/petrochemical, and hydrocarbon offshore installations. Molecular sieves and 100 µm filters are used in cryogenic installations to remove particulate matter or components that may freeze-out on the heat transfer surfaces. Systematic investigations have been performed on particulate fouling [45] and on river water fouling [46].

C4. Table 12. Fouling rates of Rhine river water for a surface temperature of 25°C [33]

Type	u, m/s	τ, Pa	dR_f/dt, 10^4 m^{2}K/kWh
Plate heat exchanger	0.13	6.7	7.4
Plate heat exchanger	0.19	14.5	4.3
Plate heat exchanger	0.77	190.0	0.6
Spiral plate exchanger	0.43	7.5	5.0

For 3 µm ferric oxide particles suspended in water, no blockage of plain fin or wavy fin channels was observed. Wavy fin channels fouled more than plain fin channels. All experiments showed asymptotic behavior. Higher deposition rates were obtained for non isothermal conditions and at higher bulk temperatures. Maximum deposition occurred at a Reynolds number of about 1500 [45].

Fibrous and biological material partially block the inlet of the aluminum plate-fin test sections when used with river water, which was filtered through a 1 mm mesh. Some deposition was found at locations where corrosion of the aluminum had occurred. In the wavy fin test section, a thin, uniform deposit of fine mud was observed. Pressure drop for the plain finning increased linearly with time, whereas asymptotic behavior was found for the wavy finning. The initial slope of the relative pressure drop vs. time curves was $5.8{\cdot}10^{-8}s^{-1}$ for the plain fins and $1.71{\cdot}10^{-7}s^{-1}$ for the wavy fins. For the latter, an initial deposition rate of $4.8{\cdot}10^{-12}$ s m^2K/W and an asymptotic – fouling resistance of $6{\cdot}10^{-6}m^2K/W$ was measured [46].

2.5.3 Printed Circuit Heat Exchanger

The passages in Printed Circuit Heat Exchangers (PCHEs) are typically between 0.3 mm and 1.5 mm deep. The specific design leads to volumetric heat transfer areas of 500–2,500 m^2/m^3, which is an order of magnitude higher than shell and tube heat exchangers. Experiments are described in [47] to compare the fouling related drop in performance of a PCHE and of a double pipe heat exchanger (DPHE). The cooling water treated against corrosion, scale formation and biofouling, and a 0.5/1.0 mm strainers was installed to reduce particulate fouling. For operating times of 500–660 h, no change in thermal effectiveness was observed for the PCHE, but the pressure drop increased by up to 55% due to the deposition of particulate material. The addition of a stainless steel mesh insert for the removal of fibrous material significantly reduced the increase in pressure drop. No deposition was observed in the parallel DPHE.

PCHEs have been used for gas cooling using seawater [47]. 200 µm strainers have been installed upstream of the heat exchanger and chlorine was added to counter biofouling. No operational problems have been reported. Another application involved the heating of tail gas in a nitric acid plant using condensing steam. After 18 months of operation, no indication of channel blockage could be detected.

2.5.4 Polymer Compact Heat Exchangers

Polymer heat exchangers are used for low pressure operations involving corrosive gases or liquids. The low surface energy and the smooth surface of their construction materials (polypropylene, fluoropolymer etc.) reduce the stickability of most deposits. Since clean heat transfer coefficients are already low (150–250 W/m^2K), these heat exchangers react less sensitively to an additional fouling resistance than metallic heat exchangers.

2.6 Effect of Fouling on Pressure Drop

The formation of deposits on the heat transfer surfaces causes an increase of the frictional pressure drop due to increased surface roughness and restricted cross-sectional flow area. According to Chenoweth [8], more heat exchangers are taken out of service because of excessive pressure drop than because of reduced heat transfer.

2.6.1 Tube-Side Pressure Drop

A rough estimate of the tube-side pressure drop can be made if it is assumed that the deposit is distributed evenly at the tube inside. The frictional pressure drop in cylindrical tubes is calculated from Eq. (5):

$$\frac{\Delta p}{\Delta L} = \xi \frac{\rho\, u^2}{2 d_i} \tag{5}$$

the friction factor for smooth tubes

$$\xi = 0.0056 + 0.5\ \mathrm{Re}^{-0,32} \tag{6}$$

and for rough tubes

$$\xi = 0.014 + 1.056\ \mathrm{Re}^{-0,42} \tag{7}$$

If the fouling resistance and the thermal conductivity of the deposit are known, the inside diameter of the fouled pipe can be determined by Eqs. (8) and (9):

$$R_f = \frac{d_i}{2\lambda_d} \ln\left(\frac{d_i}{d_f}\right) \tag{8}$$

$$d_f = d_i \exp\left(\frac{-2\lambda_d R_f}{d_i}\right) \tag{9}$$

The pressure drop for the fouled tube is obtained by using Eq. (5) in conjunction with Eqs. (7) and (9). It is generally found that the above equations under-predict the effect of fouling on pressure drop, since they assume a uniform distribution of deposit over the total heat transfer surface.

C4. Table 13. Ratio of fouled to clean shell-side pressure drop [48]

Deposit heat transfer coefficient	Shell diameter/baffle spacing		
	1.0	2.0	5.0
Laminar flow			
$1/R_f = 6000$ W/m^{2}K	1.06	1.20	1.28
$1/R_f = 2000$ W/m^{2}K	1.19	1.44	1.55
$1/R_f < 1000$ W/m^{2}K	1.32	1.99	2.38
Turbulent flow			
$1/R_f = 6000$ W/m^{2}K	1.12	1.38	1.55
$1/R_f = 2000$ W/m^{2}K	1.37	2.31	2.96
$1/R_f < 1000$ W/m^{2}K	1.64	3.44	4.77

2.6.2 Shell-Side Pressure Drop

The effect of fouling on the shell-side pressure drop can be estimated using Table 13 from Coulson et al. [48].

3 HTRI Fouling Mitigation by Design Method

Based on almost 50 years of experience as some of the world's leading heat exchanger design experts, Heat Transfer Research Incorporated (HTRI) [22–26] have developed a design methodology that yields smaller, more cost-effective shell and tube heat exchangers with extended run times between cleanings. While this methodology has, so far, only been validated for crude oil processing, its rigorous approach can be taken as an example for other fluids and heat exchangers types. These techniques were developed by HTRI with help from industry through the HTRI Exchanger Design Margin Task Force (EDMTF). The goal of the EDMTF is to develop the design philosophy for adding margins to heat exchangers to allow for process uncertainties and fouling.

Experience has shown that fouling may be mitigated for many services through proper heat exchanger design and operation. For the experienced designer, fouling resistances are not used when operating data for identical or similar services are available. In these cases, designing with the proper attention to velocity (or shear stress) and wall temperature can prevent significant fouling whereas "the mere use of a high fouling resistance will generally engender a high degree of fouling."

A small design margin may be added to the design to address design uncertainties. Rarely is this margin in excess of 30%. More than 30% excess margin calls for a root cause analysis of the problem followed by a fouling (or design) mitigation strategy. Except for rare cases of intentional high variability in throughput, more than 30% excess margin in a heat exchanger design indicates the presence of unresolved engineering issues and can often be a significant source of hidden cost to the owner.

It is good practice to design for an allowable pressure drop derived by reducing the maximum available pressure drop in the clean condition by the amount of excess margin anticipated. This permits any excess margin to be applied in such a way that design shear rates and wall temperatures are not reduced. The maximum available pressure drop in the clean condition is estimated as the maximum available pressure drop divided by the fractional pressure drop increase when the exchanger is operated in the fouled condition.

3.1 Crude Oil Best Practice Operating Conditions

The fluid scope for this design methodology is:

- Medium-to-high boiling point liquid hydrocarbon mixture with API gravity less than 45
- Heavy particulate matter (e.g., catalyst fines) absent
- Reasonable salt content (no desalter malfunctions)

a) Minimum Liquid Velocity

- Tube-side velocity of 2 m/s. This velocity limit is applicable for tubes with outside diameters of 19.05 mm and 25.4 mm. Increase velocity to 2.2 m/s for tube diameters of 31.75 mm and 38.1 mm to maintain shear stress.
- Shell-side cross flow stream should be at least 0.6 m/s. If the shell-side flow is fully longitudinal, the minimum shell-side velocity should be 1.2 m/s. For longitudinal flow bundles, tubes removed for entrance/exit considerations at the shell nozzles should be replaced in the bundle proper with plugged dummy tubes or rods of the same diameter to maintain a uniform flow field and minimize bypass streams. The bundle-to-shell diameter ratio is to be made as close to 1.0 as practical under TEMA [4] clearance rules.

b) Maximum Temperature

- The maximum tube wall temperature should be 300°C. Shell-side design with cross-flow baffles
- The B-stream fraction according to TEMA nomenclature [4] should be at least 0.65.
- Single-segmental baffles should be selected. If the shell-side pressure drop is prohibitively high, double-segmental, helical, EMbaffle, rod baffle, squared, or no-tube-in-window (NTIW) baffle configurations may be considered.
- Baffle cut orientation should normally be horizontal for TEMA type E and J shells. Baffle cut orientation for TEMA type F and G shells should be vertical. If slurry must be placed on the shell-side of a horizontal heat exchanger, consider vertical cut double-segmental baffles to allow the sediment to exit the shell.
- Baffle cut for single-segmental designs should be 20–25% of the shell inside diameter, where 20% is preferred. It may be increased up to 25% to reduce leakage streams.
- The ratio of window velocity to cross-flow velocity (including leakage streams) should be less than 2.0 for designs with tubes in the window (1.0–1.5 is preferred). For no tubes in window designs, the ratio of window velocity to cross flow velocity should be less than 3.0 (1.5–2.0 is preferred). Refinement of this guideline is an area of research.

3.2 Cooling Tower Water Best Practice Operating Conditions

For the case of those cooling water streams which are closely regulated in the plant for velocity control and are kept reasonably clean with a water maintenance program, fouling mitigation strategies apply. The cooling water temperatures should be designed and operated to not exceed a maximum bulk temperature of 50°C or a maximum wall temperature of 60°C.

In addition, there must be sufficient velocity to maintain any particulate in suspension as well as to produce enough wall shear to stabilize any fouling which does occur. There are many

sources for information on minimum cooling water velocities for design, such as those given in Table 11. In reality, the exact minimum value for any cooling water system is so dependent upon the contaminants dissolved in the water that one single value for this purpose can only be regarded as an approximation. In the final analysis, the judgment as to minimum design water velocities while adhering to prudent water temperature limitations must be made by those knowledgeable about the water used.

3.3 Excess Surface/Coefficient Adjustments

- If both fluids are within the scope outlined above, approximately 20–25% excess surface should be provided instead of applying fouling resistances. This design margin may be reduced when the designer has confidence in the fluid properties, predictive methods, and successful mitigation of fouling (usually based on prior experience for a similar service).
- If only one fluid is operating under the best practice conditions, a fouling resistance should be selected for the fluid outside scope. For non-fouling fluids outside scope, a fouling resistance of 0.000088 m^2K/W is recommended to compensate for heat transfer surface changes during start-up. For the fluid within scope, the heat transfer coefficient is multiplied by 0.83 and no fouling resistance is used. As above, the design margin may be reduced based upon operating experience.

3.4 Design Recommendations

3.4.1 Shell-Side Bundle Geometry Exit/Entrance Constraints

- Where impingement protection is required, use impingement rods. One row of rods is acceptable for 90° tube layouts, two rows for staggered pitch. Impingement plates should be avoided.
- Large baffle end spaces and correspondingly low local velocity sometimes occur due to geometry constraints. When the end baffle space is greater than or equal to 1.5 times the space between baffles, the area back from the first baffle to 1.5 times the baffle spacing is to be considered 65% effective regardless of baffle type or orientation. All remaining area to the tube-sheet is to be considered ineffective for heat transfer. Additional area should be provided in the bundle proper as compensation. An annular distributor may be considered if the affected surface area is large.

3.4.2 Allowable Pressure Drop

Pressure drop should be provided as required to meet the minimum critical velocities noted in Sect. 3.1. If the pressure drop (and hence the flow velocity) is too low, fouling may become inevitable and fouling mitigation impractical.

3.4.3 Longitudinal Baffles

If a longitudinal baffle is used in heavy fouling service where shell-side pressure drop in one shell exceeds 35 kPa (70 kPa with a "kempchen" style of seal), the baffle shall be welded to the shell. Note that welding the longitudinal baffle to the shell requires a shell inside diameter of at least 0.7 m and, for the bundle to be removable, U-tubes must be used with the U-bends in the horizontal plane (normally two or more tube passes per shell pass). The designer should investigate differential thermal stresses across the shell. In general, a welded longitudinal baffle is probably acceptable where the shell-side temperature difference across one shell does not exceed 90°C. For leaf seal construction, shell-side operating temperature differentials of 195°C across one shell have been accommodated with proper mechanical design. These rules are for 6.7 m straight-length tube bundles and will vary with bundle length. Bundle slide rails in both top and bottom portions of the bundle need to be provided.

The following segmental-baffle construction features may be considered to improve shell-side performance:

- American Petroleum Institute Standard 660 requires that a seal device (dummy tubes, rods, or strips) be implemented from 25–75 mm from the baffle tips, and for every 5–7 tube pitches thereafter. The number of seals may have to be increased to limit the bundle and pass lane leak streams.
- Where the tube-to-baffle diametral tolerance (as specified by TEMA [4]) is 0.8 mm, the tolerance may be reduced to 0.4 mm if required to reduce the leak stream between the tube and baffle hole.
- The TEMA [4] baffle-to-shell diametral clearance may be reduced to limit the baffle-to-shell leakage stream. A clearance of 0.0035–0.004 times the shell diameter is achievable for shells rolled from plate, but use this extra tight clearance only if necessary, as it is difficult to guarantee compliance. Extra tight clearance is not recommended for shells made from pipe (typically NPS 24 and smaller).
- Baffled TEMA [4] F and G shells may be considered to increase shell-side velocity, reduce the number of shells in series, and/or improve the baffle-spacing-to-shell-diameter aspect ratio.

3.5 Example for Fouling Mitigation by Design

To demonstrate the potential savings of the design methods outlined in this section, the following example will be used. This example is for the last shell-and-tube heat exchanger in the crude oil preheat train prior to the fired heater. Selection of material is important, and stainless steel or high chrome steel should be selected for the design. The process conditions are summarized in Table 14a.

3.5.1 Original Design

The original heat exchanger is a TEMA type AES consisting of two shells. The design and performance parameters for the exchanger unit are given in Table 14b.

3.5.2 Operation History with Original Design

This service was a consistent high fouling problem and would lose about 57% of its performance capacity within the first 6 months after cleaning, resulting in excess energy (fired heater fuel) and related costs of about €62.000 per month averaged over a 2 year turnaround cycle.

3.5.3 Root Cause Analysis of Performance

At the next turnaround, the bundles were pulled for cleaning. Prior to cleaning, visual bundle inspection revealed a "fuzzy" looking coating on the outside of the tubes consisting of oil and coking fines from the vacuum unit. The coating was slightly sticky but did not solidly adhere to the surface and could be easily wiped away. The tube-side fouling appeared to be slight. In addition, analyzing the fouling performance monitor over the course of the 2-year turnaround cycle indicated a performance plateau at about 6 months after which the fouling seemed to stabilize for the next 1.5 years. These data strongly indicated shear rate controlled fouling at the shell-side.

From the above data, it was estimated that a shell-side velocity slightly greater than 1.5 m/s should keep the fouling from adhering to the outside of the tubes and allow it to be carried through the exchanger without deposition. However, to do this required an appropriate redesign of the heat exchanger.

3.5.4 New Design

Using the procedures outlined in this section, a replacement heat exchanger was designed for this service as given in Table 14c.

The new design consists of a horizontal welded long baffle on the shell-side, shell nozzles located at the rear of the shell beyond the bundle U-bends so that there are no erosion concerns, and horizontal U-bends with a vertical channel pass partition to produce a removable, two tube pass bundle in a welded long baffle F-shell. Both the original and new designs employed segmental baffles on the shell-side.

3.5.5 Final Outcome

The new design used no preset fouling resistances but instead used the allowable pressure drop to produce the higher shear rate necessary to inhibit deposition. A minimum of 15% excess surface was thought prudent to handle design uncertainties in the new configuration. The new exchanger performed at or above expected design over the 2-year turnaround cycle producing an average €68.000 per month cost savings over the original heat exchanger.

C4. Table 14a. Process conditions for design example

Stream	Fluid	Flow rate	Temperature in	Temperature out	Allowable ΔP
Location	Designation	kg/s	°C	°C	kPa

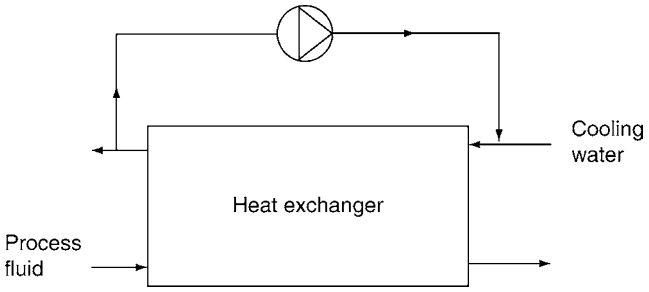
4 Online Mitigation Methods

The following section provides an overview of the broad categories of mitigation methods, and describes some general approaches. For more detailed information see [49].

4.1 Start-Up Procedures

The use of constant fouling resistances in the design of heat exchangers leads to initially oversized equipment. Heat duties in new or cleaned heat exchangers can, therefore, be considerably higher than the design specifications. In most chemical processes, however, product inlet and outlet temperatures, product flow rate and cooling water inlet temperature are specified. If this is the case, the heat exchanger is usually controlled via the flow rate of the cooling water. To reduce the heat duty, the water flow velocity must be reduced. Figure 13 shows that this procedure may cause a considerable increase of fouling as compared to fouling under design operating conditions.

Point "A" refers to the design values of flow velocity and heat transfer surface temperature. As the heat exchanger is initially overdesigned, the cooling water flow velocity is throttled which also causes an increase of the heat transfer surface temperature, see point "B." However, fouling at "B" is considerably worse and deposits created during this part of the operation may not be removed completely, even if the flow velocity is increased, later. Therefore, by specifying high fouling resistances, fouling may become a self-fulfilling prophecy. If part of the cooling water is recirculated, as shown in Fig. 14, the flow velocity and the cooling water inlet temperature can be increased to meet the required heat duty. The anticipated fouling ("C") will be similar to the design value ("A"), but a price is to be paid to provide the higher flow velocity.



C4. Fig. 14. Recirculation of cooling water

4.2 Chemical Fouling Mitigation Methods

Since about 1920, a number of companies have specialized in the mitigation of fouling and corrosion, mainly for the flow of cooling water and hydrocarbons. These companies have gained considerable expertise and have developed a wide range of additives and equipment. Services include the supply of chemicals as well as the analysis of cooling water, the evaluation of potential fouling and corrosion problems, and complete treatment programs including continuous monitoring of the system. In what follows in this subsection, only a small selection of methods to reduce fouling by chemical means is discussed. For the final selection of the treatment as well as for the dosage of treatment chemicals, specialists should be consulted. More details may be found in [49] provided by industrial fouling mitigation companies.

Commercial antifoulants usually contain a number of components. These polyfunctional antifoulants are more versatile and effective since they can be designed to combat various types of fouling that can be present in any given system. Antifoulants are designed to prevent equipment surfaces from fouling, but they are not designed to clean up existing deposits. Therefore, antifoulant addition should be started immediately after equipment is cleaned.

4.2.1 Scale Formation

In general, there are three alternatives available to mitigate or to prevent scale deposition due to high concentration of scale-forming ions in aqueous solutions:

Removal of Scaling Species

Scaling species may be removed by ion exchange and by chemical treatment. In the latter treatment, carbonic acid, and calcium hardness are removed by the addition of chemicals. If the lime treatment is used:

$$Ca(HCO_3)_2 + Ca(OH)_2 \rightarrow 2\,CaCO_3 + 2H_2O \qquad (10)$$

$$CO_2 + Ca(OH)_2 \rightarrow CaCO_3 + H_2O \qquad (11)$$

During slow decarbonization (1–3 h reactor residence time), the calcium carbonate precipitates as silt, during fast decarbonization (5–10 min reactor residence time) it precipitates in the form of particles. With the exception of installations with high

calcium hardness or large throughput, chemical removal of scaling species is not used anymore.

Instead, ion exchangers are used in which the "harmful" scaling species in the fluid are replaced by "harmless" ions (for example Ca^{++} or Mg^{++} by Na^{+}). Ion exchangers are usually manufactured from styrene based polymers. The so-called cationic exchangers contain weak and strong acids; the anionic exchangers contain weak and strong alkaline groups. With these two variations, all cations and anions can be removed from the fluid. Ion exchangers have to be regenerated regularly with the appropriate salt solution. According to [50], chemical decarbonization leaves a residual hardness of 17–30 ppm as $CaCO_3$, ion exchange can reduce the hardness down to 2 ppm as $CaCO_3$. Both methods of fluid treatment have high capital and operating costs.

In the oil industry, desalters are installed at the beginning of the crude oil heat exchanger train to replace salty water, which may otherwise cause scale formation at higher temperatures.

pH Control

The solubility of scale-forming constituents increases with decreasing pH. Many treatment programs, therefore, involve the addition of acid (usually H_2SO_4) to the system to maintain a pH in the region of 6.5–7.5. If the system contains corrosion-resistant materials, a pH may be selected at which no scaling will occur. The Langelier Saturation Index or the Ryznar Stability Index [51] are commonly used to determine the value of pH to be adjusted.

Scale Inhibitors

Growth of crystals or the nucleation of crystals can be inhibited by the addition of scale inhibitors. Many proprietary compounds are available for scale control.

Chelating agents (for example EDTA) complex strongly with the scaling cations and hence inhibit their deposition at the heat transfer surface. Inhibitor and scalant must be available in stoichiometric ratios.

Processes, which are based on physical rather than on chemical reactions are those that stabilize supersaturated solutions by adsorption at the crystal nuclei (for example polyphosphates) or that modify or weaken the crystalline structure (for example polycarboxylic acid). Table 15, which has been adopted from Harris and Marshall [52], shows the ability of additives to maintain $CaCO_3$ in solution. Lists of additives to reduce crystallization from hard waters have been compiled by Harris and Marshall [52] and by Krisher [53].

C4. Table 15. Ability of various additives to maintain $CaCO_3$ in solution [52]

Additive	% Inhibition at dose level			
	2.5 ppm	5.0 ppm	7.5 ppm	10 ppm
Polyphosphate	98%	98%	99%	100%
Aminophosphonic acid	97%	96%	95%	94%
Acetodiphosphonic acid	83%	82%	83%	90%
Polyacrylate	30%	65%	84%	93%
Polymaleic acid	26%	35%	44%	56%
EDTA	15%	20%	20%	20%

4.2.2 Particulate Fouling

Particulate fouling is usually mitigated by the addition of surfactants or dispersants. If the surface tension is reduced, large particle agglomerates can break down into smaller particles, which tend less to sedimentation. Dispersants impart like charges to both the heat transfer surface and the particles and reduce deposition. For cooling water applications polyacrylates or polysulfonates are used with molecular weights between 2000 and 3000 g/mol. According to [53], the addition of polyphosphates to reduce scaling may cause a slight reduction of the dispersion of particulates.

4.2.3 Chemical Reaction Fouling

Chemical reaction fouling increases exponentially with increasing heat transfer surface temperature according to an Arrhenius term, see Eq. (4). As activation energies E are fairly high for chemical processes, even a modest reduction of the heat transfer surface temperature due to process or design modifications may already cause a considerable reduction of fouling. Particles suspended in the fluid (e.g., from upstream corrosion) can act as catalysts. Reaction fouling may be mitigated by removing these particles.

Especially for oil refining processes a number of chemical additives to reduce reaction fouling have been developed. Most antifoulants have several functions. Generally they are oxygen scavengers, metal deactivators and dispersants [54]. For autoxidation-induced fouling, antioxidants can be added to consume oxygen or react with oxidation products in a way as to prevent the chain reaction of the autoxidation process, or metal deactivators are added to chelate metal ions thereby preventing their catalytic effect on the autoxidation process. Once insolubles form by either autoxidation or thermal decomposition, dispersants can be added to minimize agglomeration of small insoluble polymeric or coke-like particles into larger particles or deposit, or sticking of particles to the tube wall [55].

Antioxidants

Even very small amounts of oxygen can cause or accelerate polymerization. Accordingly, antioxidant type antifoulants have been developed to prevent oxygen from initiating polymerization. Antioxidants act as chain-stoppers by forming inert molecules with the oxidized free radical hydrocarbons.

Metal Deactivators

Traces of metals are invariably present in hydrocarbon streams, which may catalyze polymerization reactions. For example transition metal ions, such as Cu, Fe, Zn, and Mn are powerful hydroperoxide decomposers and provide a steady source of free

radicals for oxidation chain initiation. By complexing the metal ion, it can be prevented from participating. Thus chelating compounds are used as metal deactivators [55].

Dispersants

Dispersants or stabilizers prevent insoluble polymers, coke, and other particulate matter from agglomerating into large particles which can settle out of the process stream and adhere to the metal surfaces of process equipment. They also modify the particle surface so that polymerization cannot readily take place. Dispersants generally play an important role in antifoulant programs. The feedstock or hydrocarbon stream may already contain polymerized materials which, if allowed to agglomerate, would deposit. In most applications it is not possible to fully eliminate oxygen- or metal-induced reactions and dispersants are necessary to prevent the polymerized materials from agglomerating and depositing on heat transfer surfaces [54, 56]. Dispersants are believed to function by absorbing on the surface of materials which are insoluble in the organic fluid and converting them to stable colloidal suspensions. They generally contain polar groups which absorb on the particle surface and nonpolar hydrocarbon-soluble groups to affect dispersion by their solubilization. Mayo et al. [57–62] argue that it is the solubilizing properties of dispersants which are most important in reducing deposit formation.

Figure 15 shows the performance of the feed/effluent heat exchanger in an oil refinery with and without chemical treatment.

4.2.4 Biofouling

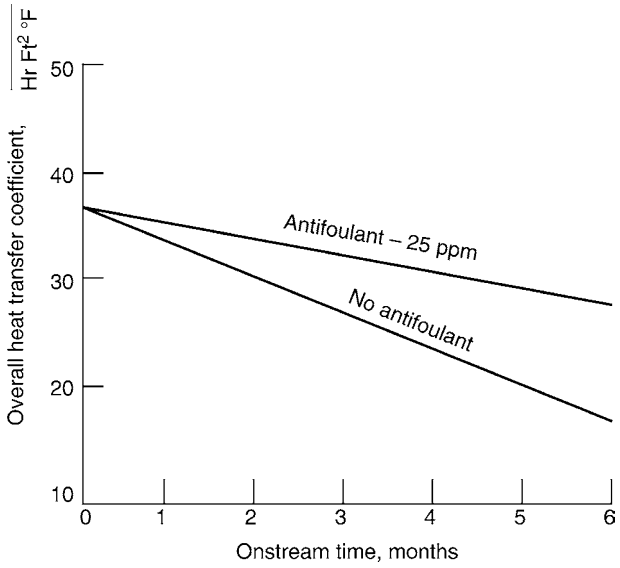
The environment in cooling towers and cooling systems is particularly conducive to the growth of microorganisms in water and on surfaces of the system. Microorganisms attach and grow on surfaces, and produce polysaccharides, which increase the stickability of suspended matter and hence promote further deposition. Biological growth is usually controlled by addition of biocides. In recent years, chlorine has most widely been used, which reacts with water to hydrochloric and hypochlorous acid:

$$Cl_2 + H_2O \rightarrow HCl + HOCl \qquad (12)$$

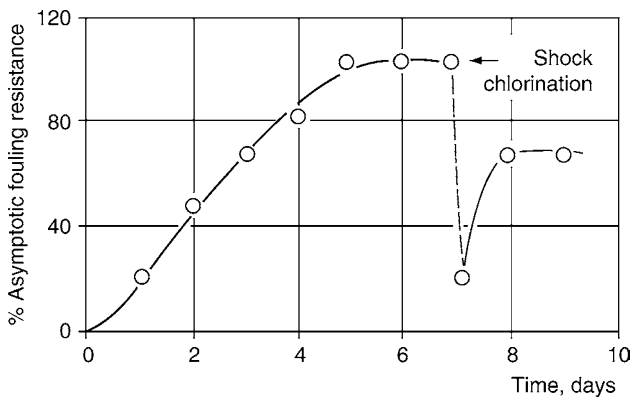
Hypochlorous acid is an extremely powerful oxidant that easily diffuses through the cellular walls of microorganisms. It is assumed [64–66] that HClO oxidizes the active sites of certain enzyme sulfhydryl groups, which constitute intermediate steps in the production of adenosine triphosphate (ATP). The system ATP-ADP allows conversion of carbohydrates and hence the energy supply for living organisms. Contrariwise to other, nonoxidizing biocides, chlorination also weakens the biofilm matrix allowing the removal of biofilms from the heat transfer surface by fluid shear forces. Continuous application of chlorine at concentrations between 0.1 and 0.5 ppm has shown to be a reliable but costly method to avoid deposition. Cheaper but less effective is a dosage of 1–10 ppm for 15 min in intervals of 4 h. However, it was found that biofilm growth is accelerated after a shock chlorination, see Fig. 16.

Biological fouling control with chlorination has the disadvantage that chlorine has to be added continuously, since it does not only react with microbes but also with process contaminants such as H_2S or NH_3. Chlorine concentration in water exceeding 0.5 ppm may give rise to corrosion problems, especially for stainless steel equipment. Due to the biocidal action of chlorine, there are increasing restrictions on the effluent chlorine concentration. For these reasons, chlorine is increasingly replaced by other chemicals such as methylene-thiocyanate or chlorophenoles, see Waite and Fagan [68].

Even though the addition of hypochlorous acid provides an effective method against the growth of a wide range of bacteria and algae, there are a number of species that can only be controlled by excessively high HOCl concentrations (>30 ppm). Since this may cause operational problems, compounds have been developed to eliminate these species, which can be added to the chlorinated water. Grade and Thomas [69] discuss treatment programs, which are effective against bacteria and algae. Generally, it is recommended to



C4. Fig. 15. Reformer feed/effluent exchanger performance [63]



C4. Fig. 16. Effect of shock chlorination on the growth of biological matter at heat transfer surfaces [67]

vary biocide treatment regularly to avoid immunization of microorganisms.

Because of the toxic effect of copper ions on biological matter, another method to reduce bacterial growth is the use of piping with a copper content above 60% or the addition of copper sulfate to the water. For potable water, the copper concentration must be below 1 ppm.

4.2.5 Corrosion Fouling

Generally, it is desirable to have a thin, passivating oxide layer on the heat transfer pipes. Epstein [11] mentions that this oxide layer is removed if the flow velocity exceeds 30 m/s. Excessive corrosion can be controlled by the addition of corrosion inhibitors (chromate or polyphosphate based) or by control of the pH. Chromate is a highly efficient and cost effective inhibitor. However, the toxicity of chromates in the environment has restricted their use. This also holds for zinc based inhibitors. Under some circumstances, corrosion inhibitors (such as phosphates) themselves can be the source of fouling in heat exchangers as they increase the total salt content of the water. However, this can be mitigated by careful control of parameters such as inhibitor concentration, flow velocity and surface temperature [70].

4.2.6 Gas-Side Fouling [3]

Removal of contaminants which promote fouling, such as sodium, sulfur, or vanadium, from fuels prior to combustion and contaminant removal from combustion gases are two approaches to mitigate gas-side fouling. Water washing has helped to overcome some of the fouling problems experienced with residual oils in marine applications by removing sodium and sediment. Inorganic sulfur can be removed from coal by gravity settling or by froth floatation if the mineral particles are well above micron size.

Electrostatic precipitators, mechanical collectors, fabric filters or wet scrubbers can be used to remove particles from combustion gas streams. Removal of gaseous constituents, which is considerably more difficult than particle removal, may involve limestone addition, wet scrubbing without sulfur recovery, MgO systems with sulfur recovery or use of dry sorbent systems.

Under certain conditions, chemical fuel additives or chemical flue gas additives can mitigate the effects of gas-side fouling and corrosion. Many proprietary additives have been marketed, with varying degrees of success in mitigating fouling. Fuel additives to improve combustion efficiency in boilers and to keep gas-side heat transfer surfaces clean by reducing soot and slag formation have been developed by companies such as Betz [71], Dearborn, Drew [72], and Nalco [73]. Additives that have been used to control gas-side fouling in boilers include aluminum oxide, ammonium bicarbonate, magnesium oxide, magnesium carbonate, silica, and zinc. For coal-fired boilers, additives are used for fly ash conditioning for electrostatic precipitation, convective tube fouling and coal-ash slag. Magnesium oxide can minimize fouling of coal-fired boilers by acting as a catalytic inhibitor to retard the formation of SO_3 and reacting to $MgSO_4$ which is inert and has a high melting point. Often, the amount of MgO required, 0.4–3% of the fuel burned, makes the practice uneconomical. However, using fine, particle-size magnesia dispersions at rates of 0.005–0.015% (weight) of the fuel has reportedly reduced fouling.

For oil-fired boilers, additives are used to control SO_3 related problems, high temperature fouling, high temperature corrosion.

4.3 Mechanical Fouling Mitigation Methods

A number of mechanical mitigation techniques have been developed which generally are based on one of the following mechanisms:

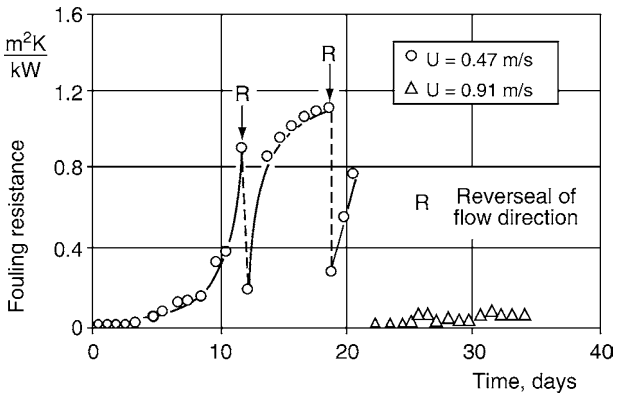
(a) Short-time overheating of the heat transfer surfaces. The different thermal expansion of tubes and tube deposits may cause cracking of the deposit
(b) Mechanical vibration of heat transfer surfaces
(c) Acoustical vibration of heat transfer surfaces
(d) Increased shear stress at fluid deposit interface.
(e) Reduced adhesion of deposits

4.3.1 Liquid Flow

Most of the commonly used fouling mitigation techniques have been developed for the tube-side liquid in shell and tube heat exchangers. Even though attempts have been made to develop mechanical online mitigation devices for non-tubular heat exchangers, their installation has not penetrated the market.

Reversal of Flow Direction

Regular reversal of the flow direction in conjunction with a short-time increase of the flow velocity is sometimes used as a method to mitigate the formation of weak deposits. Figure 17 shows that this procedure reduces the fouling resistance, but



C4. Fig. 17. Continuous cleaning by reversal of flow direction [74]

only for a short period of time. A much better performance could be achieved by operating at a higher flow velocity.

Gas Rumbling

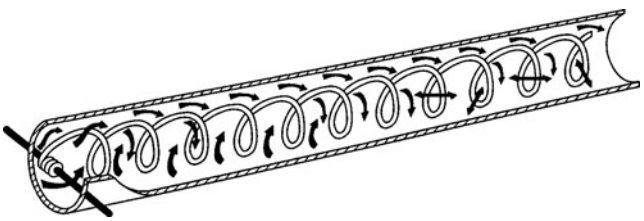
Deposits with moderate stickability to the heat transfer surfaces (e.g., particulate, and some biological deposits) can be dislocated and washed out by increasing the fluid shear forces for a short time, in regular time intervals. This can be achieved by increasing the flow velocity, if enough pump capacity is available. More effective is, however, to introduce compressed air or nitrogen into the liquid system. The resulting highly turbulent gas-liquid two-phase flow can provide shear forces and pressure fluctuations, which are substantially higher than for single-phase flow. Gas rumbling is commonly used in cooling water applications.

Ultrasound

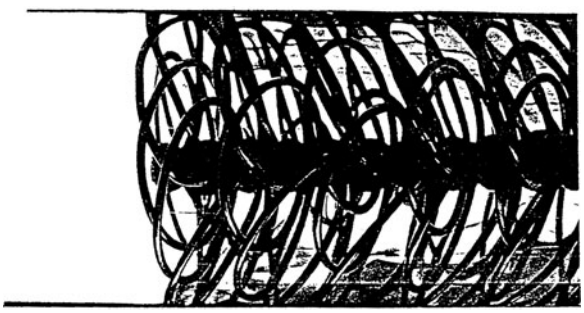
On the laboratory scale, some success has been achieved in removing/inhibiting deposits by ultrasonic vibrations. So far, however, technical limitations have prevented the extrapolation of these results into industrial practice.

Tube Inserts

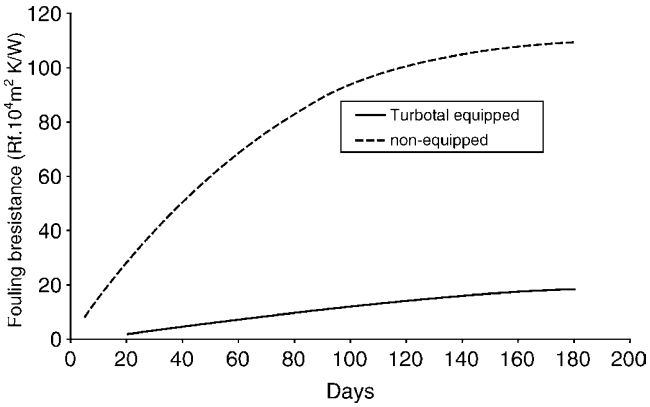
Tube corrugations and tube inserts can increase the plain tube heat transfer coefficient by a factor of 2–15 [49]. This is achieved by reducing the average thermal boundary layer thickness. As deposition rates for most fouling mechanisms are inversely dependent on fluid wall shear stress and heat transfer surface temperature, reduction of the viscous and thermal sublayer thickness may also considerably reduce fouling. It must be considered that, for constant mass flux, the increased thermal efficiency is always accompanied by an increased pressure drop per unit length; therefore, these inserts work best for flow in the laminar or transitional flow regime. In combination with further reduction of flow velocity (i.e., tube passes) design variations may be possible where significant improvements of heat transfer can be achieved with no or little increase in pressure drop. Typical inserts are twisted tapes, coils (Fig. 18) and wire matrix inserts (Fig. 19). The potential of some of these inserts with respect to reducing deposit formation is reported in [49]. Figure 20 shows the effectiveness of the TURBOTAL system in reducing fouling in a crude oil preheater [77].



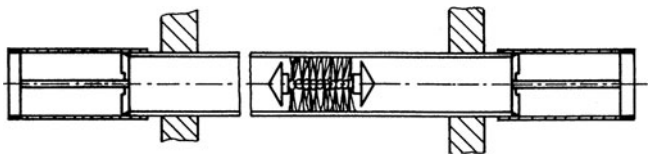
C4. Fig. 18. Spiral insert (SPIRELF system) [75]



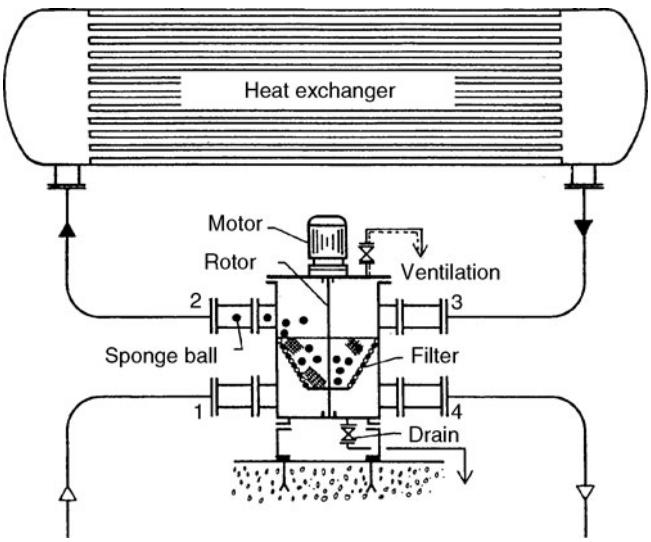
C4. Fig. 19. Cal-Gavin wire insert to increase heat transfer for flow in pipes [76]



C4. Fig. 20. Crude oil fouling mitigation with Turbotal inserts [77]



C4. Fig. 21. Continuous cleaning with wire brush system



C4. Fig. 22. Typical layout of sponge ball cleaning system [79]

Continuous Transport of Cleaning Devices Through Tubes

These methods require major modifications of the flow system and are, therefore, best implemented in the design stage. However, they have the advantage that exchangers may be kept clean over long periods of time. All systems work best if applied to an initially clean heat exchanger.

A number of companies (MAN, Water Services of America, KALVO [78], ATCS) have developed continuous tube cleaning systems using small nylon brushes which are inserted into each tube, see Fig. 21. These brushes are pushed through the tubes by the fluid flow. For continuous operation and optimum cleaning efficiency, the flow direction has to be reversed about every 8 h. Life expectancy of the brushes is about 5 years. It is claimed that the time for amortization is between 8 and 16 months.

There are many examples for the successful application of the brush tube cleaning system. However, their most effective installation is in smaller, water-cooled heat exchangers, for example, for the central air-conditioning systems of office buildings, hotels, or hospitals.

For large installations, more consistent results were obtained with a system where sponge balls with a rough surface are circulated through the heat exchanger, see Fig. 22. The diameter of the sponge balls is slightly larger than the inside diameter of the tubes and the system is designed such that each tube sees a sponge ball every 5–10 minutes. Since the diameter of the sponge balls decreases with time and because of inevitable ball losses through the screening system, the sponge balls have to be replaced regularly. For hard and adherent deposits, carborundum coated sponge balls can be used. According to the manufacturers, application of sponge ball systems may reduce the fouling resistance to close to 0 m^2K/kW. The application of sponge ball systems is limited to temperatures below 120°C. Several companies, for example, TAPROGGE or CQM supply sponge ball systems and complete maintenance packages with different levels of complexity, size, and cost.

Online cleaning systems are not effective against stones, clamshells, etc. and need upstream devices to remove debris and macroscopic organic matter from the incoming water.

4.3.2 Gas Flow

Online mechanical techniques vary greatly, but soot blowers are the most popular for gas-side use [80]. Some of other techniques such as scrapers, rappers, and chains work well in special applications but are not as readily available. Two common types of soot blowers are jet soot blowers and sonic soot blowers.

- The jet type of soot blower operates by emitting pulses of steam, air or water at programmed intervals directed at the tubes and/or down tube lanes to dislodge the deposits and re-entrain them in the gas stream. These soot blowers work best if used frequently, thus avoiding the build-up of material. When build-up occurs, it insulates the surface from the coolant, allowing a temperature rise that can produce a glassy deposit. Glassy deposits are much harder to dislodge and frequently require shutdown for their removal. Jet soot blowers come in two types: (i) The fixed position rotating type is installed inside the heat exchanger and (ii) the retractable type periodically passes an externally mounted nozzle through the heat exchanger. The fixed position soot blowers require little additional floor space, but they can usually not be used if the temperature exceeds 1000°C. As more than 100 soot blowers may be installed in large fired boilers, steam, and pressurized air consumption may cause considerable costs.
- According to the manufacturers, installation, and operation costs of sonic soot blowers are only 10% of those of jet soot blowers. Sonic soot blowers perform best in the cooler regions of furnaces or in other apparatus where glassy phases of deposits are not encountered. They operate by emitting sound pressure waves that loosen the particulates and allow them to be carried away with the gas stream. Under normal operations, sonic horns need only sound for 15–30 s every 10–30 min. Horns are constructed of materials that can withstand temperatures up to 1000°C. Sonic soot blowers may not, however, be able to loosen the harder deposits that can be removed by the high velocity steam, air or water jets. Sonic soot blowers are available at sonic or infrasonic range.

For very sticky deposits or if jet soot blowing may cause the temperature to drop below the acid dew point, 5 mm diameter cast iron spheres may be poured over the pipe arrangement. For extremely severe gas-side fouling problems, fluidized bed technology should be considered as an alternative.

The control of operating conditions is a very important consideration in the prevention of gas-side fouling. Some of the most important controls are:

- Maintain surface temperature above acid dew-point temperature
- Control amount of excess air, which governs the conversion of SO_2 to SO_3 and hence the amount of H_2SO_4 formed
- Control combustion parameters such as fuel injection pattern, fuel injection schedule and fuel viscosity
- Use fuel/air premixing to eliminate soot production
- Quench hot flue gases to solidify molten and soft particles to prevent attachment at cooler heat transfer surfaces

The control of combustion conditions is a difficult task due to the great variability in the quality of fuel supplies. Variability of fuel characteristics is a particular problem for those industries that burn waste products.

4.3.3 Other Devices for Fouling Mitigation

When it comes to commercial mitigation of scale formation, one of the most frequently and emotionally discussed topics are devices, which claim to reduce scaling by magnetic, electronic, or catalytic means. To-date, no conclusive scientific proof or theory for the mechanisms, which may be responsible for the beneficial effects of such technologies, has been found. A considerable number of investigations have been reported in the literature; many of them claim some sort of success with the

applied technology. Most of the research-related literature originates from the former Soviet Union, the UK and the USA, while several systematic investigations have been performed by public and private organizations in Austria, Germany, and Switzerland. German Industry Standards (DIN) have been formulated for performance evaluation of physical water conditioners. Pilot plant and laboratory scale investigations have provided contradicting results. For example, [81, 82] report that the installation of magnets considerably reduced cooling water fouling, whereas [83, 84] found no effect of the water conditioner. Even the mechanisms of scale inhibition are highly disputed. There are claims that clatherate formation or impact on the nuclear spin of dissolved ions will reduce the chemical reaction on the surface; or that very high frequency current favors bulk precipitation of scale-forming materials and hence weakly adhering particulate deposit rather than a strong crystalline layer. Other investigators believe that minute changes in local pH may affect the $CaCO_3$ equilibrium in the solution. More recently, claims have been made that the key mechanism is the release of iron ions or iron oxide into the water, which has an adverse effect on the growth behavior of crystals. Another plausible explanation is that the electrical field, together with dissolved impurities, changes the crystal form of $CaCO_3$ from Calcite to Aragonite. Some agreement exists that magnetic or electromagnetic fields are effective for a relatively narrow range of flow velocities only [85].

Manufacturers of such equipment have impressive reference lists of successful installations, where the formation of crystalline deposits has been substantially reduced or even avoided. However, it is also fair to say that there have been numerous cases where no improvement has been achieved. Until the applications and limitations of these installations have been clearly established, no general statement can be made about their economic evaluation with respect to other available scale prevention methods. While most suppliers of physical water treatment facilities recommend installation of their devices at a relatively short distance upstream of the heat exchanger which is to be protected, others claim "memory effects" in the fluid of up to 6 months.

5 Cleaning of Heat Exchangers

Periodical cleaning of heat exchangers will be necessary, even if the heat exchanger is well-designed and the fluid treatment is effective. Additionally, conditions in the heat exchanger may deviate from the design conditions due to changes in flow rates and temperatures, plant failures, ingress of air and bacteria, changes in the fluid composition or upstream corrosion, which all may promote fouling. If a heat exchanger or pipeline suffers from deposit formation, this can be the start of a whole series of problems. Corrosion processes may take place under the deposit, fouling rates may be increased due to the surface roughness of the deposit or irregular behavior of the exchanger may be observed due to build-up and removal of deposits. It is, therefore, advantageous to remove non-protective deposits soon after the onset of their formation. Heat exchangers may be cleaned by chemical or mechanical methods or by a combination of both.

5.1 Chemical Cleaning Methods

Chemical cleaning methods have a number of advantages over mechanical methods, namely:

(a) They are relatively quick.
(b) Surfaces do not experience mechanical damage.
(c) Chemical solutions reach normally inaccessible areas.
(d) They are less labor intensive than mechanical cleaning.
(e) Cleaning can be performed in situ.

5.1.1 The Basic Process

Most chemical cleans consist of five distinct processes, each being monitored for results before proceeding to the next. The five stages are:

1. The alkaline clean primarily aims to remove the organic portion of the deposit (oil, fat) in order to render the inorganic surface hydrophilic. This is necessary to make the following acid cleaning effective.
2. Before and after each chemical step, high flow water flushes are required to physically remove loose or softened material.
3. Once the surface is hydrophilic, the deposit is softened and/or dissolved by application of the appropriate acid blend. This blend usually contains an inhibitor, which prevents corrosion of the base metal by the acid. The analysis of the spent acid strength and the concentration of dissolved scale species indicate whether the acid clean is completed.
4. After the acid stage, water rinsing is required to remove loose debris, sludge, and residual acid. Water rinsing may be accompanied by inert gas purging and sequestrant addition, depending on the cleaning technique and the plant configuration.
5. After the acid and rinse stages, the base metal which has been exposed as a result of the cleaning operation is in a very active state. If left and exposed to the atmosphere, the surface would rapidly reoxidize in an uncontrolled fashion. A passivation process is performed to form a tightly adherent, protective oxide film on the base metal.

Particular applications may require modifications of the above sequence. The selection of the cleaning agent and the cleaning procedure strongly depend on the type of deposit, the material and configuration of the installation and on economical and environmental considerations.

5.1.2 Cleaning Procedure

Among the many possible choices available for cleaning procedures are ambient temperature treatments, high temperature treatments, fill-and-soak techniques, circulating techniques, on-stream techniques, vapor phase techniques, foam techniques and emulsion techniques. Soaking treatments are effective in many instances. Their application generally reduces equipment costs while increasing chemical costs and downtime costs.

Obviously, it is advantageous to circulate the cleaning agent in order to improve evenly mixing of the chemicals and to reduce concentration profiles near the fouled surfaces. Circulation also increases physical disintegration of the deposit by mechanical scouring. As chemical reaction rates increase exponentially with temperature, the cleaning process may be improved if the cleaning agent is heated. Foaming reduces the cleaning agent requirements and increases the effectiveness of cleaning. Also, the foaming treatment may be faster in some cases. It allows for good contact in large shell and tube heat exchanger.

Research on the mechanisms of chemical cleaning of heat transfer surfaces is far less developed than research of fouling mechanisms. Nevertheless, some first modelling has been attempted, assuming that the cleaning process is an inverse fouling process.

5.1.3 Cleaning Agents

Table 16 shows typical deposits that can be removed chemically [86]. Deposits that can not be removed are given in Table 17.

Table 18 lists a number of chemicals used for cleaning. Sulfuric acid and hydrochloric acid are the most widely used chemical cleaning agents. When used properly, they are safe, relatively low-cost materials. However, these mineral acids are highly ionized and strong, which may cause rapid corrosion if the solution is insufficiently inhibited. Therefore, weaker organic acids and chelating agents are coming into wider use.

Generally, a mixture of several chemicals is used to attack complex deposits. Dispersants are added to disperse oils or fats and to allow better penetration of the deposit. Sometimes, the addition of small quantities of a second cleaning agent (e.g., the addition of 0.25% ammonium bifluoride or 0.5% sodium bromate to citric solutions) may considerably increase the effectiveness of the cleanup [87].

The type of cleaning agent to be chosen has a major effect on the economics of the cleaning job. The selection of cleaning chemicals is not only depending on the type of deposit, but also on the exchanger material and the cleaning conditions. In many cases, chemical cleaning of heat exchangers involves the use of acids. Although some metal loss is inevitable, the addition of inhibitors greatly reduces corrosion. It must be emphasized that inhibitors are only suitable for specific metal under specific conditions. Personal danger and disposal problems have to be

C4. Table 16. Typical deposits removed by chemical cleaning [86]

Organic
Oil, grease, fat, waxes, soft carbon, tars, silt, vegetation, biological matter, polymers, resins, paints
Inorganic
Rust, magnetite, calcium carbonate, calcium sulfate, magnesium hydroxide, calcium phosphate, silica, magnesium silicate, copper, copper oxides, alumina, nickel oxides

C4. Table 17. Intractable deposits [86]

Glasses, ceramics, hard carbon, inert plastics, vulcanized rubber, rubber latex

C4. Table 18. Common types of chemicals utilized for in-situ chemical cleaning [87]

Acids	Alkalis	Complexing agents
Hydrochloric	Caustic Soda	EDTA
Nitric	Ammonia	Gluconates
Sulfuric	Trisodium phosphate	
Hydrofluoric	Sodium metasilicate	
Citric	Soda ash	
Formic		
Sulphamic		
Oxidants	**Solvents**	**Others**
Potassium permangangate	Aromatic	Biocides
Sodium bromate	Aliphatic	Surfactants
Sodium nitrite	Chlorinated	Inhibitors
Sodium hypochlorite	Emulsifiers	Antifoams
Ammonium persulfate	Dewatering formulations	Dispersants
		Hydrazine bifluoride

C4. Table 19. Scale and deposit removal [87]

Deposit	Cleaning method
Calcium sulfate	Boil with Na_2CO_3 solution, treat with inhibited acid
Calcium carbonate	Inhibited acid
Magnesium hydroxide	Inhibited acid
Calcium phosphate sludge	Inhibited acid
Magnesium silicate	Inhibited acid + small % of HF
Sodium aluminum silicate	Hydrofluoric acid
Ferric oxide (Fe_2O_3)	Inhibited acid or ammoniated citric acid
Ferrous oxide (Fe_3O_4)	Inhibited acid or ammoniated citric acid. Add 0.25–0.5% stannous chloride for protection against ferric ion attack. Ammoniated EDTA
Copper	Ammoniated bromate, ammoniated EDTA
Organic material	High velocity liquids or circulate 20% chromic acid heated to 95°C. Hot alkaline solutions useful for removing light oils, grease, or other sludge materials

considered, too. Table 19 shows some deposits and scales with the recommended cleaning agents [87].

For plants in operation, the timing of cleaning operations is of economical importance. Energy losses, production losses and safety aspects have to be compared with cleaning costs and losses due to shutdown. Table 20 shows typical application of some of the most common cleaning agents.

C4. Table 20. Chemical cleaning agents [87]

Agent	Application
Hydrochloric acid	General removal of rust and scale for non-stainless steel piping
Inhibited HCL	Same as above
Sulfuric acid	General usage for stainless steel for removal of rust and scale. H_2SO_4 is dangerous to personnel and must be used with caution
Inhibited H_2SO_4	Same as above
Hydroxyacetic acid	General acidizing. Safer than H_2SO_4
Formic acid	Often used as 1% formic, 2% hydroxy-acetic acid solution for cleaning of supercritical "once-through" boilers where stainless steel is the prevalent material of construction and chloride ions must be avoided. Also used for non-ferrous metals as a 1–2% solution. Must be heated to 95°C. Safter than mineral acids
Citric acid	Used as 0.01 solution to chelate iron. Used at ambient temperature or slightly warm
Ammoniated citric acid	Very safe (corrosion and handling) cleaning agent. By changing pH and adding sodium nitrite, the same solution. may be used for passivation. pH is adjusted by adding NH_3 and resulting solution is effective for copper removal
Hydrofluoric acid	Used for new piping and for stainless steel where chloride ions are critical as a 3–5% solution. Also used for silica deposit removal. Dangerous!
Sulphamic acid	Fairly safe. Used at a 5–10% solution for removal of iron oxides. Must be maintained below 60°C or decomposes to ammonium bisulfate
Ammoniated bromate	Use for removal of copper. Does not attack scale or iron oxides. For each kg of copper use
	0.9 kg $NaBrO_3$
	1.4 kg $(NH_4)_2CO_3$
	4.5 l NH_4OH 30%
Phosphoric acid	Less aggressive than sulfuric acid and more aggressive than sulphamic acid. Use for general removal of oxides and scales, particularly for stainless steel
Ammoniated EDTA	Use for removal of iron oxides or copper, as a 5–10% solution. Safe material!
Sodium salt	Use for removal of water hardness scales as a 5–10% solution

5.1.4 OnStream Chemical Cleaning

In most cases, chemical cleaning is done while the heat exchanger is off-line. However, there have been several attempts to develop chemicals that can be used for onstream cleaning to avoid expensive plant shutdown. Examples for these chemicals are complexing agents which can be added during operation of boilers.

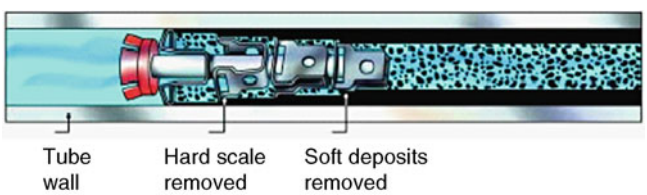
Shock dosage of chlorine (>15 ppm) is often used to remove bio-deposits while the exchanger is onstream. However, it was found that biofilms regrow at an accelerated rate after the chlorine dosage. As chlorination has come under increasing regulatory control, methods to use chlorine more efficiently and to minimize the amount of chlorine discharged to the water ways become increasingly important.

5.1.5 Problems Associated with Chemical Cleaning

Problems associated with chemical cleaning of heat exchangers are due to the danger of handling (burn, toxic), due to elevated application temperatures, due to the costs of cleaning agents, due to the chemical attack on the heat exchanger material (overcleaning, uneven cleaning, corrosion) and due to disposal problems. Acids and alkalis must be neutralized, organic materials may be burned and fluorides must be reacted to inactive solid residues. Some of the organic acids, such as citric acid and gluconic acid are biodegradable.

5.2 Mechanical Cleaning Methods

For the following cleaning methods, heat exchangers have to be taken off-line and dismantled. Some of the deposits may then be removed manually, for example from the water box. Steam-blasting and hydro-blasting with pressures up to 1500 bar are probably the most common mechanical cleaning methods, see [49]. They can be performed completely manually or semiautomatically in cleaning stations. If deposits are very tenacious, sand can be added to the pressurized water to increase the cleaning efficiency. Both, steam- and hydro-blasting are labor intensive and keep the exchanger off-line for a considerable time. Blasting may not completely eliminate all deposits and some significant roughness can remain. The shell-side of tube bundles can only be cleaned completely if the tubes are arranged in-line. The particular geometry of twisted tubes provides flow lanes for pressurized water or steam which facilitates cleaning. Experienced maintenance crews are required and strict safety regulations must be obeyed due to the danger of handling equipment at very high pressures.



C4. Fig. 23. CONCO cleaning device [89]

While blasting is the only available alternative for the shell-side of the tube bundle, several cleaning methods can be used for the inside of straight tubes. The continuous cleaning sponge ball system described in detail in Sect. 4.3 can also be used as a transportable, off-line cleaning system, particularly if used with corundum-coated sponge balls. Very dirty and plugged tubes can be cleaned with drills equipped with drill bits, brushes, or bit-brush combinations.

To avoid damage of the heat transfer surfaces, cleaning must be done carefully, thus increasing costs for labor and downtime.

Using air- or hydropressure, rubber plugs or metal scrapers can be shot through the tubes. These techniques are considerably faster than the above methods, cleaning up to 15,000 tubes in 24 h. Rubber plugs fail for hard deposits. Shooting metal scrapers through the tubes at a water pressure of 35 bar and a scraper velocity of 3–6 m/s results in the removal of most deposits [88]. An example of those scrapers is shown in Fig. 23. In general, water pressure systems are safer than air pressure systems, due to the compressibility and subsequent rapid expansion of gases.

Most mechanical cleaning methods remove not only the deposit but also the protective oxide layer. Under certain circumstances, this may create a corrosion problem. On the other hand, regular cleaning removes deposit and avoids flow conditions, which promote corrosion due to chemical reaction or stagnant flow. For very severe fouling problems, a combination of chemical and mechanical cleaning may be recommended.

6 Symbols

CF	Cleanliness factor
E	Activation energy (J/mol)
K	Constant
R	Universal Gas Constant, 8.314 J/(mol K)
Re	Reynolds Number
R_f	Fouling resistance (m^2K/W)
s	Deposit thickness (m)
u	Flow velocity (m/s)
τ_w	Wall shear stress (N/m^2)
ξ	Friction factor
1,2	Fluid 1, fluid 2

Subscript/Superscripts

c	Clean
d	Deposit
f	Fouled

C5 Heat Exchanger Networks

Xing Luo · Wilfried Roetzel
Helmut-Schmidt-Universität, Universität der Bundeswehr Hamburg, Hamburg, Germany

1 Introduction

Many process industries are energy-intensive. A large amount of heat energy applied to process streams is normally dissipated through cooling utilities. It is possible to reuse the heat energy of hot process streams for heating cold process streams by means of additional heat exchangers. Such a system is called heat recovery system. The heat recovery system consists of a set of heat exchangers including heaters, coolers, condensers, reboilers, or other equipment and attachments for heat transfer between process streams. It can be treated as a heat exchanger network with different kinds of exchangers in which hot process streams can be cooled by the cold streams to be heated, and vice versa. In this way, the heating and cooling loads from external sources (hot and cold utilities) can be dramatically reduced. However, the reduction in utility costs is often accompanied by the increase in investment costs. Therefore, a balance between utility costs and investment costs should be established.

The optimal design of a heat exchanger network is to structure a system capable of performing the prescribed tasks at the minimum total annual costs, which is the sum of the utility costs and investment costs [1]. Because of its structural characteristics, it is also named the synthesis of heat exchanger networks. A further extension of the network synthesis is the optimal retrofit design of existing networks. Principally, the methodologies of optimal design of heat exchanger networks do not focus on the determination of detailed parameters of heat exchangers of a network. It takes the network as a system and determines the network configuration and heat loads of the exchangers used in the network for the further detailed unit design. The well-known synthesis methodologies are the Pinch design method [2], mathematical programming [3], and stochastic or heuristic algorithms such as genetic algorithm [4], simulated annealing algorithm [5] and Tabu search procedure [6]. The genetic algorithm was also combined with simulated annealing algorithm for the synthesis of multistream heat exchanger networks [7, 8]. This chapter introduces only the fundamental theories of the design of heat exchanger networks.

2 Temperature Calculation of Heat Exchanger Networks

2.1 Temperature Calculation of a Single Heat Exchanger

For a single heat exchanger, the heat load can be determined by

$$\dot{Q} = (\dot{M}c_p)_h(\vartheta'_h - \vartheta''_h) = (\dot{M}c_p)_c(\vartheta''_c - \vartheta'_c) = FkA\Delta\vartheta_{LM} \quad (1)$$

where the subscripts "h" and "c" denote hot stream and cold stream, ϑ' and ϑ'' are inlet and outlet temperatures, k is the overall heat transfer coefficient, A the heat transfer area, $\dot{M}$ the mass flow rate, and c_p the specific heat capacity at constant pressure. The product term $(\dot{M}c_p)$ is also named heat capacity flow rate. The correction factor F is the ratio of the real mean temperature difference to the logarithmic mean temperature difference of the counterflow heat exchanger $\Delta\vartheta_{LM}$ (see also Chap. C1),

$$\Delta\vartheta_{LM} = \frac{(\vartheta'_h - \vartheta''_c) - (\vartheta''_h - \vartheta'_c)}{\ln[(\vartheta'_h - \vartheta''_c)/(\vartheta''_h - \vartheta'_c)]} \quad (2)$$

If $(\vartheta'_h - \vartheta''_c) \approx (\vartheta''_h - \vartheta'_c)$, the arithmetic mean can be used,

$$\Delta\vartheta_{LM} \approx \frac{1}{2}[(\vartheta'_h - \vartheta''_c) + (\vartheta''_h - \vartheta'_c)] \quad (3)$$

Equation (1) is used to determine the exchanger size according to known stream temperatures. In Chap. C1 the two flow streams are denoted with indexes "1" and "2," as defined for the channels of each flow arrangement. For heat exchanger networks the notations "h" and "c" is more appropriate.

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_8,

For an existing heat exchanger, the outlet stream temperatures are given by

$$\begin{bmatrix} \vartheta''_h \\ \vartheta''_c \end{bmatrix} = \begin{bmatrix} v_{hh} & v_{hc} \\ v_{ch} & v_{cc} \end{bmatrix} \begin{bmatrix} \vartheta'_h \\ \vartheta'_c \end{bmatrix} \tag{4}$$

or in the matrix form

$$\Theta'' = \mathbf{V}\Theta' \tag{5}$$

in which Θ' and Θ'' are the inlet and outlet temperature vectors of the exchanger, respectively, and

$$\mathbf{V} = \begin{bmatrix} v_{hh} & v_{hc} \\ v_{ch} & v_{cc} \end{bmatrix} = \begin{bmatrix} \frac{(1-R_h)e^{-NTU_h^*(1-R_h)}}{1-R_h e^{-NTU_h^*(1-R_h)}} & \frac{1-e^{-NTU_h^*(1-R_h)}}{1-R_h e^{-NTU_h^*(1-R_h)}} \\ \frac{R_h[1-e^{-NTU_h^*(1-R_h)}]}{1-R_h e^{-NTU_h^*(1-R_h)}} & \frac{1-R_h}{1-R_h e^{-NTU_h^*(1-R_h)}} \end{bmatrix} \tag{6}$$

$$R_h = 1/R_c = (\dot{M}c_p)_h/(\dot{M}c_p)_c \tag{7}$$

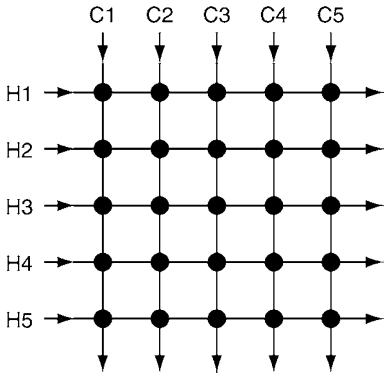
$$NTU_h^* = R_c NTU_c^* = FkA/(\dot{M}c_p)_h \tag{8}$$

Special cases:

$$R_h \to 0 : \mathbf{V} = \begin{bmatrix} e^{-NTU_h^*} & 1-e^{-NTU_h^*} \\ 0 & 1 \end{bmatrix} \tag{9}$$

$$R_h \to \infty : \mathbf{V} = \begin{bmatrix} 1 & 0 \\ 1-e^{-NTU_c^*} & e^{-NTU_c^*} \end{bmatrix} \tag{10}$$

$$(FkA) \to 0 : \mathbf{V} = \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \tag{11}$$



C5. Fig. 1. Heat exchanger network with sequential flow arrangement.

If the parameters appearing in the above equations depend on temperature, they can be modified with newly calculated outlet stream temperatures. The procedure will be repeated until the iteration deviation is less than the required accuracy.

2.2 Temperature Calculation of Heat Exchanger Networks with Sequential Flow Arrangements

For sequential flow arrangements the stream temperatures can be calculated from their entry positions. One of such arrangements is shown in Fig. 1, in which each cross-point of hot and cold streams indicates a possible heat exchanger. Hot streams are to be cooled down and cold streams are to be heated up. The hot and cold streams Hi and Ci ($i = 1, 2, 3, \cdots$) are arranged according to the network structure to be calculated. Usually they are arranged in the order of their supply temperatures, beginning with the highest temperatures. The calculation begins from the upper left exchanger and the calculated outlet stream temperatures of an exchanger become the inlet stream temperatures of the following exchangers. Thus, Eq. (4) can be applied to the exchangers sequentially, and the exit stream temperatures of the network can be finally obtained.

Example 1

This example was taken from the network design given by Ravagnani et al. [9]. The original problem data is listed in Table 1. The network design given by Ravagnani et al. [9] is shown in Fig. 2, where the data in brackets are the heat capacity flow rates in the branches. Its sequential relation is illustrated in Fig. 3.

The calculation begins from EX4.

$$\text{EX4: } R_h = (\dot{M}c_p)_h/(\dot{M}c_p)_c = 33.33/20 = 1.6665$$

$$k = (1/\alpha_h + 1/\alpha_c)^{-1} = (1/1.333 + 1/0.917)^{-1} = 0.54327\ \text{kW/m}^2\text{K}$$

$$NTU_h^* = FkA/(\dot{M}c_p)_h = 1 \times 0.54327 \times 202.23/33.33 = 3.2963$$

$$v_{hh} = \frac{(1-R_h)e^{-NTU_h^*(1-R_h)}}{1-R_h e^{-NTU_h^*(1-R_h)}} = \frac{(1-1.6665)\times e^{-3.2963\times(1-1.6665)}}{1-1.6665\times e^{-3.2963\times(1-1.6665)}} = 0.42852$$

$$v_{hc} = 1 - v_{hh} = 1 - 0.42852 = 0.57148$$

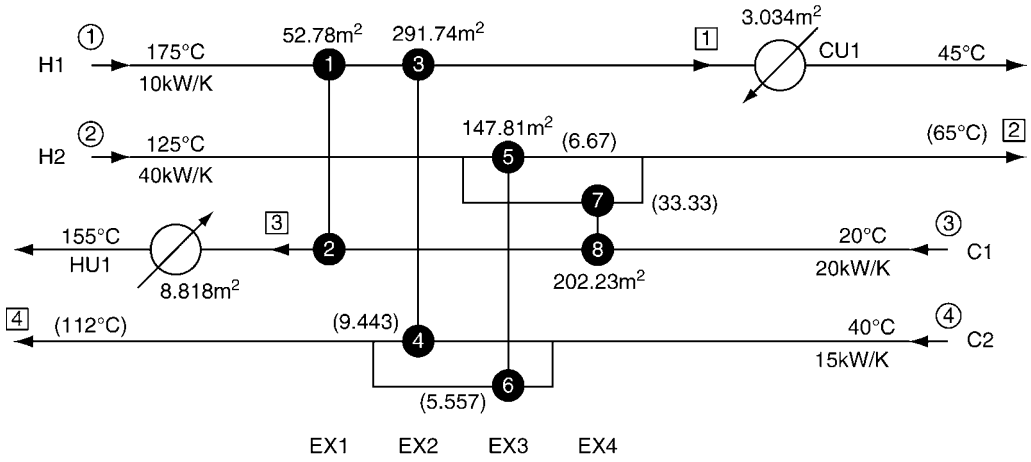
$$v_{cc} = \frac{1-R_h}{1-R_h e^{-NTU_h^*(1-R_h)}} = \frac{1-1.6665}{1-1.6665\times e^{-3.2963\times(1-1.6665)}} = 0.04762$$

$$v_{ch} = 1 - v_{cc} = 1 - 0.04762 = 0.95238$$

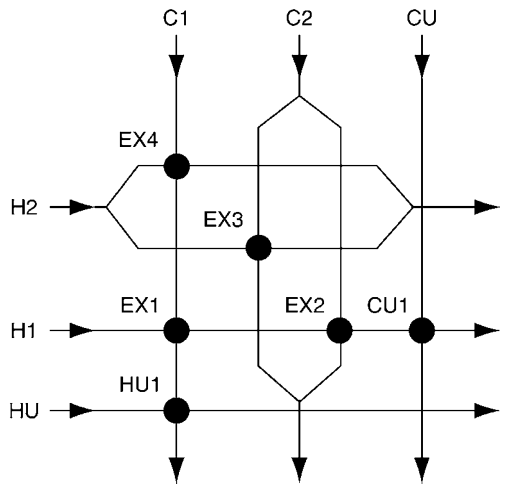
C5. Table 1. Problem data [9]

Stream	ϑ'(°C)	ϑ''(°C)	$\dot{M}_{c_p}$ (kW/K)	α(kW/m²K)	Cost ($/kW year)
H1	175	45	10	2.615	–
H2	125	65	40	1.333	–
C1	20	155	20	0.917	–
C2	40	112	15	0.166	–
Steam	180	179	–	5.000	110
Cooling water	15	25	–	2.500	10

Heat exchanger cost = 1,200 $A^{0.57}$ $/year ($A$ in m²). Correction factor $F = 1$ for all heat exchangers including heaters and coolers.



C5. Fig. 2. A network design given by Ravagnani et al. [9], 117,069 $/year.



C5. Fig. 3. Heat exchanger network with the sequential flow arrangement.

$$\begin{bmatrix}\vartheta''_h\\ \vartheta''_c\end{bmatrix}=\begin{bmatrix}0.42852 & 0.57148\\ 0.95238 & 0.04762\end{bmatrix}\begin{bmatrix}125\\ 20\end{bmatrix}=\begin{bmatrix}64.99\\ 120.0\end{bmatrix}$$

The outlet stream temperatures of other exchangers can be obtained with the same method and the results are listed in Table 2. The heating and cooling loads and heat transfer areas of the heater HU1 and cooler CU1 are calculated by Eq. (1).

$$\text{CU1: } \dot{Q}=(\dot{M}c_p)_h(\vartheta'_h-\vartheta''_h)=10\times(57.02-45)=120.2\,\text{kW}$$

$$\Delta\vartheta_{LM}=\frac{(\vartheta'_h-\vartheta''_c)-(\vartheta''_h-\vartheta'_c)}{\ln[(\vartheta'_h-\vartheta''_c)/(\vartheta''_h-\vartheta'_c)]}=\frac{(57.02-25)-(45-15)}{\ln[(57.02-25)/(45-15)]}$$

$$=31.00^\circ\text{C}$$

$$k=(1/\alpha_h+1/\alpha_c)^{-1}=(1/2.615+1/2.5)^{-1}=1.2781\,\text{kW/m}^2\text{K}$$

$$A=\dot{Q}/(kF\Delta\vartheta_{LM})=120.2/(1.2781\times1\times31.00)=3.034\,\text{m}^2$$

$$\text{HU1: }\dot{Q}=(\dot{M}c_p)_c(\vartheta''_c-\vartheta'_c)=20\times(155-145)=200\,\text{kW}$$

$$\Delta\vartheta_{LM}=\frac{(180-155)-(179-145)}{\ln[(180-155)/(179-145)]}=29.27^\circ\text{C}$$

$$k=(1/5+1/0.917)^{-1}=0.7749\,\text{kW/m}^2\text{K}$$

$$A=200/(0.7749\times1\times29.27)=8.818\,\text{m}^2$$

2.3 Temperature Calculation of General Heat Exchanger Networks

In general cases the heat exchanger networks might have loops and the inlet stream temperatures of some exchangers might be unknown. An easy way is the use of iteration method. However, for complex networks the convergence of the iteration method might not be ensured. An alternative solution is the matrix method [10, 11].

Consider a heat exchanger network with N' stream entrances, N'' stream exits and N_{EX} heat exchangers. Each exchanger has two channels: the hot stream channel and the cold stream channel; therefore, the number of channels $N=2N_{EX}$. The channel indexes are related to the exchanger indexes, i.e., the index of the hot stream in the ith exchanger is $2i-1$, and that of the cold stream is $2i$. The indexes of the network entrances and network exits can be arbitrarily labeled.

Extending Eq. (5) to the whole network yields,

$$\Theta''_{EX}=\mathbf{V}\Theta'_{EX} \tag{12}$$

in which,

$$\mathbf{V}=\begin{bmatrix}\mathbf{V}_1 & & \mathbf{0}\\ & \ddots & \\ \mathbf{0} & & \mathbf{V}_{N_{EX}}\end{bmatrix} \tag{13}$$

$$\mathbf{V}_i=\begin{bmatrix}v_{hh,i} & v_{hc,i}\\ v_{ch,i} & v_{cc,i}\end{bmatrix}=\begin{bmatrix}\frac{(1-R_i)e^{-\text{NTU}_i^*(1-R_i)}}{1-R_ie^{-\text{NTU}_i^*(1-R_i)}} & \frac{1-e^{-\text{NTU}_i^*(1-R_i)}}{1-R_ie^{-\text{NTU}_i^*(1-R_i)}}\\ \frac{R_i[1-e^{-\text{NTU}_i^*(1-R_i)}]}{1-R_ie^{-\text{NTU}_i^*(1-R_i)}} & \frac{1-R_i}{1-R_ie^{-\text{NTU}_i^*(1-R_i)}}\end{bmatrix}$$

$$(i=1,2,\cdots,N_{EX}) \tag{14}$$

$$R_i=\frac{(\dot{M}c_p)_{h,i}}{(\dot{M}c_p)_{c,i}},\text{NTU}_i^*=\frac{(FkA)_i}{(\dot{M}c_p)_{h,i}}\quad(i=1,2,\cdots,N_{EX}) \tag{15}$$

Θ'_{EX} and Θ''_{EX} are the temperature vectors containing the inlet and outlet stream temperatures of N_{EX} exchangers, respectively,

$$\Theta'_{EX}=\left[\vartheta'_{h,1},\vartheta'_{c,1},\vartheta'_{h,2},\vartheta'_{c,2},\cdots,\vartheta'_{h,N_{EX}},\vartheta'_{c,N_{EX}}\right]^T \tag{16}$$

$$\Theta''_{EX} = \left[\vartheta''_{h,1}, \vartheta''_{c,1}, \vartheta''_{h,2}, \vartheta''_{c,2}, \cdots, \vartheta''_{h,N_{EX}}, \vartheta''_{c,N_{EX}}\right]^T \quad (17)$$

To illustrate the interconnections among the streams, the following four matching matrices need to be introduced [12]:

Interconnection matrix **G**: $N \times N$ matrix whose elements g_{ij} are defined as the ratio of the heat capacity flow rate flowing from channel j into channel i to that flowing through channel i.

Entrance matching matrix $\mathbf{G}'$: $N \times N'$ matrix whose elements g'_{ik} are defined as the ratio of the heat capacity flow rate flowing from the entrance k to channel i to that flowing through channel i.

Exit matching matrix $\mathbf{G}''$: $N'' \times N$ matrix whose elements g''_{li} are defined as the ratio of the heat capacity flow rate flowing from channel i to the exit l to that flowing out of exit l.

Bypass matrix $\mathbf{G}'''$: $N'' \times N'$ matrix whose elements g'''_{lk} are defined as the ratio of the heat capacity flow rate flowing from entrance k to exit l to that flowing out of exit l.

In a heat exchanger network, there might be such a knot at which the streams mix and split again, which can be defined as a mixer. If there is a mixer before channel i or exit l, then, in the above definitions of the matrices, the denominator should be the heat capacity flow rate flowing through the mixer.

By the use of the aforementioned matrices, the stream temperatures in the network can be obtained by

$$\Theta'_{EX} = (\mathbf{I} - \mathbf{GV})^{-1}\mathbf{G}'\Theta'_N \quad (18)$$

$$\Theta''_{EX} = \mathbf{V}\Theta'_{EX} = \mathbf{V}(\mathbf{I} - \mathbf{GV})^{-1}\mathbf{G}'\Theta'_N \quad (19)$$

$$\Theta''_N = \mathbf{G}'''\Theta'_N + \mathbf{G}''\Theta''_{EX} = [\mathbf{G}''' + \mathbf{G}''\mathbf{V}(\mathbf{I} - \mathbf{GV})^{-1}\mathbf{G}']\Theta'_N \quad (20)$$

in which $\mathbf{I}$ is the unit matrix, Θ'_N and Θ''_N are two vectors containing the stream temperatures at the network entrances and exits before entering the external heaters and coolers.

A more complicated problem is the temperature calculation of multistream heat exchangers and their networks. For general cases a numerical procedure should be adopted. However, if the stream arrangement in a multistream heat exchanger is one-dimensional, e.g., parallel flow and counterflow, an analytical solution of the stream temperatures can be obtained [13].

Example 2

The network shown in Fig. 4 is the optimal solution of the design problem given by Table 1. The indexes of channels, entrances, and exits are labeled in Fig. 4.

The entrance temperature vector is $\Theta'_N = [175\ \ 125\ \ 20\ \ 40]^T$. For EX1,

$$\text{EX1: } R_1 = \frac{(\dot{M}c_p)_{H1}}{(\dot{M}c_p)_{C1}} = \frac{10}{20} = 0.5$$

$$k_1 = (1/\alpha_{H1} + 1/\alpha_{C1})^{-1} = (1/2.615 + 1/0.917)^{-1} = 0.6789\,\text{kW/m}^2\text{K}$$

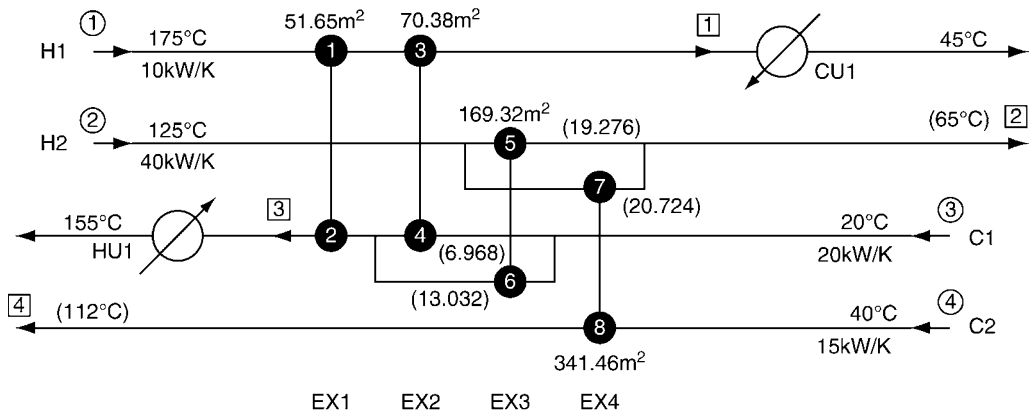
$$\text{NTU}_1^* = \frac{(FkA)_1}{(\dot{M}c_p)_{H1}} = \frac{1 \times 0.6789 \times 51.65}{10} = 3.5066$$

$$\nu_{hh,1} = \frac{(1 - R_1)e^{-\text{NTU}_1^*(1-R_1)}}{1 - R_1 e^{-\text{NTU}_1^*(1-R_1)}} = \frac{(1 - 0.5) \times \exp[-3.5066 \times (1 - 0.5)]}{1 - 0.5 \times \exp[-3.5066 \times (1 - 0.5)]} = 0.09481$$

$$\nu_{hc,1} = 1 - \nu_{hh,1} = 1 - 0.09481 = 0.90519$$

C5. Table 2. Calculation results of example 1

	ϑ'_h (°C)	ϑ'_c (°C)	A (m²)	R_h	NTU^*_h	ϑ''_h (°C)	ϑ''_c (°C)
EX4	125	20	202.23	1.6665	3.2963	64.99	120.00
EX3	125	40	147.81	1.2003	3.2713	65.00	112.02
EX1	175	120.00	52.78	0.5000	3.5834	125.00	145.00
EX2	125.00	40	291.74	1.0590	4.5538	57.02	111.99
	ϑ'_h (°C)	ϑ''_h (°C)	ϑ'_c (°C)	ϑ''_c (°C)	$\dot{Q}$ (kW)	$\Delta\vartheta_{LM}$ (°C)	A (m²)
CU1	57.02	45	15	25	120.2	31.00	3.034
HU1	180	179	145	155	200	29.27	8.818



C5. Fig. 4. Optimal design of heat exchanger network, 108,072 $/year.

$$v_{cc,1}=\frac{1-R_1}{1-R_1 e^{-\mathrm{NTU}_1^*(1-R_1)}}=\frac{1-0.5}{1-0.5\times\exp[-3.5066\times(1-0.5)]}=0.54740$$

$$v_{ch,1}=1-v_{cc,1}=1-0.54740=0.45260$$

The calculations for EX2, EX3, and EX4 are similar, which yields,

$$\mathbf{v}=\begin{bmatrix}0.09481 & 0.90519 & 0 & 0 & 0 & 0 & 0 & 0\\ 0.45260 & 0.54740 & 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0.33214 & 0.66786 & 0 & 0 & 0 & 0\\ 0 & 0 & 0.95847 & 0.04153 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0.34782 & 0.65218 & 0 & 0\\ 0 & 0 & 0 & 0 & 0.96465 & 0.03535 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0.38690 & 0.61310\\ 0 & 0 & 0 & 0 & 0 & 0 & 0.84706 & 0.15294\end{bmatrix}$$

According to the stream arrangement and channel indexes shown in Fig. 4, the matching matrices are

$$\mathbf{G}=\begin{bmatrix}0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 6.968/20 & 0 & 13.032/20 & 0 & 0\\ 1 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 0\end{bmatrix}$$

$$\mathbf{G}'=\begin{bmatrix}1 & 0 & 0 & 0\\ 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0\\ 0 & 0 & 1 & 0\\ 0 & 1 & 0 & 0\\ 0 & 0 & 1 & 0\\ 0 & 1 & 0 & 0\\ 0 & 0 & 0 & 1\end{bmatrix}$$

$$\mathbf{G}''=\begin{bmatrix}0 & 0 & 1 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 19.276/40 & 0 & 20.724/40 & 0\\ 0 & 1 & 0 & 0 & 0 & 0 & 0 & 0\\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & 1\end{bmatrix}$$

$$\mathbf{G}'''=\mathbf{0}$$

The calculation of Eqs. (18–20) yields,

$$\Theta'_{EX}=\begin{bmatrix}175.00\\ 121.63\\ 126.69\\ 20.00\\ 125.00\\ 20.00\\ 125.00\\ 40.00\end{bmatrix},\ \Theta''_{EX}=\begin{bmatrix}126.69\\ 145.78\\ 55.43\\ 122.26\\ 56.52\\ 121.29\\ 72.89\\ 112.00\end{bmatrix},\ \Theta''_{N}=\begin{bmatrix}55.43\\ 65.00\\ 145.78\\ 112.00\end{bmatrix}$$

The matrix calculation can also be performed with Microsoft Excel© by the use of matrix multiplication function MMULT and matrix inverse function MINVERSE.

The calculation of hot and cold utilities depends on the calculated exit stream temperatures of the network Θ''_N and their target values Θ''_{N^*}. In this network, streams H1 and C1 should be further cooled and heated, respectively:

CU1: $\dot{Q}=(\dot{M}c_p)_h(\vartheta'_h-\vartheta''_h)=10\times(55.43-45)=104.34\,\mathrm{kW}$

$$\Delta\vartheta_{LM}=\frac{(\vartheta'_h-\vartheta''_c)-(\vartheta''_h-\vartheta'_c)}{\ln[(\vartheta'_h-\vartheta''_c)/(\vartheta''_h-\vartheta'_c)]}=\frac{(55.43-25)-(45-15)}{\ln[(55.43-25)/(45-15)]}=30.22^\circ\mathrm{C}$$

$$k=(1/\alpha_h+1/\alpha_c)^{-1}=(1/2.615+1/2.5)^{-1}=1.2781\,\mathrm{kW/m^2K}$$

$$A=\dot{Q}/(kF\Delta\vartheta_{LM})=104.34/(1.278\times1\times30.22)=2.702\,\mathrm{m^2}$$

HU1: $\dot{Q}=(\dot{M}c_p)_c(\vartheta''_c-\vartheta'_c)=20\times(155-145.78)=184.35\,\mathrm{kW}$

$$\Delta\vartheta_{LM}=\frac{(180-155)-(179-145.78)}{\ln[(180-155)/(179-145.78)]}=28.91^\circ\mathrm{C}$$

$$k=(1/5+1/0.917)^{-1}=0.7749\,\mathrm{kW/m^2K}$$

$$A=184.35/(0.7749\times1\times28.91)=8.228\,\mathrm{m^2}$$

3 Synthesis of Heat Exchanger Networks with the Pinch Design Method

The parameters of a heat exchanger network can be classified into three sets: (1) Design parameters, e.g., flowsheet of the network, heat exchanger type, heat transfer area, and other structural parameters. (2) Operation parameters, e.g., supply stream temperatures and flow rates. Their values might be disturbed or passively changed but cannot be regulated. (3) Control parameters, e.g., bypass flow rates and flow rates in stream split branches. Their values can be manually or automatically regulated by controlling units. A fundamental synthesis problem can be stated as: For given operation parameters of a heat recovery system, find the design parameters and control parameters of the heat exchanger network in their feasible regions so that the target temperatures of the process streams and other additional constraints (e.g., pressure drop, flow rate, and size limitations) can be fulfilled; meanwhile the sum of investment and operation costs reaches the minimum.

In a typical synthesis task, the supply temperatures, heat capacity flow rates (or mass flow rates) and target temperatures of the process streams, and the temperature levels of the available hot and cold utilities are given as the operation parameters. The heat transfer coefficients of the process streams and utility mediums as well as the equipment and utility costs are previously specified. The design and control parameters to be optimized include: (1) the flowsheet of the heat exchanger network, (2) the area of each heat exchanger in the network, and (3) the heat capacity flow rates of hot and cold streams in each heat exchanger. As the number of possible flowsheets could be astronomical figures, traditional optimization solvers are not suitable for such a task. In the past 3 decades, many synthesis methodologies have been developed. As a practical procedure, the Pinch design method is introduced in this section in detail.

3.1 The Problem Table

The problem table proposed by Linnhoff and Flower [14] is used to find the position of the Pinch and the minimum hot and cold utility duties. For a given synthesis task dealing with N_h hot streams and N_c cold streams, Let

$$\Theta'_{\mathrm{h}} = \begin{bmatrix} \vartheta'_{\mathrm{h},1} \\ \vartheta'_{\mathrm{h},2} \\ \vdots \\ \vartheta'_{\mathrm{h},N_{\mathrm{h}}} \end{bmatrix}, \Theta''_{\mathrm{h}} = \begin{bmatrix} \vartheta''_{\mathrm{h},1} \\ \vartheta''_{\mathrm{h},2} \\ \vdots \\ \vartheta''_{\mathrm{h},N_{\mathrm{h}}} \end{bmatrix},$$

$$\Theta'_{\mathrm{c}^*} = \begin{bmatrix} \vartheta'_{\mathrm{c}^*,1} \\ \vartheta'_{\mathrm{c}^*,2} \\ \vdots \\ \vartheta'_{\mathrm{c}^*,N_{\mathrm{c}}} \end{bmatrix} = \begin{bmatrix} \vartheta'_{\mathrm{c},1} + \Delta\vartheta_{\min} \\ \vartheta'_{\mathrm{c},2} + \Delta\vartheta_{\min} \\ \vdots \\ \vartheta'_{\mathrm{c},N_{\mathrm{c}}} + \Delta\vartheta_{\min} \end{bmatrix},$$

$$\Theta''_{\mathrm{c}^*} = \begin{bmatrix} \vartheta''_{\mathrm{c}^*,1} \\ \vartheta''_{\mathrm{c}^*,2} \\ \vdots \\ \vartheta''_{\mathrm{c}^*,N_{\mathrm{c}}} \end{bmatrix} = \begin{bmatrix} \vartheta''_{\mathrm{c},1} + \Delta\vartheta_{\min} \\ \vartheta''_{\mathrm{c},2} + \Delta\vartheta_{\min} \\ \vdots \\ \vartheta''_{\mathrm{c},N_{\mathrm{c}}} + \Delta\vartheta_{\min} \end{bmatrix} \tag{21}$$

in which $\Delta\vartheta_{\min}$ is the minimum temperature difference in the network. Let the set

$$\begin{aligned} \mathrm{S_T} = &\{\vartheta'_{\mathrm{h},1}, \vartheta'_{\mathrm{h},2}, \cdots, \vartheta'_{\mathrm{h},N_{\mathrm{h}}}\} \cup \{\vartheta''_{\mathrm{h},1}, \vartheta''_{\mathrm{h},2}, \cdots, \vartheta''_{\mathrm{h},N_{\mathrm{h}}}\} \\ &\cup \{\vartheta'_{\mathrm{c}^*,1}, \vartheta'_{\mathrm{c}^*,2}, \cdots, \vartheta'_{\mathrm{c}^*,N_{\mathrm{c}}}\} \cup \{\vartheta''_{\mathrm{c}^*,1}, \vartheta''_{\mathrm{c}^*,2}, \cdots, \vartheta''_{\mathrm{c}^*,N_{\mathrm{c}}}\} \end{aligned} \tag{22}$$

then define a temperature level vector

$$\Theta = [\vartheta_1 \quad \vartheta_2 \quad \cdots \quad \vartheta_{N_{\mathrm{SN}}+1}]^{\mathrm{T}} \tag{23}$$

in which the temperature levels $\vartheta_i \in \mathrm{S_T} (i = 1, 2, \cdots, N_{\mathrm{SN}} + 1)$ and $\vartheta_1 > \vartheta_2 > \cdots > \vartheta_{N_{\mathrm{SN}}+1}$. The streams in each temperature interval $[\vartheta_i, \vartheta_{i+1}]$ constitute a subnetwork SN_i $(i = 1, 2, \cdots, N_{\mathrm{SN}})$. The heat transport difference between the heat input I_i and heat output O_i in SN_i can be calculated by means of Eq. (24),

$$D_i = I_i - O_i = \Delta\dot{H}_{\mathrm{c},i} - \Delta\dot{H}_{\mathrm{h},i} \tag{24}$$

in which

$$\Delta\dot{H}_{\mathrm{h},i} = (\vartheta_i - \vartheta_{i+1}) \sum_{j=1}^{N_{\mathrm{h}}} \dot{C}_{\mathrm{h},ij} \tag{25}$$

$$\Delta\dot{H}_{\mathrm{c},i} = (\vartheta_i - \vartheta_{i+1}) \sum_{j=1}^{N_{\mathrm{c}}} \dot{C}_{\mathrm{c},ij} \tag{26}$$

$$\dot{C}_{\mathrm{h},ij} = \begin{cases} (\dot{M}c_{\mathrm{p}})_{\mathrm{h},j}, & \vartheta''_{\mathrm{h},j} \le \vartheta_{i+1} \text{ and } \vartheta_i \le \vartheta'_{\mathrm{h},j} \\ 0, & \text{others} \end{cases} \tag{27}$$

$$\dot{C}_{\mathrm{c},ij} = \begin{cases} (\dot{M}c_{\mathrm{p}})_{\mathrm{c},j}, & \vartheta'_{\mathrm{c}^*,j} \le \vartheta_{i+1} \text{ and } \vartheta_i \le \vartheta''_{\mathrm{c}^*,j} \\ 0, & \text{others} \end{cases} \tag{28}$$

At first, assume a zero heat input to SN_1, that is, $I_1 = 0$. If there is no additional connection between SN_{i+1} and heat utility, the heat input of SN_{i+1} should be equal to the heat output of SN_i,

$$I_{i+1} = O_i \tag{29}$$

The assumption $I_1 = 0$ might yield negative values of heat inputs and heat outputs of the sub-networks. This is not allowed because the heat cannot flow from a lower temperature region to a higher temperature region. The modification is performed by subtracting the minimum value of heat inputs/outputs to I_1,

$$I_1 = -\dot{Q}_{\min} = -\min\{I_i, O_i | i = 1, 2, \cdots, N_{\mathrm{SN}}\} \tag{30}$$

and repeating the calculation. This can also be done by subtracting $\dot{Q}_{\min}$ from all heat inputs and outputs. After the modification, the minimum hot utility duty $\dot{Q}_{\mathrm{HU,min}} = I_1$ and the minimum cold utility duty $\dot{Q}_{\mathrm{CU,min}} = O_{\mathrm{SN}}$ is obtained. The position where the heat input is zero is called the Pinch.

3.2 The Composite Curves

Let j_1 and j_2 indicate the maximum and minimum temperature levels of the hot streams, respectively; k_1 and k_2 indicate those of the cold streams, so that

$$\vartheta_{j_1} = \max\{\vartheta'_{\mathrm{h},1}, \vartheta'_{\mathrm{h},2}, \cdots, \vartheta'_{\mathrm{h},N_{\mathrm{h}}}, \vartheta''_{\mathrm{h},1}, \vartheta''_{\mathrm{h},2}, \cdots, \vartheta''_{\mathrm{h},N_{\mathrm{h}}}\} \tag{31}$$

$$\vartheta_{j_2} = \min\{\vartheta'_{\mathrm{h},1}, \vartheta'_{\mathrm{h},2}, \cdots, \vartheta'_{\mathrm{h},N_{\mathrm{h}}}, \vartheta''_{\mathrm{h},1}, \vartheta''_{\mathrm{h},2}, \cdots, \vartheta''_{\mathrm{h},N_{\mathrm{h}}}\} \tag{32}$$

$$\vartheta_{k_1} = \max\{\vartheta'_{\mathrm{c},1}, \vartheta'_{\mathrm{c},2}, \cdots, \vartheta'_{\mathrm{c},N_{\mathrm{c}}}, \vartheta''_{\mathrm{c},1}, \vartheta''_{\mathrm{c},2}, \cdots, \vartheta''_{\mathrm{c},N_{\mathrm{c}}}\} \tag{33}$$

$$\vartheta_{k_2} = \min\{\vartheta'_{\mathrm{c},1}, \vartheta'_{\mathrm{c},2}, \cdots, \vartheta'_{\mathrm{c},N_{\mathrm{c}}}, \vartheta''_{\mathrm{c},1}, \vartheta''_{\mathrm{c},2}, \cdots, \vartheta''_{\mathrm{c},N_{\mathrm{c}}}\} \tag{34}$$

The points for the composite curve of hot and cold streams are $(\vartheta_j, \dot{H}_{\mathrm{h},j})$ $(j = j_1, j_1 + 1, \cdots, j_2)$ and $(\vartheta_k, \dot{H}_{\mathrm{c},k})$ $(k = k_1, k_1 + 1, \cdots, k_2)$, respectively, in which $\dot{H}_{\mathrm{h},j}$ and $\dot{H}_{\mathrm{c},k}$ are enthalpy flow rates of the hot and cold streams in the jth (or kth) subnetwork,

$$\dot{H}_{\mathrm{h},j} = \sum_{i=j}^{j_2-1} \Delta\dot{H}_{\mathrm{h},i} \tag{35}$$

$$\dot{H}_{\mathrm{c},k} = \sum_{i=k}^{k_2-1} \Delta\dot{H}_{\mathrm{c},i} + O_{\mathrm{SN}} \tag{36}$$

3.3 Pinch Design Method

Because any network design that transfers heat across the Pinch will cause both heating and cooling duties larger than their minimum, there are three principles:

1. Do not use cold utilities above the Pinch
2. Do not use hot utilities below the Pinch
3. Do not transfer heat across the Pinch

Therefore, for the network design there are three consequences:

1. Divide the network at the Pinch into two parts
2. Design each part separately
3. Avoid the use of coolers in the part above the Pinch (hot end part); avoid the use of heaters in the part below the Pinch (cold end part)

For the matching of streams there are the following two rules:

1. In the part above the Pinch, the number of the hot streams (including their branches) should be less than or equal to that of the cold streams (including their branches), that is,

$$N_{\mathrm{h}} \le N_{\mathrm{c}} \text{ (above the Pinch)} \tag{37}$$

otherwise, the stream splitting is necessary to ensure that Eq. (37) is fulfilled. Similarly, in the part below the Pinch, the inequality is inversed,

$$N_h \geq N_c \text{ (below the Pinch)} \tag{38}$$

2. For a match in the part above the Pinch, the heat capacity flow rate of the hot stream (or the branch of a hot stream) should be less than or equal to that of the cold stream (or the branch of a cold stream) to be matched, that is,

$$(\dot{M}c_p)_h \leq (\dot{M}c_p)_c \text{ (above the Pinch)} \tag{39}$$

otherwise, the stream splitting is necessary. For a match in the part below the Pinch, the inequality is inversed,

$$(\dot{M}c_p)_h \geq (\dot{M}c_p)_c \text{ (below the Pinch)} \tag{40}$$

In the Pinch design method $\Delta\vartheta_{min}$ is an important parameter for the balance between the investment costs and utility costs. A large value of $\Delta\vartheta_{min}$ would decrease the investment costs but increase the utility costs, and vice versa. Further more, the Pinch position could also change with $\Delta\vartheta_{min}$. The value of $\Delta\vartheta_{min}$ can be optimized by taking the total costs of the network as the objective function.

The Pinch design method focuses on the matches of streams near the Pinch because at that point the temperature difference is the minimum. For the matches away from the Pinch, the above rules must not be fulfilled. In some cases there might be multiple Pinches or no Pinch. A detailed description of the Pinch design method can be found in [15].

Example 3

We use the problem data in Table 1 to illustrate the calculation of problem table and composite curves and let $\Delta\vartheta_{min} = 5K$. The temperature intervals are formed according to the following temperatures,

$$\Theta'_h = \begin{bmatrix} 175 \\ 125 \end{bmatrix}, \Theta''_h = \begin{bmatrix} 45 \\ 65 \end{bmatrix}, \Theta'_{c^*} = \begin{bmatrix} 20+5 \\ 40+5 \end{bmatrix} = \begin{bmatrix} 25 \\ 45 \end{bmatrix},$$
$$\Theta''_{c^*} = \begin{bmatrix} 155+5 \\ 112+5 \end{bmatrix} = \begin{bmatrix} 160 \\ 117 \end{bmatrix}$$

Put the above temperatures into Eq. (23) and arrange them according to their magnitude; six subnetworks are obtained, $N_{SN} = 6$, and the temperature levels are,

$$\Theta = [175 \quad 160 \quad 125 \quad 117 \quad 65 \quad 45 \quad 25]^T$$

Equations (24–29) are applied to the following calculations.

$$SN_1 : \vartheta_1 = 175, \vartheta_2 = 160$$
$$\Delta\dot{H}_{c,1} = 0$$
$$\Delta\dot{H}_{h,1} = (\vartheta_1 - \vartheta_2)(\dot{M}c_p)_{h,1} = (175 - 160) \times 10 = 150$$
$$I_1 = 0$$
$$D_1 = \Delta\dot{H}_{c,1} - \Delta\dot{H}_{h,1} = 0 - 150 = -150$$
$$O_1 = I_1 - D_1 = 0 - (-150) = 150$$
$$SN_2 : \vartheta_2 = 160, \vartheta_3 = 125$$
$$\Delta\dot{H}_{c,2} = (\vartheta_2 - \vartheta_3)(\dot{M}c_p)_{c,1} = (160 - 125) \times 20 = 700$$
$$\Delta\dot{H}_{h,2} = (\vartheta_2 - \vartheta_3)(\dot{M}c_p)_{h,1} = (160 - 125) \times 10 = 350$$
$$I_2 = O_1 = 150$$
$$D_2 = \Delta\dot{H}_{c,2} - \Delta\dot{H}_{h,2} = 700 - 350 = 350$$
$$O_2 = I_2 - D_2 = 150 - 350 = -200$$

The calculation results are provided in Table 3, where the modified heat input and output are denoted with "*". At the temperature level $\vartheta_3 = 125°C$, the heat input $I_3^* = 0$, that means that there is no heat flowing through this interface. This position is the pinch at which the temperature difference reaches the given minimum value, $\Delta\vartheta_{min} = 5°C$. The corresponding minimum heating duty is 200 kW, and the minimum cooling duty is 120 kW. The composite curves are shown in Fig. 5. The point data of the curves are also provided in Table 3.

To design the network, the problem is divided into two parts at the Pinch as is shown in Fig. 6. In the part above the Pinch (the left part in Fig. 6), there is only one match: H1C1, i.e., $N_h = N_c = 1$, therefore, Eq. (37) is fulfilled. Since $(\dot{M}c_p)_{H1} = 10$ kW/K and $(\dot{M}c_p)_{C1} = 20$ kW/K, Eq. (39) is also valid and no splitting is necessary.

In the part below the Pinch (the right part in Fig. 6), $N_h = N_c = 2$, which meets Eq. (38). The matches H1C1 and H2C2 can be considered due to their temperature intervals. Since $(\dot{M}c_p)_{H1} = 10$kW/K and $(\dot{M}c_p)_{C1} = 20$ kW/K, according to Eq. (40), a splitting in C1 is necessary, $(\dot{M}c_p)_{C1(H1C1)} \leq 10$ kW/K, and a new match H2C1 should be added with $(\dot{M}c_p)_{C1(H2C1)} = (\dot{M}c_p)_{C1} - (\dot{M}c_p)_{C1(H1C1)} \geq 10\,kW/K$, which yield a splitting in stream H2 with $(\dot{M}c_p)_{H2(H2C1)} \geq (\dot{M}c_p)_{C1(H2C1)} \geq 10\,kW/K$.

For the match H2C2, since $(\dot{M}c_p)_{C2} = 15\,kW/K$, then, Eq. (40) indicates

$$15\,kW/K \leq (\dot{M}c_p)_{H2(H2C2)} = (\dot{M}c_p)_{H2} - (\dot{M}c_p)_{H2(H2C1)} \leq 30\,kW/K$$

This design step yields a network structure shown in Fig. 7. At first it is assumed that the branches are isothermally mixed, i.e., the split-flows of a stream at the branch outlets have the

C5. Table 3. The problem table, $\Delta\vartheta_{min} = 5K$

7	25									20	120

same temperature before they are mixed. Further more, as has been analyzed in the aforementioned problem table, the minimum cooling duty is 120 kW for stream H1; therefore, a cooler is added to stream H1. The detailed calculations for EX1 and EX4 are given as follows:

$$\text{EX1}: \dot{Q} = (\dot{M}c_p)_{H1}(\vartheta'_{H1} - \vartheta_{h,Pinch}) = 10 \times (175 - 125) = 500\ \text{kW}$$

$$\vartheta''_{C1} = \vartheta_{c,Pinch} + \dot{Q}/(\dot{M}c_p)_{C1} = 120 + 500/20 = 145^\circ\text{C}$$

$$\Delta\vartheta_{LM} = \frac{(\vartheta'_{H1} - \vartheta''_{C1}) - (\vartheta_{h,Pinch} - \vartheta_{c,Pinch})}{\ln[(\vartheta'_{H1} - \vartheta''_{C1})/(\vartheta_{h,Pinch} - \vartheta_{c,Pinch})]}$$

$$= \frac{(175 - 145) - (125 - 120)}{\ln[(175 - 145)/(125 - 120)]} = 13.95^\circ\text{C}$$

$$k = (1/\alpha_{H1} + 1/\alpha_{C1})^{-1} = (1/2.615 + 1/0.917)^{-1}$$

$$= 0.6789\ \text{kW/m}^2\text{K}$$

$$A = \dot{Q}/(kF\Delta\vartheta_{LM}) = 500/(0.6789 \times 1 \times 13.95) = 52.78\ \text{M}^2$$

$$\text{EX4}: \dot{Q} = (\dot{M}c_p)_{C2}(\vartheta''_{C2} - \vartheta'_{C2}) = 15 \times (112 - 40) = 1{,}080\ \text{kW}$$

$$(\dot{M}c_p)_{H2(H2C2)} = \dot{Q}/(\vartheta'_{H2} - \vartheta''_{H2}) = 1080/(125 - 65) = 18\ \text{kW/K}$$

$$\Delta\vartheta_{LM} = \frac{(\vartheta'_{H2} - \vartheta''_{C2}) - (\vartheta''_{H2} - \vartheta'_{C2})}{\ln[(\vartheta'_{H2} - \vartheta''_{C2})/(\vartheta''_{H2} - \vartheta'_{C2})]}$$

$$= \frac{(125 - 112) - (65 - 40)}{\ln[(125 - 112)/(65 - 40)]} = 18.35^\circ\text{C}$$

$$k = (1/\alpha_{H2} + 1/\alpha_{C2})^{-1} = (1/1.333 + 1/0.166)^{-1}$$

$$= 0.1476\ \text{kW/m}^2\text{K}$$

$$A = \dot{Q}/(kF\Delta\vartheta_{LM}) = 1080/(0.1476 \times 1 \times 18.35) = 398.69\ \text{m}^2$$

More calculation results can be found in Fig. 7. The investment costs and utility costs can then be calculated according to the cost data in Table 1:

$$\text{EX1: } C_{EX,1} = 1{,}200A^{0.57} = 1{,}200 \times 52.78^{0.57} = 11{,}508\,\$/\text{year}$$

$$\text{EX2: } C_{EX,2} = 1{,}200 \times 62.65^{0.57} = 12{,}688\,\$/\text{year}$$

$$\text{EX3: } C_{EX,3} = 1{,}200 \times 133.47^{0.57} = 19{,}527\,\$/\text{year}$$

$$\text{EX4: } C_{EX,4} = 1{,}200 \times 398.69^{0.57} = 36{,}437\,\$/\text{year}$$

$$\text{CU1: } C_{U,1} = 1{,}200A^{0.57} + 10(\dot{M}c_p)_{H1}(\vartheta''_{N,H1} - \vartheta''_{N*,H1})\,\$/\text{year}$$

$$= 1{,}200 \times 3.03^{0.57} + 10 \times 10 \times (57 - 45)$$

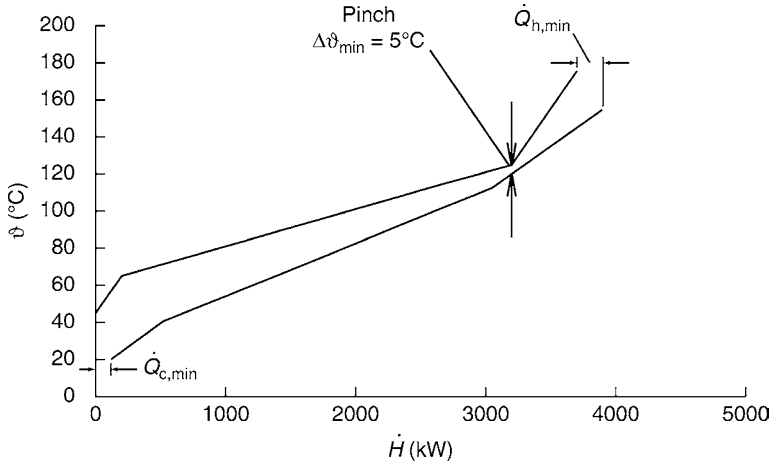
$$= 3{,}457\,\$/\text{year}$$

$$\text{HU1: } C_{U,2} = 1{,}200 \times 8.82^{0.57} + 110 \times 20 \times (155 - 145)$$

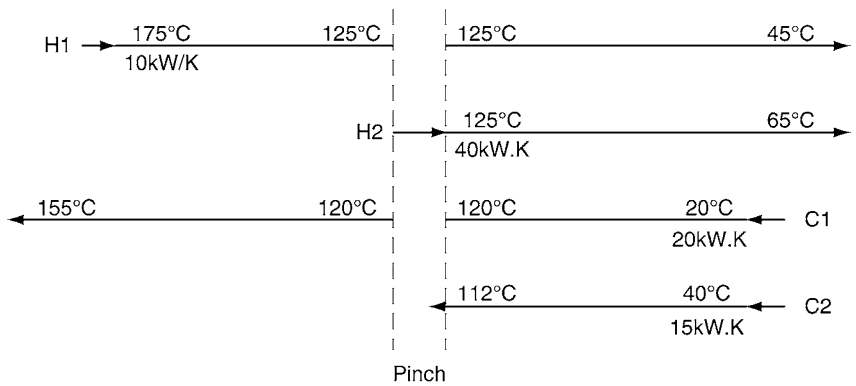
$$= 26{,}150\,\$/\text{year}$$

The total annual cost of the network is the sum of the above costs,

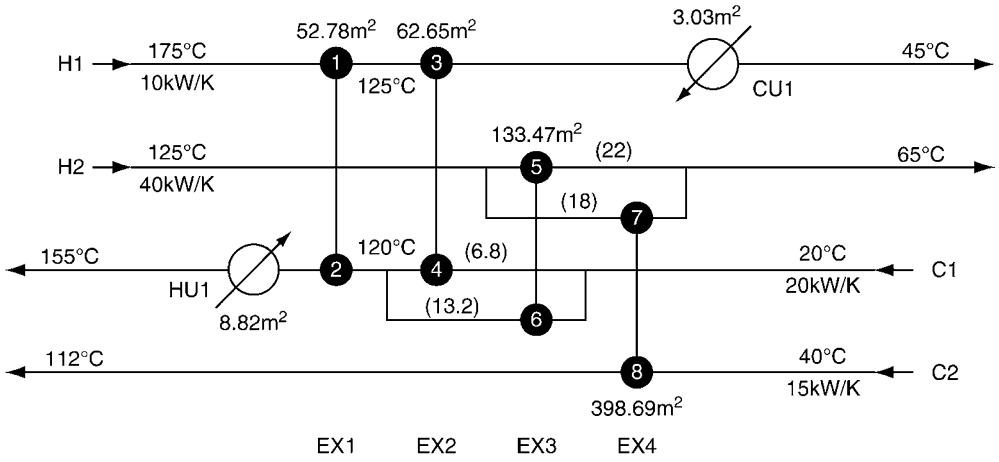
$$C_{tot} = \sum_{n=1}^{4} C_{EX,n} + \sum_{n=1}^{2} C_{U,n} = 109{,}768\,\$/\text{year}$$



C5. Fig. 5. Composite curves of Example 3.



C5. Fig. 6. The Pinch decomposition.



C5. Fig. 7. The structure design of the heat exchanger network, 109,768 $/year.

As has been mentioned, the isothermal mixing is assumed in the above calculation, and $\Delta t_{\min}$ is also an empirical value. Therefore, it is possible to optimize the solution. Let $x_1 = \dot{Q}_{CU1}$, $x_2 = \dot{Q}_{EX2}$, $x_3 = (\dot{M}c_p)_{EX2,c}$, and $x_4 = (\dot{M}c_p)_{EX3,h}$, and take them as the controlling variables to be optimized. The optimal design can be obtained by means of the iteration procedure of the Newton method,

$$x_i = x_i^* - \frac{\frac{\partial C_{tot}}{\partial x_i}}{\frac{\partial^2 C_{tot}}{\partial x_i^2}} \approx x_i^* - \frac{\Delta x}{2}\frac{C_{tot}(x_i+\Delta x) - C_{tot}(x_i-\Delta x)}{C_{tot}(x_i+\Delta x) + C_{tot}(x_i-\Delta x) - 2C_{tot}(x_i)} \quad (i=1,2,3,4) \tag{41}$$

which yields the optimal network design with the total annual cost of 108,072 $/year, as is shown in Fig. 4. This procedure is simple, but might not converge in some cases. For such cases other optimization solvers can be used.

Example 3 deals with only four process streams; therefore, it is suitable to use the Pinch design method. For more complicated synthesis problems, e.g., the synthesis of large-scale heat exchanger networks, the stochastic algorithms such as the hybrid genetic algorithm [16] and monogenetic algorithm [17] are recommended to solve the optimization problem.

4 Symbols

C	annual cost (monetary unit/year)
F	correction factor of logarithmic mean temperature difference
$\dot{H}$	enthalpy flow rate (kW)
N	number of stream channels
N'	number of stream entrances of network
N''	number of stream exits of network
N_{EX}	number of heat exchangers
NTU^*	modified number of transfer units defined by Eq. (8)
R	ratio of heat capacity flow rates
Θ	temperature vector (°C)
ϑ	temperature (°C)
$\Delta\vartheta_{LM}$	logarithmic mean temperature difference (K)

Superscripts

T	transpose
$'$	inlet
$''$	outlet

Subscripts

1 Introduction

Heat exchangers are essential components in process technology. Therefore, the economic selection and design of heat exchangers plays an important role for the profitability of a process.

In this connection profitability means the ratio of income to costs. Income and costs are value quantities (monetary units per unit time) which are linked to the physical variables used in engineering by cost coefficients. Applying the notion of profitability to heat exchangers allows either to compare marginal cost and marginal utility of a transferred heat flow or to consider the amount of heat transferred during a period of time as an externally specified quantity. The definition of marginal values in economics is given by W. H. Bartzsch [1].

In the former case the increase in income (usually in the form of lower energy costs) must be compared to the additional cost for the higher amount of transferred heat or for heat integration (Chap. C5). The additional costs for increasing the heat transfer surface area of an exchanger for heat recovery entail lower energy costs. However, the heat flow rate per unit surface area decreases with increasing surface area (Chap. C1). Consequently, a plot of the net amount of saved annual costs (saved energy costs less operating expenses including depreciation) versus the investment costs for the heat exchanger shows a maximum [2]. The actual heat exchanger should be smaller than at this maximum because the marginal return of the invested capital becomes just zero at this point. The optimal surface area of the heat exchanger for a requested return on investment can graphically be determined from the chart at the point where the gradient of the curve equals this return on investment.

The following considerations are limited to the case where the amount of heat to be transferred is an externally specified quantity, given, for example, by the requirements for the proper functioning of the whole process. In this case the income is fixed, albeit usually not explicitly but only as an inseparable part of the income of the whole plant, and a cost-effectiveness study is limited to the minimization of costs by comparative cost methods.

2 Costs

The total costs C_{tot} (monetary units/year) can be subdivided into costs of capital C_{CA} composed of the annual depreciation or amortization, the (imputed) interest, and the operating expenses for energy and supplies C_E as well as the other operating expenses C_S (for maintenance, repair, staff, and replacement of heat transfer fluids):

$$C_{tot} = C_{CA} + C_E + C_S. \quad (1)$$

2.1 Costs of Capital

The annual costs of capital depend on the capital requirements for the heat exchanger I_{EX} (price or acquisition value), for pumps or compressors I_{P1} plus I_{P2} to convey the fluids through both channels of the exchanger, the number n of years of the recovery period, and the interest rate z:

$$C_{CA} = \left(\frac{1}{n} + \frac{z}{2}\right)(I_{EX} + I_{P1} + I_{P2}) = a(I_{EX} + I_{P1} + I_{P2}) \quad (2)$$

where linear depreciation and a declining balance of zero are assumed. Equation (2) takes into account the fact that over the whole recovery period on average only half the capital employed is tied up.

The value of the payback coefficient a falls usually between 0.1/year and 0.25/year (recovery period 5–20 years, interest rate 5–15%). While the recovery period and the interest rate are externally given, the capital requirements for the heat exchanger and pumps or compressors depend on the design of the exchanger. For the precise determination of I quotations from different manufacturers should be solicited. Several publications [2–5] give numerous methods and data for the estimation of acquisition costs of heat exchangers. However, these are associated with a high degree of uncertainity and are also not transferable offhand to other regions of the world.

In order to estimate costs previously carried out projects or quotations for "similar" heat exchangers of different size or

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_9,

materials may be taken. The effect of the size on the equipment price I_{EX} may be taken into account using the surface area A:

$$I_{EX} = I_{EX0}\left(\frac{A}{A_0}\right)^{m_{EX}}, \tag{3}$$

where I_{EX0} is the reference price of an exchanger with surface area A_0. The value of the exponent m_{EX} is usually less than 1 and is called degression exponent. Following the so-called 6/10-rule [6] a value of $m = 0.6$ can be used for rough estimates. For shell-and-tube heat exchangers with surface areas between 2 and 2,000 m^2 a value of $m_{EX} = 0.59$ is recommended [7].

Accordingly, the pumping power $\dot{L}$ may be used as a reference variable for pumps or compressors:

$$I_P = I_{P0}\left(\frac{\dot{L}}{\dot{L}_0}\right)^{m_P}. \tag{4}$$

Values of $m_P = 0.30$ for small centrifugal pumps (0.35–30 kW), $m_P = 0.67$ for large centrifugal pumps (30–300 kW), and $m_P = 0.84$ for compressors (0.75–1,500 kW) are recommended by F. A. Holland and J. K. Wilkinson [7].

Different materials may be taken into account by correction coefficients for the price of the construction using a reference material. Values of such material correction coefficients for a shell-and-tube heat exchanger with a surface area of 140 m^2 are given in Table 1 [2]. Both values for the tubes and for the whole heat exchanger are specified. Carbon steel is used as the reference material. For smaller heat exchangers the correction coefficients tend to be smaller and vice versa.

Prices of the past have to be corrected by means of price indexes:

$$I_{j2} = I_{j1}\frac{j_2}{j_1} \tag{5}$$

with I_{j1} and j_1 as the price and the price index at a particular time in the past and I_{j2} and j_2 as the current price and the current price index. A common index is the Chemical Engineering Plant Cost Index (CEPCI) which is published periodically in the magazine *Chemical Engineering* [8] or is available online [9]. The CEPCI contains subindexes for heat exchangers and tanks as well as for pumps and compressors.

C6. Table 1. Material correction coefficients for a shell-and-tube heat exchanger [2]

Material	Tubes	Heat exchanger
Unalloyed carbon steel	1.0	1.0
Stainless steel 304L, welded	2.2	1.6
Stainless steel Cu/Ni-90/30, welded	2.4	1.6
Stainless steel Cu/Ni-70/30, seamless	2.9	1.8
Stainless steel 316L, welded	3.2	1.8
Titanium, 20 BWG, welded	3.6	1.9
E-Brite 26-1, welded	5.2	2.4
Titanium, welded	6.8	2.8
Monel 400, welded	7.5	3.0
Incoloy 825, welded	7.6	3.0
Carpenter 20/CB3, welded	8.6	3.3
Inconel 625, welded	15.1	5.0
Zirconium 20 BWG, seamless	15.8	5.2
Hastelloy C276, welded	18.2	5.9
Zirconium, seamless	25.1	7.7

2.2 Energy Costs and Other Operating Expenses

The total costs for energy and supplies C_E are composed of the pumping costs on both sides, of the additional energy costs $C_{\Delta T}$ for increasing the temperature difference in the heat exchanger and of the costs of supplies C_M. They are proportional to the annual operating time τ (hours/year):

$$C_E = c_{el}\tau\left(\frac{\dot{M}_1\Delta p_1}{\rho_1\eta_{P1}} + \frac{\dot{M}_2\Delta p_2}{\rho_2\eta_{P2}}\right) + C_{\Delta T} + C_M \tag{6}$$

with the price of electrical energy c_{el} (monetary units/kWh) and the mass flow rate $\dot{M}_i$, the absolute pressure drop Δp_i, the mean fluid density ρ_i, and the pump efficiencies η_{Pi} on both sides ($i = 1$ or 2). The additional energy costs $C_{\Delta T}$ for increasing the temperature difference in the exchanger result from the costs for combustibles, steam, or electrical energy.

In many cases Eq. (6) may be simplified. While pumping costs always arise at least on one side, additional energy costs $C_{\Delta T}$ for increasing the temperature difference do not occur for heat transfer between two process fluids or for cooling with fluids at ambient temperature. Moreover, for cooling with water there may be costs. Costs of supplies do not occur for heat transfer between process fluids or for cooling with air.

The other operating expenses primarily include maintenance and cleaning costs. Although they are at least partially proportional to the annual operating time like the energy costs, it is usual practice to assume them to be proportional to the equipment price like the capital costs [10]:

$$C_s = sI_{EX}. \tag{7}$$

For cost estimation purposes with the objective of economic design this is justified as well because operating time-dependent or constant parts of the maintenance costs do not depend on the construction of the heat exchanger. Rough values for the coefficient s are given by Schnell [10]:

s = 0.01 to 0.02 for low maintenance requirements (no danger of fouling and corrosion),

s = 0.02 to 0.05 for medium maintenance requirements (planned maintenance and cleaning intervals),

s = 0.05 to 0.10 for high maintenance requirements (rapid fouling, high corrosion).

Maintenance costs for the pumps may be taken into account accordingly.

3 Economic Design

In general the following parameters are specified for the design of a heat exchanger:

- Mass flow rate of one of both streams (process fluid)
- Inlet and outlet temperature of the process fluid

In many cases the inlet temperature of the fluid on the other side is also defined (supplies like air or water for cooling) or restricted to a few discrete values (heating steam).

The objective of the economic design is the selection of a heat exchanger (type, heat transfer surface area, design details) and the specification of operating conditions (mass flow rate and inlet temperatures of supplies where necessary) in order both to meet above specifications and to minimize the annual total costs according to Eq. (1).

Generally the total costs depend on many factors, some of them having only discrete values. The formal way for determining the minimum of the cost function Eq. (1) by means of analytical or numerical partial derivation with respect to all relevant variables would require either simple analytical relations or an extensive data base. This formal way is rarely justified because of the high costs for collection of the required data.

In the special case of heat transfer between two process fluids mass flow rates and terminal temperatures of both streams are specified. Additional energy costs for increasing the temperature difference do not occur. The cost function is reduced to

$$C_{\mathrm{tot}} = (a+s) I_{\mathrm{EX0}} \left(\frac{A}{A_0}\right)^{m_{\mathrm{EX}}} + c_{\mathrm{el}} \tau \left(\frac{\dot{M}_1 \Delta p_1}{\rho_1 \eta_{\mathrm{P1}}} + \frac{\dot{M}_2 \Delta p_2}{\rho_2 \eta_{\mathrm{P2}}}\right) \tag{8}$$

where costs of capital and maintenance for the pumps are neglected. According to Chap. C1, Eq. (3), the required surface area A depends on the mean overall heat transfer coefficient k and the mean temperature difference $\Delta\vartheta_{\mathrm{m}}$. The overall heat transfer coefficient k, in turn, depends on the geometry of the flow channels and the mean flow velocities (Chap. C2 and Part G), and the mean temperature difference $\Delta\vartheta_{\mathrm{m}}$depends on the flow arrangement (Chap. C1). Pressure drops Δp_1 and Δp_2 depend on the mean flow velocities and the geometries of the flow paths, especially on their lengths (Part L).

Minimization of the cost function Eq. (8) may be considerably simplified by using an analogy between heat transfer and pressure drop. Martin [11] has shown that an analogy following the generalized Lévêque equation may be used for the economic design of plate heat exchangers, tube bundles, packed beds, and other types of compact heat exchangers.

4 Thermodynamic Analysis

The economic valuation on the basis of costs is expensive and unreliable. On the other hand, a thermodynamic analysis for minimization of the entropy production or of the exergy loss by means of entropy or exergy balances may be carried out easily and quickly. There is no general relation between entropy production or exergy loss on the one hand and total costs on the other hand. However, in cases where energy costs preponderate the thermodynamic analysis may provide indications for the most economic solution (see Chap. C5 about the optimization of heat exchanger networks).

An exergy balance for an adiabatic heat exchanger with two streams in steady-state operation according to Chap. C1, Fig. 1, yields the exergy loss $\dot{E}_{\mathrm{V}}$:

$$\dot{E}_{\mathrm{V}} = T_u \left[\dot{M}_1 \left(s_1'' - s_1'\right) + \dot{M}_2 \left(s_2'' - s_2'\right)\right] \tag{9}$$

where T_{u} is the ambient thermodynamic temperature and $\dot{M}_1$ and $\dot{M}_2$ are the mass flow rates of both streams. By heat losses to the surroundings an additional exergy loss is generated. This additional exergy loss, however, is usually small and may be neglected in most cases, especially if the heat exchanger is properly insulated.

Evaluation of Eq. (9) for single-phase systems requires inlet and outlet temperatures and pressures of both streams in order to determine the specific entropies s_1', s_1'', s_2', and s_2''. For wet vapor of a pure fluid, temperature or pressure and vapor quality at the inlet and outlet must be known; for mixtures, additionally the compositions of vapor and liquid must be known.

For the single-phase model fluids "perfect gas" and "incompressible fluid," which are good approximations for real gases at low pressures and liquids, respectively, the following simple equations for the calculation of the exergy loss may be used. They have been derived for constant heat capacities [12].

The exergy loss is composed of three parts:

$$\dot{E}_{\mathrm{V}} = \dot{E}_{\mathrm{V,Q}} + \dot{E}_{\mathrm{V},\Delta\mathrm{p},1} + \dot{E}_{\mathrm{V},\Delta\mathrm{p},2}. \tag{10}$$

The first term $\dot{E}_{V,Q}$ represents the main exergy loss due to heat transfer at finite temperature difference. Included is a small fraction which is caused by the mixing of fluid parts of different temperatures at the outlet.

For gases and liquids the exergy loss $\dot{E}_{\mathrm{V,Q}}$ is calculated according to

$$\dot{E}_{\mathrm{V,Q}} = \dot{Q}_{12} T_{\mathrm{u}} \left(\frac{1}{T_{\mathrm{M},2}} - \frac{1}{T_{\mathrm{M},1}}\right) \geq 0. \tag{11}$$

In Eq. (11) $\dot{Q}_{12}$ means the heat flow rate transferred from stream 1 to stream 2 and $T_{\mathrm{M,i}}$ means the logarithmic mean values of the thermodynamic inlet and outlet temperatures of stream $i = 1$ and 2:

$$T_{\mathrm{Mi}} = \frac{T_{\mathrm{i}}' - T_{\mathrm{i}}''}{\ln \frac{T_{\mathrm{i}}'}{T_{\mathrm{i}}''}}. \tag{12}$$

If stream 1 is the hot stream, $\dot{Q}_{12} > 0$ and $T_{\mathrm{M1}} > T_{\mathrm{M2}}$. If stream 1 is the cold stream, $\dot{Q}_{12} < 0$ and $T_{\mathrm{M1}} < T_{\mathrm{M2}}$.

The second and third term in Eq. (10) represent the exergy loss due to frictional pressure drop of stream $i = 1$ and 2, respectively. For gases this exergy loss is calculated according to

$$\dot{E}_{\mathrm{V},\Delta\mathrm{p,i}} = \dot{M}_{\mathrm{i}} R_{\mathrm{i}} \ln \frac{p_{\mathrm{i}}'}{p_{\mathrm{i}}''} \tag{13}$$

where R_{i} is the specific gas constant and p_{i}' and p_{i}'' are the gas pressures at the inlet and outlet of the heat exchanger. The following equation applies to liquids:

$$\dot{E}_{\mathrm{V},\Delta\mathrm{p,i}} = \frac{\dot{M}_{\mathrm{i}} \Delta p_{\mathrm{i}}}{\rho_{\mathrm{i}} T_{\mathrm{M,i}}} \tag{14}$$

with $\dot{M}_{\mathrm{i}}$ as the mass flow rate, ρ_{i} the density, $\Delta p_{\mathrm{i}} = p_{\mathrm{i}}' - p_{\mathrm{i}}''$ the absolute value of the pressure drop, and $T_{\mathrm{M,i}}$ the logarithmic mean value of the temperature according to Eq. (12).

Equating Eqs. (13) and (14) reveals that Eq. (14) can also be applied to gases provided the mean density is determined for the mean temperature according to Eq. (12) and the mean pressure

$$p_M = \frac{p' - p''}{\ln \frac{p'}{p''}}.$$

The considerations refer also to Eqs. (6) and (8).

Unlike the general exergy balance Eq. (9), Eqs. (10–14) allow the separate evaluation of exergy losses caused by heat transfer with finite temperature difference and those caused by frictional pressure drop on both sides. This becomes important if they are covered by exergy sources which are energetically unequal (e.g., fuel oil for the exergy loss caused by finite temperature differences and electrical energy for the exergy loss caused by pressure drop). This is not so important if all exergy losses are eventually covered by the same source as in heat exchangers of thermal power plants.

Thermophysical Properties

D1 Calculation Methods for Thermophysical Properties

Michael Kleiber[1] · *Ralph Joh*[2]
[1]Uhde GmbH, Bad Soden, Germany
[2]Siemens AG, Frankfurt, Germany

1 Introduction

For the description of the heat transfer, the knowledge of thermophysical properties is essential. They occur as parameters in particular equations and have usually a significant influence on the results. For example, the thermal conductivity, the dynamic viscosity, the density, and the specific heat capacity are important for the calculation of heat transfer in a single-phase forced convection.

In case of natural convection, the movement of the fluid is caused by temperature differences in the gravitational field. Therefore, the temperature-dependence of the density is important to know. If a phase change happens (condensation or evaporation), the vapor pressure curve is necessary to determine the temperature at the interface between the two phases. The enthalpy of vaporization then determines the heat flux, whereas the surface tension is an important parameter to describe the formation of such an interface, for example, the bubble formation in a vessel containing a boiling liquid. In fluid mixtures, the heat transfer is always connected with a simultaneous mass transfer, where the particular diffusion coefficients are decisive for the evaluation.

All these thermophysical properties depend on the thermodynamic state, which is characterized by two coordinates in the single-phase region. Normally, it is convenient to use temperature and pressure. The temperature-dependence is usually strong, whereas the dependence on the pressure is not negligible, but comparably weak. Only the density of gases is an exception. For mixtures, the dependence on the concentration has to be taken into account.

Values for thermophysical properties should, if possible, always be based on reliable experimental data. Extensive measurements have been performed for various technically important pure substances. These data have been collected in tables in Chap. D2, for example, for water, carbon dioxide, nitrogen, or air, which is often treated like a pure substance. High-precision equations of state have been developed and published for these substances, which ensure the reproduction of all thermodynamic quantities with extraordinary accuracy [1]. The structure of these equations is not based on physical relationships but on the numerical optimization of the terms contributing to the equation. For a large number of other substances, values and correlations are listed in Subchap. D3.1.

However, the heat transfer must often be determined in fluids for which no measured data are available. For multicomponent mixtures, this is even the normal case. Therefore,

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_10,

methods for the estimation of physical properties are required. In the following sections, a collection of simple correlation and estimation methods for the calculation of thermophysical properties of fluids is compiled.

2 Systematics of Calculation Methods

Physical properties are determined by the internal structure of the molecules and the intermolecular forces between them. Therefore, most of the practical calculation methods are based on considerations in the molecular scale. Nevertheless, the step from the molecular scale to measurable thermophysical properties is extremely difficult. An independent calculation of properties without using experimental data points will not be possible in the near future. Instead, the molecular theories deliver the structure of the calculation methods, and parameters of the particular methods are adjusted to experimental data. The calculation methods, which are established today, are a combination of a theoretically founded structure and parameters determined by experimental data.

It must be distinguished between correlation and estimation methods. The target of correlations is to reproduce a certain number of data points as exactly as possible, to interpolate between the data points safely and to extrapolate beyond the range covered by the data points in a reasonable way. Certainly, care must be taken for the latter case. Many correlations are so well established that the quality of the parameter adjustment can be taken as a consistency test, that is, data points are only accepted if the correlation can reproduce them within their experimental uncertainty.

In contrast, estimation methods shall predict thermophysical properties with or without a few experimental information available. Accuracy is not the main focus of estimation methods; it is more important that unacceptably high deviations from the true values are avoided.

In this chapter, only those estimation methods are listed, which can be recommended to a non-specialized user as a useful compromise between general applicability, accuracy in the sense mentioned above, and simplicity. The use of commercial programs is not necessary. All the calculation methods introduced are mainly founded on two basic elements, that is, the description of the structure of the molecules by group contribution methods and the calculation of molecular interactions by means of the principle of corresponding states.

Group contributions are contributions of the particular functional groups of a molecule to a thermophysical property. It is usually assumed that the contributions of the structural groups are independent of the kind of structural groups in the neighborhood. Then, comparably few structural groups can describe a huge number of chemical substances. The success of the group contribution methods demonstrates that the assumption mentioned above is reasonably justified.

The 3-parameter corresponding states principle is based on the assumption that intermolecular forces can be described by a generalized function, where the substance itself is characterized by few constant parameters. If a calculation function depending on these constants has been derived for a thermophysical property by adjustment to experimental data, this function can be applied to substances where the particular property is unknown. The use of the corresponding states principle is, in most cases, easier to perform than the use of group contributions.

For mixtures, the composition must be introduced into the calculation equations. Essentially, there are two ways to do that. If the pure component data are reliable, so-called mixing rules can be used to evaluate the mixture data from the pure component values. These mixing rules are different for each property, and there are also different forms for different thermodynamic states. Less frequently, mixing rules are applied to the characteristic property constants of the components involved. In this way, a pseudo-pure component is generated with property constants that depend on the concentration of the mixture. The properties of the mixture are then determined with the corresponding pure component methods.

Altogether, the combination of group contribution methods, the 3-parameter corresponding states principle and the mixing rules form a powerful but not perfect system of calculation methods for thermophysical properties of fluid substances.

For all generalized calculation methods, the structural formula is sufficient for the characterization of a substance. Especially, it allows the group assignment of a molecule with structural groups.

3 Characteristic Property Constants

Physical property estimation methods based on the 3-parameter corresponding states principle revert to the characteristic property constants critical temperature (T_c), critical pressure (p_c), and acentric factor (ω). These constants are mainly the basis of the cubic equations of state, which are valuable tools for the description of density and enthalpy of real gases. As the results of an estimation method mainly depend on the quality of the input data, it is worth to determine them carefully.

However, the evaluation of critical data is related with a huge experimental effort, not to mention the fact that many substances already decompose before the critical point can be reached. In these cases, estimation methods are necessary.

In the following section, a number of estimation methods for T_c, p_c, and ω are introduced. Other scalar properties such as normal boiling point (T_{NBP}), critical volume (v_c), melting point (T_m) and enthalpy of fusion (q_m), standard enthalpy of formation (Δh^{0f}), and standard Gibbs energy of formation (Δg^{0f}) as well as the dipole moment (μ), which are used in property estimation methods and process simulations, are also considered. In combination with the correlation and estimation methods for temperature-dependent properties, a system is formed where the optimal calculation method can be found to determine unknown properties with an arbitrary set of known data points for a substance. The extreme case would be to determine all the data required just on the basis of the structural formula as the only ensured information. This case occurs in practical applications; however, it should of course not be aspired, as uncertainties and error propagation might yield in bad results. The standard strategy should be to gain as much information as possible from databanks or experiments and to estimate only the missing information.

3.1 Critical Data

Critical temperature, critical pressure, and critical volume can be quite well-determined with group contribution methods. The methods of Joback [2] and Constantinou/Gani [3] are well-established in this area. A more complicated but accurate method has been developed by Rarey et al. [4].

The Joback method uses only the structural formula as input information. For the estimation of the critical temperature, the normal boiling point is additionally needed; if it is not known, it can be estimated from the structural formula as well (Sect. 3.3). The calculation equations are:

$$\frac{T_c}{K} = \frac{T_{NBP}}{K}\left[0.584 + 0.965\sum\Delta_T - \left(\sum\Delta_T\right)^2\right]^{-1} \quad (1)$$

$$\frac{p_c}{\text{bar}} = \left(0.113 + 0.0032\ n_A - \sum\Delta_p\right)^{-2} \quad (2)$$

$$\frac{v_c}{\text{cm}^3/\text{mol}} = 17.5 + \sum\Delta_v \quad (3)$$

The group contributions for Δ_T, Δ_p, and Δ_v can be taken from Table 1. n_A is the number of atoms in the molecule. The group assignment of the Joback method is simple, as the increments are directly listed. It is only distinguished between chain and ring increments; there is no difference between aromatic and aliphatic rings. It is worth mentioning that there are two kinds of OH groups for alcohols and phenols.

The Constantinou/Gani method uses only the structural formula for all quantities as input information. The authors have introduced the so-called second-order groups, where special configurations of structural groups are assigned with their own group contributions which can simply be added to the normal "first-order" groups. However, acceptable results can also be obtained using only the first-order groups; the improvement achieved with the second-order groups turned out to be relatively small in tests.

The calculation equations for the Constantinou/Gani method are:

$$\exp\frac{T_c}{181.128\ K} = \sum_i \Delta_{T,i} + \sum_j \Delta_{T,j} \quad (4)$$

$$\left(\frac{p_c}{\text{bar}} - 1.3705\right)^{-0.5} = 0.10022 + \sum_i \Delta_{p,i} + \sum_j \Delta_{p,j} \quad (5)$$

$$\frac{v_c}{\text{m}^3/\text{kmol}} = \sum_i \Delta_{v,i} + \sum_j \Delta_{v,j} - 0.00435 \quad (6)$$

where the indices i and j represent the first-order and the second-order groups, respectively. The group contributions for Δ_T, Δ_p, and Δ_v are listed in Tables 2 and 3. The first-order groups are molecular segments which can easily be assigned. Consistently, it is distinguished between aromatic (AC) and aliphatic carbon atoms. As mentioned above, the second-order groups are additive contributions to the first-order groups; they do not replace them.

The quality of the estimation is usually very good for the critical temperature; in most of the cases, the true value is met within a few *K*. Poling et al. [2] indicate an average error of 1.1% of the absolute temperature for the Joback method, if the normal boiling point is known. Only 1% of the test substances have an average error larger than 5%. The average error for the Constantinou/Gani method is reported to be somewhat higher (2.3%) due to the fact that the normal boiling point is not used as input information. Approximately, 11% of the tested substances had an average error larger than 5%. However, the Constantinou/Gani method is superior if the normal boiling point has to be estimated itself.

For the critical pressure, the average errors are reported according to Poling et al. [2] to be 4.6% (Joback) and 5.5% (Constantinou/Gani). As the case may be, these errors can be transferred to the estimation of the vapor pressure (Sect. 5) or to the accuracy of cubic equations of state (Sect. 4.2).

The critical volume is of less importance. It has an influence on the estimation of the density with the COSTALD method (Sect. 4.1), if no reference value is available. The average errors are reported to be 3.1% (Joback) and 3.7% (Constantinou/Gani).

The numbers reported for the average errors refer in all cases to molecules with more than three carbon atoms, since for substances with less carbon atoms property estimations do not make much sense, as usually experimental data are available.

As for the Constantinou/Gani method only the structural formula is used as input, it is also possible to take similar substances with known critical data as reference and to exchange or add only the differing structural groups. Often, but not in every case, this procedure results in an improvement. The target of this procedure is in fact to reduce the probability of a large error. An example is shown below.

If values for T_c, p_c, and v_c are available, it is strongly recommended to check the consistency of the values by calculating the critical compressibility factor

$$Z_c = \frac{p_c v_c}{\tilde{R} T_c} \quad (7)$$

Z_c is usually in the range $0.21 < Z_c < 0.29$.

Example 1:
Estimate the critical properties of m-xylene (Fig. 1). The normal boiling point is T_{NBP} = 412.25 K.

(a) Joback's method

The group assignment of m-xylene is given by:

4 x = CH– (ring)
2 x = C < (ring)
2 x –CH_3

The group contributions are:

$$\sum\Delta_T = 4\cdot(0.0082) + 2\cdot(0.0143) + 2\cdot(0.0141) = 0.0896$$

$$\sum\Delta_p = 4\cdot(0.0011) + 2\cdot(0.0008) + 2\cdot(-0.0012) = 0.0036$$

$$\sum\Delta_v = 4\cdot(41) + 2\cdot(32) + 2\cdot(65) = 358$$

Thus, the critical data can be calculated to be:

$$T_c = 412.25\,\text{K}/(0.584 + 0.965\cdot 0.0896 - 0.0896^2) = 622.32\,\text{K}$$

$$p_c = (0.113 + 0.0032\cdot 18 - 0.0036)^{-2}\text{bar} = 35.86\,\text{bar}$$

$$v_c = (17.5 + 358)\,\text{cm}^3/\text{mol} = 0.3755\,\text{m}^3/\text{kmol}$$

(b) Method of Constantinou/Gani

The group assignment of m-xylene is:

4 × ACH

2 × $ACCH_3$

Second-Order-Groups cannot be assigned.

The results for the group contributions are:

$$\sum \Delta_T = 4 \cdot (3.7337) + 2 \cdot (8.213) = 31.3608$$

$$\sum \Delta_p = 4 \cdot (0.007542) + 2 \cdot (0.01936) = 0.068888$$

$$\sum \Delta_v = 4 \cdot (0.04215) + 2 \cdot (0.10364) = 0.37588$$

C_4H_3S				5.7093		
C_4H_2S				5.8260		

The critical data can be calculated to be:

$$T_c = 181.128\,\text{K} \cdot \ln 31.3608 = 624.09\,\text{K}$$
$$p_c = [(0.10022 + 0.068888)^{-2} + 1.3705]\,\text{bar} = 36.34\,\text{bar}$$
$$v_c = (0.37588 - 0.00435)\,\text{m}^3/\text{kmol} = 0.37153\ \text{m}^3/\text{kmol}$$

(c) Method of Constantinou/Gani with toluene as reference substance

The critical data of toluene are:

$$T_c = 591.75\,\text{K},\ p_c = 41.1\,\text{bar},\ v_c = 0.3156\,\text{m}^3/\text{kmol}$$

A backwards calculation to obtain the group contributions of toluene (Fig. 2) yields:

$$\sum \Delta_{T,\text{toluene}} = \exp(591.75/181.128) = 26.233$$
$$\sum \Delta_{p,\text{toluene}} = (41.1 - 1.3705)^{-0.5} - 0.10022 = 0.05843$$
$$\sum \Delta_{v,\text{toluene}} = 0.3156 - 0.00435 = 0.31125$$

The difference in the structural formulas of toluene and m-xylene is that one ACH group has to be replaced by an $ACCH_3$ group. Thus, the group contributions for m-xylene can be determined to be:

$$\sum \Delta_T = 26.233 - (3.7337) + (8.213) = 30.7123$$
$$\sum \Delta_p = 0.05843 - (0.007542) + (0.01936) = 0.070248$$
$$\sum \Delta_v = 0.31125 - (0.04215) + (0.10364) = 0.37274$$

Therefore, the critical data can be estimated:

$$T_c = 181.128\,\text{K} \cdot \ln 30.7123 = 620.3\,\text{K}$$
$$p_c = [(0.10022 + 0.070248)^{-2} + 1.3705]\,\text{bar} = 35.78\,\text{bar}$$
$$v_c = (0.37274 - 0.00435)\,\text{m}^3/\text{kmol} = 0.36839\ \text{m}^3/\text{kmol}$$

The experimental values for m-xylene are:

$$T_c = 617.05\,\text{K}$$
$$p_c = 35.4\,\text{bar}$$
$$v_c = 0.37516\,\text{m}^3/\text{kmol}$$

For all the three calculation options, the agreement between estimated and experimental values is remarkably good. The check of the critical compressibility factor yields

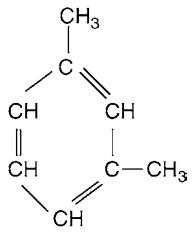
$$Z_c = \frac{35.4 \cdot 10^5 \cdot 0.37516 \cdot 10^{-3}}{8.3143 \cdot 617.05} = 0.259$$

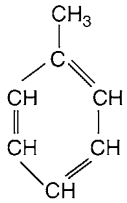
which is a reasonable value between 0.21 and 0.29.

3.2 Acentric Factor

The simple 2-parameter principle of corresponding states says that it is possible to set up a generalized equation of state valid



D1. Fig. 1. Structural formula of m-xylene.



D1. Fig. 2. Structural formula of toluene.

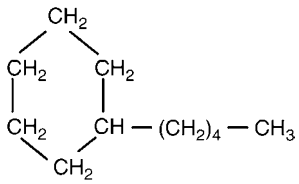
for all substances with only two specific parameters, for example, T_c and p_c. The success of this approach was limited to simple, spherical molecules like Ar, Kr, Xe, or CH_4, where vapor pressure and compressibility factor could be adequately reproduced. For other molecules, the 2-parameter principle of corresponding states yielded results with considerable deviations. Therefore, it was replaced by the extended 3-parameter principle of corresponding states, where a third parameter has been introduced, which gives additional information about the vapor pressure line. The most popular parameter of this kind is the acentric factor ω, which is defined as

$$\omega = -1 - \log_{10}\left(\frac{p_s}{p_c}\right)_{T/T_c=0.7} \tag{8}$$

Physically, ω takes into account the influence of the intermolecular forces depending on the orientation of the molecules. The parameter is used in many correlations for the estimation of thermophysical properties. Especially, ω is decisive for the application of cubic equations of state (Sect. 4.2). The definition given in Eq. (8) makes sense, as the vapor pressure is a quantity with high significance and accessibility. The reference temperature $T = 0.7\ T_c$ has been chosen because it is often in the neighborhood of the normal boiling point. An estimation of ω is therefore equivalent to an estimation of the vapor pressure curve or, respectively, the normal boiling point.

Although estimation methods for the acentric factor are available (e.g., group contribution method of Constantinou/Gani [5]), this concept is not recommended in this transaction, as it is, as mentioned above, a redundancy to the estimation of the normal boiling point. To avoid inconsistencies, it is instead recommended to evaluate ω directly via the definition Eq. (8) from the vapor pressure equation. If a vapor pressure equation is not available at all, it is still possible to estimate the normal boiling point (Sect. 3.3) and the critical point (Sect. 3.1) and to determine the vapor pressure curve as described in Sect. 5.

The acentric factor increases with the size of the molecule. Only in single cases, values $\omega > 1$ occur. Helium ($\omega = -0.39$) and hydrogen ($\omega = -0.216$), the so-called quantum gases, have negative acentric factors. Methane and the noble gases argon, krypton, xenon, and neon have values that are near zero. In other cases, $\omega \leq 0$ can strictly be excluded. If a value like this is evaluated, the conclusion must be that the vapor pressure curve or the critical point or both of them are wrong.



D1. Fig. 3. Structural formula of pentyl cyclohexane.

3.3 Normal Boiling Point

The normal boiling point is an easily accessible property and well known for a wide variety of substances. Even values from chemical catalogues, safety datasheets, or from the Internet (e.g., www.nist.gov) can give reasonable values, although high-precision data should not be expected.

In case no information is available, the normal boiling point (NBP) can be estimated using the methods of Joback [2] or Constantinou/Gani [3], analogously to the estimation of the critical temperature. The corresponding relationships are:

Joback:

$$T_{NBP}/\mathrm{K} = 198 + \sum \Delta_{NBP} \tag{9}$$

Constantinou/Gani:

$$\exp\frac{T_{NBP}}{204.359\ \mathrm{K}} = \sum_i \Delta_{NBP,i} + \sum_j \Delta_{NBP,j} \tag{10}$$

The corresponding group contributions can again be taken from Tables 1, 2 and 3. In both cases, the accuracy is much lower than for the estimation of the critical data.

As for the critical data, the possibility of taking a reference substance with a similar structure can be made use of. Because of the high uncertainties of the normal boiling point estimation, this procedure is strongly recommended if possible to avoid large errors.

Example 2:
Estimate the normal boiling point of pentyl cyclohexane (Fig. 3).

(a) Joback method

The group assignment of pentyl cyclohexane is:
- 5 × CH_2 (ring)
- 1 × CH (ring)
- 1 × CH_3
- 4 × CH_2

The group contribution can be added up to:

$$\sum \Delta_{NBP} = 5 \cdot (27.15) + 1 \cdot (21.78) + 1 \cdot (23.58) + 4 \cdot (22.88) = 272.63$$

Thus, the normal boiling point is calculated to be:

$$T_{NBP} = (198 + 272.63)\,K = 470.63\,K$$

(b) Method of Constantinou/Gani

The group assignment of pentyl cyclohexane is:

$9 \times CH_2$
$1 \times CH_3$
$1 \times CH$

As second-order groups can be assigned:

$1 \times$ 6 membered ring
$1 \times$ C-chain attached to ring

The sum of the group contributions is:

$$\sum \Delta_{NBP} = 9 \cdot (0.9225) + 1 \cdot (0.8894) + 1 \cdot (0.6033) + 1 \cdot (0.1957) + 1 \cdot (0.0511) = 10.042$$

The normal boiling point is determined to be:

$$T_{NBP} = 204.359\,K \cdot \ln 10.042 = 471.41\,K$$

(c) Joback method with methyl cyclohexane as reference substance

The normal boiling point of methyl cyclohexane (Fig. 4) is:

$$T_{NBP} = 373.95\,K.$$

To evaluate the sum of group contributions for methyl cyclohexane, a backward calculation yields:

$$\sum \Delta_{NBP,Methylcyclohexan} = 373.95 - 198 = 175.95$$

The difference in the structural formulas of pentyl cyclohexane and methyl cyclohexane is that four aliphatic CH_2-groups have been added. In this way, the sum of group contributions for pentyl cyclohexane can be determined to be:

$$\sum \Delta_{NBP} = 175.95 + 4 \cdot (22.88) = 267.47$$

Thus, what is obtained for the normal boiling point is:

$$T_{NBP} = (198 + 267.47)\,K = 465.47\,K$$

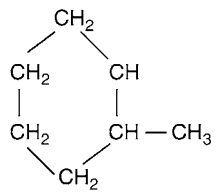
(d) Methode of Constantinou/Gani with methyl cyclohexane as reference substance

The normal boiling point of methyl cyclohexane is:

$$T_{NBP} = 373.95\ K.$$

For the group contributions of methyl cyclohexane, a backward calculation yields:

$$\sum \Delta_{NBP,Methylcyclohexan} = \exp(373.95/204.359) = 6.233$$



D1. Fig. 4. Structural formula of methyl cyclohexane.

The difference in the structural formulas of pentyl cyclohexane and methyl cyclohexane is that four aliphatic CH_2-groups have been added. Moreover, the contribution of the second-order group "C-chain attached to ring", which is only valid for $m > 1$, has to be supplemented. In this way, the sum of group contributions for pentyl cyclohexane can be evaluated to be:

$$\sum \Delta_{NBP} = 6.233 + 4 \cdot (0.9225) + 0.0511 = 9.9741$$

Thus, the result for the normal boiling point is:

$$T_{NBP} = 204.359\,K \cdot \ln 9.9741 = 470.02\,K$$

The experimental value for pentyl cyclohexane is: $T_{NBP} = 476.75$ K. All the methods shown above yield a reasonable result. Again, the use of a reference substance does not necessarily guarantee a better result, but it lowers the probability of a large error.

A new recommendable method for the estimation of the normal boiling point has been developed by Rarey et al. [6]. However, its group assignment is somewhat more complicated.

3.4 Melting Point and Enthalpy of Fusion

Besides normal boiling point and liquid density at 20°C, the melting point is the thermophysical property which can be found most frequently and is often found in chemical catalogues and handbooks. The estimation of melting points is a very complex task, as is determined both by the enthalpy of fusion, which depends on intermolecular forces, and by the entropy of fusion, which is a function of the symmetry of the molecule. Therefore, the applicability of group contribution methods is limited, as information about the molecular symmetry is lost if a group contribution concept is applied. Joback [2] lists, in fact, group contributions for the melting point; however, the average error is expected to be more than 20 K even for simple molecules, which is not acceptable for practical applications.

The enthalpy of fusion itself depends partly on the crystalline form that is transformed into a liquid, which can hardly be expressed in terms of mathematics for complex substances. In principle, the Clausius-Clapeyron equation can be applied, but information on the pressure dependence of the melting point is also usually missing. For aromatic compounds like benzene and naphthalene derivatives, the Walden rule [6, 7] can be applied:

$$\widetilde{M}\,\Delta h_m(T_m)/T_m \approx 13\ \text{cal}\cdot\text{K}^{-1}\cdot\text{mol}^{-1} = 54.4\ \text{J}\cdot\text{mol}^{-1}\cdot\text{K}^{-1} \quad (11)$$

3.5 Standard Enthalpy of Formation and Gibbs Energy of Formation

The enthalpy of formation Δh^{0f} and the Gibbs energy of formation Δg^{0f} are decisive for the calculation of enthalpies of reaction and chemical equilibria. For heat exchange calculations of chemical reactors, they are relevant as well, as these quantities determine the maximum possible product temperature or the heat to be removed. The reference state for Δh^{0f} and Δg^{0f} is $T_0 = 298.15$ K and $p_0 = 1$ atm in the ideal gas state.

In process simulation, the enthalpy of formation is also taken as the reference state for the calculation of enthalpies

(Sect. 6.4), so that these enthalpies are then consistent if chemical reactions are considered.

Further explanations, especially for the switch to liquid and solid phases, can be found in the textbook of J. Gmehling and B. Kolbe [8]. In both cases, the problem of the difference of large numbers has to be taken into account. Small relative deviations of Δh^{0f} or Δg^{0f} can cause severe errors when differences are calculated. Therefore, estimation methods for these quantities must be taken as rough numbers for orientation.

Analogously to the estimation of the critical data, the methods of Joback and Constantinou/Gani are recommended. The equations for calculation are:

Joback [2]:

$$\frac{\Delta h^{0f}}{\mathrm{kJ/mol}} = 68.29 + \sum \Delta_H \tag{12}$$

$$\frac{\Delta g^{0f}}{\mathrm{kJ/mol}} = 53.88 + \sum \Delta_G \tag{13}$$

Constantinou/Gani [3]:

$$\frac{\Delta h^{0f}}{\mathrm{kJ/mol}} = \sum_i \Delta_{H,i} + \sum_j \Delta_{H,j} + 10.835 \tag{14}$$

$$\frac{\Delta g^{0f}}{\mathrm{kJ/mol}} = \sum_i \Delta_{G,i} + \sum_j \Delta_{G,j} - 14.828 \tag{15}$$

where the second-order group concept is again applied. The group contributions for both methods can be found in Tables 1, 2 and 3.

Example 3:

Determine the enthalpy of formation and the Gibbs energy of formation for ethyl acetate with the Joback method (structural formula in Fig. 7).The group assignment of ethyl acetate is

2 × CH_3
1 × CH_2
1 × COO

Thus, one gets for the group contributions:

$$\sum \Delta_H = 2 \cdot (-76.45) + 1 \cdot (-20.64) + 1 \cdot (-337.92) = -511.46$$

$$\sum \Delta_G = 2 \cdot (-43.96) + 1 \cdot (8.42) + 1 \cdot (-301.95) = -381.45$$

The values finally obtained are:

$$\frac{\Delta h^{0f}}{\mathrm{kJ/mol}} = 68.29 - 511.46 = -443.17$$

$$\frac{\Delta g^{0f}}{\mathrm{kJ/mol}} = 53.88 - 381.45 = -327.57$$

The values obtained from databanks are $\Delta h^{0f} = -444.5$ kJ/mol and $\Delta g^{0f} = -328$ kJ/mol. The excellent agreement can be explained by the fact that ethyl acetate is very well known from esterification reactions.

3.6 Dipole Moment

For polyatomic molecules containing atoms with different electronegativity, the charge distribution can be asymmetric according to the geometry of the molecule. In the simplest case, this can be described as an electric dipole, which consists of two charges q of the same magnitude but with opposite sign, where the distance between them is r. The product of charge q and distance r is called dipole moment μ:

$$\mu = rq \tag{16}$$

As the charges are smaller than the elementary charge, that is, approximately 10^{-20} C, and the distances like an atom, that is, 10^{-10} m, the order of magnitude of dipole moments is 10^{-30} m. Usually, the unit debye is used:
1 debye = $3.3356 \cdot 10^{-30}$ Cm. Some values are given in Table 4.

For complex molecules, higher electrical moments may occur, for example, the quadrupolar moment, which consists of two pairs of charges with opposite sign. Dipole moments can be determined by measurement of the electric capacity or by molecular simulations.

D1. Table 4. Some numbers for the dipole moment

Substance	Formula	Dipole moment ($\mu/10^{-30}$ Cm)	Debye
Hydrogen chloride	HCl	3.44	1.03
Carbon monoxide	CO	0.40	0.12
Carbon dioxide	CO_2	0.00	0.00
Water	H_2O	6.00	1.80
Ammonia	NH_3	4.97	1.49
Methane	CH_4	0.00	0.00
Ethanol	C_2H_6O	5.67	1.70
Benzene	C_6H_6	0.00	0.00
Chlorobenzene	C_6H_5Cl	5.90	1.77
Nitrobenzene	$C_6H_5NO_2$	13.40	4.02

4 Density

4.1 Density of Liquids

The density of liquids is one of the most important quantities for equipment design. There are considerable demands on the accuracy. Simple equations of state do usually not fulfill these requirements; therefore, direct correlations for the liquid density on the saturation line are used. The most popular one is the Rackett equation

$$\frac{\rho_{liq}}{\mathrm{kg/m^3}} = \frac{A}{B^{1+\left(1-\frac{T/K}{C}\right)^D}} \tag{17}$$

Currently, the PPDS equation

$$\frac{\rho_{liq}}{\mathrm{kg/m^3}} = \frac{\rho_c}{\mathrm{kg/m^3}} + \left[A\left(1-\frac{T}{T_c}\right)^{0.35} + B\left(1-\frac{T}{T_c}\right)^{2/3} + C\left(1-\frac{T}{T_c}\right) + D\left(1-\frac{T}{T_c}\right)^{4/3}\right] \tag{17a}$$

is considered to be the most precise one. For this correlation, coefficients for approximately 270 substances are given in Subchap. D3.1.

For the estimation of liquid densities or, respectively, specific liquid volumes on the saturation line, the COSTALD equation [9] has been widely applied:

$$v_s = \tilde{\rho}^{-1} = v^* v_R^{(0)} \left[1 - \omega\, v_R^{(\delta)}\right] \tag{18}$$

$$v_R^{(0)} = 1 + a(1 - T_r)^{1/3} + b(1 - T_r)^{2/3} + c(1 - T_r) + d(1 - T_r)^{4/3};\ 0.25 < T_r < 0.95 \tag{19}$$

$$v_R^{(\delta)} = \left(e + fT_r + gT_r^2 + hT_r^3\right)/(T_r - 1.00001);\ 0.25 < T_r < 1.0 \tag{20}$$

$$T_r = T/T_c \tag{21}$$

where

$a = -1.52816$; $b = 1.43907$; $c = -0.81446$;
$d = 0.190454$; $e = -0.296123$; $f = 0.386914$;
$g = -0.0427458$; $h = -0.0480645$

The characteristic volume v^* is an adjustable parameter which can be fitted to one or more experimental data points. If no information is available, it is useful to replace it by the critical volume v_c, which often yields reasonable results.

Example 4:
Estimate the liquid density of n-hexane at $T = 293.15$ K with the COSTALD method:

The given data are:
$T_c = 507.5$ K
$v^* = v_c = 370$ cm^3/mol
$\omega = 0.299$
$M = 86.18$ g/mol
Using Eqs. (18)–(21), one can obtain:

$$v_R^{(0)} = 0.3799$$
$$v_R^{(\delta)} = 0.2277$$
$$v_s = 130.99\ \text{cm}^3/\text{mol} \Rightarrow \rho_{liq} = 657.9\ \text{kg/m}^3$$

The value given in the literature is 659 kg/m^3.

For a first approximation, liquids can be regarded as incompressible. If the pressure dependence plays a major role, the application of high-precision equations of state [1] would be desirable. If such an equation is not available, some equations for estimation are given in [2].

The evaluation of the density of liquid mixtures should be performed via the linear mixing rule for the specific volume:

$$v_{mix} = \sum_i \tilde{x}_i v_i \tag{22}$$

or, respectively:

$$\rho_{liq}^{mix} = \left(\sum_i x_i \rho_{liq,i}^{-1}\right)^{-1} \tag{23}$$

Equation (22) is not exact, as the mixture influence, the so-called excess volume, is neglected. However, the error of Eq. (22) can hardly be larger than 2–3%.

4.2 Density of Gases

At moderate pressures up to approximately 5 bar, the ideal gas law

$$pv = \tilde{R}T \tag{24}$$

can be used for the calculation of gas phase densities of non-associating compounds with sufficient accuracy.

At higher pressures, the cubic equations of state like Peng-Robinson [10] (PR) and Soave-Redlich-Kwong [11] (SRK) are well-suited for nonassociating compounds, as they are sufficiently accurate and comparably easy to apply. The equations are derived from the van der Waals equation and can be written as follows:

Peng-Robinson:

$$p = \frac{\tilde{R}T}{v - b} - \frac{a(T)}{v^2 + 2bv - b^2} \tag{25}$$

Soave-Redlich-Kwong:

$$p = \frac{\tilde{R}T}{v - b} - \frac{a(T)}{v^2 + bv} \tag{26}$$

It can be shown by mathematical rearrangement that these equations can be reduced to the search for the roots of a cubic function of the specific volume. In the subcritical region, they can deliver three real solutions for a given temperature and pressure, where the smallest solution describes the liquid phase and the largest solution represents the vapor phase. Nevertheless, the cubic equations are not suitable for the calculation of liquid densities, as long as no additional terms have been introduced into the equation [12]. The middle solution has no physical meaning. Above the critical point and at pressures far below saturation one gets one real and two complex solutions, where the real solution describes the fluid phase. The particular solutions can be obtained by application of the Cardanic formula [13] or by iteration.

To evaluate gas densities with the PR or the SRK equation, critical temperature, critical pressure and acentric factor have to be known. Using the reduced temperature $T_r = T/T_c$, the following relationships can be set up:

Peng-Robinson:

$$a(T) = a_c \alpha(T)$$
$$\alpha(T) = \left[1 + \left(0.37464 + 1.54226\omega - 0.26992\omega^2\right)\left(1 - T_r^{0.5}\right)\right]^2$$
$$a_c = 0.45724 \frac{\tilde{R}^2 T_c^2}{p_c} \tag{25a}$$
$$b = 0.0778 \frac{\tilde{R}T_c}{p_c}$$

Soave-Redlich-Kwong:

$$a(T) = a_c \alpha(T)$$
$$\alpha(T) = \left[1 + \left(0.48 + 1.574\omega - 0.176\omega^2\right)\left(1 - T_r^{0.5}\right)\right]^2$$
$$a_c = 0.42748 \frac{\tilde{R}^2 T_c^2}{p_c} \tag{26a}$$
$$b = 0.08664 \frac{\tilde{R}T_c}{p_c}$$

If these equations are applied to mixtures, the parameters can be calculated via the mixing rules

$$a_{\mathrm{mix}} = \sum_i \sum_j \tilde{y}_i \tilde{y}_j \left(a_{ii} a_{jj}\right)^{0.5} (1 - k_{ij}) \tag{27}$$

$$b_{\mathrm{mix}} = \sum_i \tilde{y}_i b_i \tag{28}$$

The binary parameters k_{ij} can be set to zero as long as phase equilibria are not involved (Part D). For the calculation of vapor densities, their influence is negligible.

Example 5:

Determine the vapor density of R22 (chlorodifluoromethane) at $T = 301.15$ K, $p = 11.308$ bar using the Peng-Robinson equation.

The following input data are given:

$T_c = 369.28$ K

$p_c = 49.88$ bar

$\omega = 0.221$

$\tilde{M} = 86.47$ g/mol

Thus, one gets the following coefficients:

$$\alpha(301.15\,\mathrm{K}) = \left[1 + \left(0.37464 + 1.54226 \cdot 0.221 - 0.26992 \cdot 0.221^2\right)\left(1 - (301.15/369.28)^{0.5}\right)\right]^2 = 1.1408$$

$$a_c = 0.45724 \frac{8.3143^2 \cdot 369.28^2}{49.88 \cdot 10^5} \frac{\mathrm{Pa \cdot m^6}}{\mathrm{mol^2}} = 0.864133 \frac{\mathrm{Pa \cdot m^6}}{\mathrm{mol^2}}$$

$$b = 0.0778 \frac{8.3143 \cdot 369.28}{49.88 \cdot 10^5} \frac{\mathrm{m^3}}{\mathrm{mol}} = 4.789 \cdot 10^{-5} \frac{m^3}{\mathrm{mol}}$$

$$a(301.15\,K) = a\alpha(301.15\,\mathrm{K}) = 0.98581 \frac{\mathrm{Pa \cdot m^6}}{\mathrm{mol^2}}$$

The Peng-Robinson equation can be rearranged to

$$f(Z) = Z^3 + Z^2\left(\frac{bp}{\tilde{R}T} - 1\right) + Z\left(\frac{ap}{\tilde{R}^2T^2} - 3\frac{p^2b^2}{\tilde{R}^2T^2} - 2\frac{pb}{\tilde{R}T}\right) + \frac{p^3b^3}{\tilde{R}^3T^3} + \frac{p^2b^2}{\tilde{R}^2T^2} - \frac{abp^2}{\tilde{R}^3T^3} = 0 \tag{29}$$

with Z as the compressibility factor $Z = pv/(RT)$. For this example, one gets:

$$f(Z) = Z^3 - 0.978372\ Z^2 + 0.133153\ Z - 0.003368 = 0$$

with the derivation

$$f'(Z) = 3\ Z^2 - 1.956744\ Z + 0.133153$$

The compressibility factor can then iteratively be determined either with the Cardanic formula or iteratively with Newton's method, where f and f' are evaluated with an estimated value for Z. As long as the results for Z and the estimated value do not sufficiently agree, the calculation is repeated with a new estimated value

$$Z_{n+1} = Z_n - \frac{f(Z)}{f'(Z)}$$

In this example, the calculation procedure is as follows, starting with an estimated value of $Z_0 = 1$ (ideal gas):

$Z_0 = 1$	$f(Z_0) = 0.15141$	$f'(Z_0) = 1.17641$	$Z_1 = 0.87129$
$Z_1 = 0.87129$	$f(Z_1) = 0.03136$	$f'(Z_1) = 0.70571$	$Z_2 = 0.82686$
$Z_2 = 0.82686$	$f(Z_2) = 0.00314$	$f'(Z_2) = 0.56629$	$Z_3 = 0.82123$
$Z_3 = 0.82131$	$f(Z_3) = 4.606.10^{-5}$	$f'(Z_3) = 0.54971$	$Z_4 = 0.82123$
$Z_4 = 0.82123$	$f(Z_3) = 1.043.10^{-8}$	$f'(Z_3) = 0.54946$	$Z_4 = 0.82123$ o.k.

The final result $Z = 0.82123$ corresponds to a specific volume $v = 0.0018184$ m³/mol and a density $\rho = 47.55$ kg/m³. The value obtained from a high precision equation of state is $\rho = 48.02$ kg/m³, corresponding to $v = 0.001801$ m³/mol and $Z = 0.81326$.

Strongly polar and associating substances show large deviations from the ideal gas behavior even at low pressures, which is not in line with the cubic equations of state. The reason for this deviation is the formation of dimers or higher associates in the vapor phase. In these cases, the chemical theory [8] is a good tool for the description of the vapor phase nonidealities. Its main assumption is that the association is comparable to a chemical reaction. Normally, it is sufficient to regard only the formation of dimers, as it is the case for carboxylic acids. An exception is hydrogen fluoride, where hexamers are formed. Besides the overall mole fraction $\tilde{y}$, a true mole fraction $\tilde{z}$ is defined, which considers the particular associates as own species.

For the formation of dimers (D) from monomers (M) the following reaction can be defined:

$$2M_i \leftrightarrows D_{ii}$$

The equilibrium of this reaction can be described with the law of mass actions:

$$K_D = \frac{f_D/f_D^0}{\left(f_M/f_M^0\right)^2} \tag{30}$$

using the standard fugacity

$$f_D^0 = f_M^0 = f^0 = 1\,\mathrm{bar} \tag{31}$$

The fugacity of a component i can be expressed with the fugacity coefficient φ_i, the true mole fraction $\tilde{z}_i$ and the pressure p:

$$f_i = \tilde{z}_i \varphi_i p \tag{32}$$

Thus, the equilibrium constant is given by:

$$K_D = \frac{\tilde{z}_D \varphi_D f^0}{\tilde{z}_M^2 \varphi_M^2 p} \tag{33}$$

Values for K_D can be obtained by the measurement of vapor densities and vapor heat capacities. K_D depends on the temperature and can be correlated by

$$\ln K_D = \left(A - \frac{B}{T}\right)\frac{f^0}{\mathrm{bar}} \tag{34}$$

In Table 5, some constants A and B for carboxylic acids are listed.

Furthermore, for the calculation of the true mole fractions of monomers and dimers the fugacity coefficients are necessary. At low pressures, the behavior of the particular species can be

D1. Table 5. Equilibrium constants for vapor phase association

Substance	Formula	A / bar^{-1}	B/K bar^{-1}
Formic acid	HCOOH	–18.117	–7099
Acetic acid	CH_3COOH	–17.374	–7290
Propionic acid	$CH_3–CH_2–COOH$	–18.347	–7635
Butanoic acid	$CH_3–CH_2–CH_2–COOH$	–16.636	–7000

considered to be ideal, that is, $\varphi_M = \varphi_D = 1$. With this assumption, one gets:

$$K_D^* = \frac{K_D p}{f^0} = \frac{\tilde{z}_D}{\tilde{z}_M^2} \tag{35}$$

As the sum of the true mole fractions must be 1

$$\tilde{z}_D + \tilde{z}_M = 1 \tag{36}$$

one gets for given temperature and pressure

$$\tilde{z}_M^2 K_D^* = 1 - \tilde{z}_M \tag{37}$$

or, respectively,

$$\tilde{z}_M = \frac{\sqrt{1 + 4K_D^*} - 1}{2K_D^*} \tag{38}$$

The specific volume can then be determined by

$$v = \frac{\tilde{M}}{\rho} = \frac{\tilde{R}T}{p} \frac{1}{\tilde{z}_M + 2\tilde{z}_D} \tag{39}$$

Example 6:
Calculate the vapor density of acetic acid (AA) at the normal boiling point (T_{NBP} = 391.35 K).

Given data:
Association constants: A = −17.374 bar^{-1}, B = −7290 K bar^{-1}
Standard fugacity f^0 = 1bar
$\tilde{M}_{AA}$ = 60.05 g/mol
The results are:
K_D = 3.504
K_D* = 3.55
$\tilde{z}_M$ = 0.408
$\tilde{z}_D$ = 0.592
and finally, for the specific volume:

$$v = \frac{\tilde{M}}{\rho} = \frac{8.3143 \cdot 391.35}{101325} \frac{1}{0.408 + 2 \cdot 0.592} \text{m}^3/\text{mol}$$
$$= 0.0202\,\text{m}^3/\text{mol} \Rightarrow \rho = 2.977\,\text{kg/m}^3$$

This result is in line with experimental values and exceeds the result obtained with the ideal gas equation by approximately 60%.

4.3 Coefficient of Thermal Expansion

The coefficient of thermal expansion β is defined as

$$\beta = \frac{1}{v} \frac{\Delta v}{\Delta T} \tag{40}$$

At standard conditions (273.15 K, 1.01325 bar), the coefficient of thermal expansion for ideal gases is

$$\beta = 1/273.15\text{K}^{-1}.$$

Example 7:
At p = 1.013 bar and T = 273.15 K, the specific volume of helium is 0.02242 m^3/mol. To which extent will the specific volume increase, if the gas is heated up by ΔT = 100 K?

$$\Delta v = v \cdot \frac{1}{273.15\ \text{K}} \cdot \Delta T = 0.008207\text{m}^3/\text{mol}$$

5 Vapor Pressure

For many process calculations, the vapor pressure is the most important quantity. It is decisive for the determination of the number of separation stages of distillation columns and for the evaluation of temperature profiles in general. Therefore, data should be carefully searched, measured and correlated. Additionally, a good vapor pressure curve is helpful for the estimation of other thermophysical properties, especially of the enthalpy of vaporization (Sect. 6.1).

Good data points for the vapor pressure should be correlated with deviations considerably less than 1%, the average deviation of a good data set should be by far less than 0.5%. Values with deviations greater than 1% should be regarded as outliers and removed from the database, as long as enough other data points are available.

Exceptions are values below approximately 1 mbar, as their accuracy is much lower. It is recommended to set their weighting factor in the regression to 0 but keep an eye on the correct order of magnitude, when the vapor pressure curve is extrapolated to low temperatures.

Vapor pressure curves are strictly monotonically increasing. They exist between triple point and critical point of a particular substance, where a vapor–liquid equilibrium is possible.

For the description of vapor pressures several equations are available. The most frequently used one is the Antoine equation with three adjustable parameters

$$\ln \frac{p_s}{\text{Pa}} = A + \frac{B}{T + C} \tag{41}$$

It is appropriate for the reproduction of data sets within a certain temperature range. For thermodynamic reasons, both B and C must have a negative sign. There are many different notations in the literature, which has always to be taken into account.

The Antoine equation (41) is well-known for its bad extrapolation behavior. The temperature range from the triple point to the critical point cannot be covered with sufficient accuracy. Often two equations are given for vapor pressures below and above 1 atm; however, such an approach usually implies a discontinuity in the junction point. There is a singularity at $T = -C$, and in the vicinity of this point the application of the Antoine equation does not make sense.

The Wagner equation [14]

$$\ln \frac{p_s}{p_c} = \frac{1}{T_r} \left[A(1 - T_r) + B(1 - T_r)^{1.5} + C(1 - T_r)^3 + D(1 - T_r)^6 \right] \tag{42}$$

with

$$T_r = T/T_c \tag{42a}$$

can describe the whole temperature range from the triple point to the critical point and should be applied for the precise adjustment of good data in sufficient quantity. The correct reproduction of the critical point is ensured by the mathematical form of Eq. (42). The only weakness of the equation is the extrapolation to low temperatures. In most cases, the ranges of the coefficients are

$$A = -9 \ldots -5$$
$$B = -10 \ldots 10$$
$$C = -10 \ldots 10$$
$$C = -20 \ldots 20$$

If these conditions are not fulfilled, a critical check of the data should take place, especially for the critical point used. Further constraints and many good parameter sets have been set up by McGarry [15].

In the recent years, the so-called 3-6-form (Eq. (42); the numbers refer to the exponents of the last two terms) has mostly been replaced by the 2.5-5-form, which is considered to be slightly more accurate:

$$\ln\frac{p_s}{p_c} = \frac{1}{T_r}\left[A(1-T_r) + B(1-T_r)^{1.5} + C(1-T_r)^{2.5} + D(1-T_r)^5\right] \quad (42c)$$

The reasonable ranges for the coefficients stay the same. For Eq. (42c), coefficients for 275 substances are given in Subchap. D3.1.

The estimation of vapor pressures is one of the most difficult problems in thermodynamics. There are several methods based on the 3-parameter principle of corresponding states or group contributions [16–18]. A new method developed by Rarey et al. [19] yields good results but is difficult to apply.

One of the most reliable methods is the application of the vapor pressure curve of Hoffmann-Florin [20], which has only two adjustable parameters:

$$\ln\frac{p_s}{\mathrm{Pa}} = A + Bf(T) \quad (43)$$

with

$$f(T) = \frac{1}{T/\mathrm{K}} - 7.9151\cdot 10^{-3} + 2.6726\cdot 10^{-3}\log_{10}\frac{T}{\mathrm{K}} - 0.8625\cdot 10^{-6}\frac{T}{\mathrm{K}} \quad (43a)$$

The equation can be fitted to two or more experimental data points. As a correlation equation it is not very accurate, but its extrapolation behavior is supposed to be quite good. Especially, it is superior to the widely used simplified Antoine equation with $C = 0$ in Eq. (41). If only one or, in the extreme case, no data point is available, normal boiling point and/or critical point can be estimated, and the parameters A and B can be adjusted to these artificial data. It should be emphasized that the two points for adjustment must be far away from each other to obtain significant coefficients.

For two arbitrarily given data points of the vapor pressure curve (T_1,p_{s1}), (T_2,p_{s2}), the coefficients of the Hoffmann-Florin equation can be determined to be

$$A = \ln\frac{p_{s1}}{\mathrm{Pa}} - \ln\frac{p_{s1}}{p_{s2}}\cdot\frac{f(T_1)}{f(T_1)-f(T_2)} \quad (44)$$

$$B = \frac{\ln(p_{s1}/p_{s2})}{f(T_1)-f(T_2)} \quad (45)$$

Because of the exponential relationship between vapor pressure and temperature, a high accuracy in the estimation of vapor pressures should not be expected. Deviations of 5% have to be regarded as excellent. For the assessment of a vapor pressure estimation method, the number of substances where the method yields completely unusable results is decisive. In this context, especially, the method described above has considerable advantages in comparison with several group contribution methods.

Example 8:
Estimate the vapor pressure of chloroform at $t = -41.7°C$, $t = 4.5°C$, and $t = 120.1°C$. Using the Joback method, the estimated values for normal boiling point and critical point are:
$T_{NBP} = 334.13$ K (true value: 334.26 K)
$T_c = 532.11$ K (true value: 536.45 K)
$p_c = 49.8$ bar (true value: 55.54 bar)
With
$T_1 = 334.13$ K
$p_{s1} = 1.01325$ bar
$T_2 = 532.11$ K
$p_{s2} = 49.8$ bar
we get
$A = 19.5596$
$B = -5233.61$
The results are:
$p_s(-41.7°C) = 5.69$ mbar
$p_s(4.5°C) = 99.94$ mbar
$p_s(120.1°C) = 5.18$ bar
The values calculated with the Wagner equation (Subchap. D3.1) are $p_s = 5.04$ mbar ($t = -41.7°C$), $p_s = 100$ mbar ($t = 4.5°C$), and $p_s = 5.01$ bar ($t = 120.1°C$). As in this case, the quality of the normal boiling point or another reference value is usually decisive. The relatively large error in the critical pressure does not have a large influence in this example.

The estimation of vapor pressures of mixtures does not make sense physically, as the concentrations of the vapor and liquid are different. Moreover, boiling point and dew point of a mixture are not identical. Azeotropic mixtures are often treated as a pure substance, but even this is only valid within a certain temperature range, as the azeotropic composition is temperature-dependent. The vapor–liquid equilibria of mixtures are explained in Subchap. D5.1.

6 Enthalpy Determination

Enthalpies are the key quantity for heat transfer problems, as the difference of the enthalpies of the particular streams determines the energy balance of the process and therefore the state of the outlet streams. Enthalpy changes can be caused:

- By a phase change. The most important one is the vapor–liquid transition, which is determined by the enthalpy of vaporization.
- By heating or cooling of a homogeneous phase. In this case, the most important quantity is the heat capacity of the particular phase.

- By pressure change of a phase, which is, however, only relevant for gases.
- By mixing or separating mixture components.
- By chemical reaction.

All of these processes can run in parallel, for example, in a heat exchanger with high pressure drop. Therefore, a thermodynamically consistent enthalpy description, which connects the vapor and the liquid region, is needed. This enthalpy is then calculated using the standard enthalpy of formation as the starting point to make the enthalpy consistent with respect to chemical reactions, the specific heat capacities of liquid and ideal gas, the enthalpy of vaporization, and the real gas correction. The difficulty is that the two heat capacities are not independent from each other and can be calculated in different ways. The consequences are explained in Sect. 6.5.

6.1 Enthalpy of Vaporization

In Fig. 5, typical curvatures of the enthalpy of vaporization as a function of temperature are given. It is a strictly monotonic decreasing function, at low temperatures with a small slope, at high temperatures with an increasing slope. At the critical point, vapor and liquid become identical, and the enthalpy of vaporization approaches zero. A different curvature is shown by substances with association in the vapor phase, where a more or less well-defined maximum occurs (e.g., formic acid in Fig. 5).

Enthalpies of vaporization can be very well correlated with the extended Watson equation

$$\frac{\Delta h_v}{\mathrm{J/kg}} = A\,(1 - T_r)^{B+CT_r+DT_r^2+ET_r^3} \tag{46}$$

with

$$T_r = T/T_c \tag{46a}$$

The order of magnitude of their deviation should be approximately 0.5%; at temperatures in the vicinity of the critical point, where the values are low and the slopes are large, higher deviations can be accepted. The parameters C, D, and E are needed only for a good data situation; otherwise, they could be set to zero. If $C = D = E = 0$, $B = 0.38$ is often a good first guess.

For high precision data, the PPDS equation

$$\Delta h_v = RT_c(A\tau^{1/3} + B\tau^{2/3} + C\tau + D\tau^2 + E\tau^6) \tag{46b}$$

with

$$\tau = 1 - T/T_c \tag{46c}$$

is a very useful correlation tool. In Subchap. D3.1, this equation has been fitted to approximately 275 substances.

There is a peculiarity for the estimation of the enthalpy of vaporization. The Clausius-Clapeyron equation

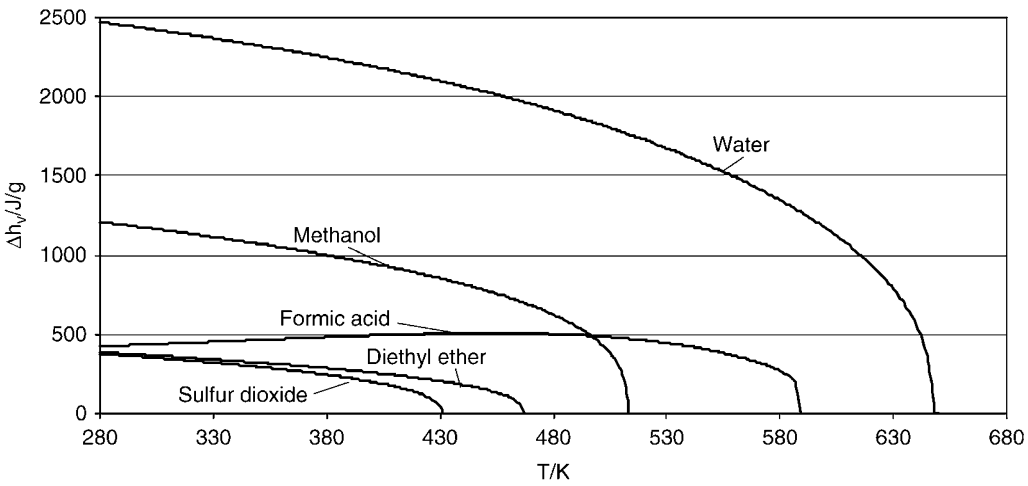
$$\Delta h_v = T\,(v'' - v')\,\frac{\mathrm{d}p_s}{\mathrm{d}T} \tag{47}$$

is an exact thermodynamic relationship, using the easily available quantities vapor pressure curve, bubble point volume, and dew point volume. In fact, most of the data points available have been evaluated this way and not by direct measurement.

However, there are some restrictions for the application of the Clausius-Clapeyron equation in practical applications. It is important to check that only the temperature range is considered where the vapor pressure curve is validated. The most important vapor pressure equations Wagner (Eqs. (42) and (42c)) and Antoine (Eq. (41)) extrapolate badly to low temperatures. Even if data points are available, the relative errors, which of course have an influence on the slope, are often still quite large. As a rule of thumb, it is recommended not to apply the Clausius-Clapeyron equation for vapor pressures $p_s < 1$ mbar.

The term $(v'' - v')$ is decisive for the accuracy. v' is negligible in comparison with v'' with the exception of the region just below the critical point. Moreover, in this region the quality of the correlations for the liquid density is low. If v'' is determined with the ideal gas equation, the error can be tolerated in the low pressure region, but the curve has a concave curvature instead of a convex one, which becomes less and less acceptable when the saturation pressure increases.

Therefore, v'' is usually calculated with a cubic equation of state (Sect. 4.2). From test calculations, it can be concluded that



D1. Fig. 5. Curvature of the enthalpy of vaporization as a function of temperature.

an error of 1%...2% might occur. In the region just below the critical point, the deviations are larger. As both v'' and v' are much less accurate in the vicinity of the critical point and the term $(v''–v')$ behaves as a difference of large numbers, the application of the Clausius-Clapeyron equation should be excluded in this area. As a rule of thumb, the application should be restricted to $T < T_c - 30$ K.

Values outside the application range of the Clausius-Clapeyron equation can be estimated by correlating values generated with the Clausius-Clapeyron equation in the valid range with Eq. (46) or (46b) and extrapolate this equation towards the critical point. For associating substances, it should be taken into account that the chemical theory (Sect. 4.2) is not valid for high pressures.

In case no information is available, one can estimate the normal boiling point (Sect. 3.3) and critical point (Sect. 3.1). Then, a vapor pressure curve could be estimated with the Hoffmann-Florin equation. The acentric factor can also be determined by its definition (Eq. 8). Thus, all information for the application of the Clausius-Clapeyron equation is available.

Example 9:
Estimate the enthalpy of vaporization of acetone at $t = 0°C$. The following values are given:

$\rho_{liq} = 812.9$ kg/m^3, $T_c = 508.1$ K, $p_c = 46.924$ bar, $\omega = 0.3064$, $M = 58.08$ g/mol

Wagner-coefficients $A = -7.67033$, $B = 1.96469$, $C = -2.4438$, $D = -2.90162$ (Eq. (42c))

The vapor pressure at $t = 0°C$ can be determined with the Wagner equation to be $p_s = 0.093$ bar. The specific volumes are:

$v' = 7.145 \cdot 10^{-5}$ m^3/mol

$v'' = 0.2431$ m^3/mol (from Peng-Robinson equation)

The derivative of the modified Wagner Equation (42c) is:

$$\frac{dp_s}{dT} = -\frac{p_s}{T}\left[\ln\frac{p_s}{p_c} + A + 1.5\,B\,(1-T_r)^{0.5} + 2.5\,C\,(1-T_r)^{1.5} + 5\,D\,(1-T_r)^4\right] \quad (48)$$

At $t = 0°C$, the result is $dp_s/dT = 492.84$ Pa/K. Thus, one gets:

$$\Delta h_v = 273.15\,\text{K} \cdot (0.2453 - 7.145 \cdot 10^{-5})\,\text{m}^3/\text{mol} \cdot 492.84\,\text{Pa/K} = 32721\ \text{J/mol} = 563.4\ \text{J/g}$$

The value listed in Subchap. D3.1 is 558.9 J/g. The deviation is 0.8%.

For mixtures, an enthalpy of vaporization is not a useful quantity, as during the vaporization temperatures, the compositions of both vapor and liquid vary. For reasonable calculations, it is recommended that the calculation of the energy balance be performed by determining the exact enthalpy differences according to Sect. 6.4.

For an isothermal evaporation, a linear mixing rule can be applied as an approximation:

$$\Delta h_{v,Gem} = \sum_i \tilde{x}_i\,\Delta h_{vi} \quad (49)$$

For the isobaric evaporation, Eq. (49) is not appropriate at all, as the enthalpies of vaporization would then have to be evaluated at their particular boiling temperatures, and the temperature increase of the liquid is not taken into account.

6.2 Specific Heat Capacity of Ideal Gases

The specific heat capacity of ideal gases is a measure of the capability of a molecule to store energy. c_p^{id} is defined as the heat a molecule must be exposed to at constant pressure to achieve a certain change in temperature. It must be strongly distinguished between the isobaric specific heat capacity c_p^{id} at constant pressure and the isochoric specific heat capacity c_v^{id} at constant volume. Both quantities are related by

$$c_v^{id} = c_p^{id} - R \quad (50)$$

The following considerations are focusing on the specific isobaric heat capacity. It depends only on temperature and increases in a strictly monotonic way.

In general, there are two contributions to c_p^{id}: the temperature-independent one describing the kinetic energy and the rotational energy of the molecules, and a vibration contribution, which is only activated at high temperatures and that causes the temperature-dependence of the molecule [21, 22]. If a molecule consists only of 1 atom (He, Ne, Ar, Kr, Xe), the vibration and the rotational contributions are zero, and c_p^{id} is constant.

Typical curvatures of c_p^{id} as a function of temperature are depicted in Fig. 6. On the left hand side, only the constant contributions for the kinetic and for the rotational contributions are active. Then, the function increases monotonically until all the vibration options in the molecules are fully active. Then, the function becomes constant again.

The curvature can be well represented with the Aly-Lee equation [23], which is based on statistical thermodynamics:

$$\tilde{c}_p^{id} = A + B\left(\frac{C/T}{\sinh(C/T)}\right)^2 + D\left(\frac{E/T}{\cosh(E/T)}\right)^2 \quad (51)$$

During the recent years, a PPDS equation

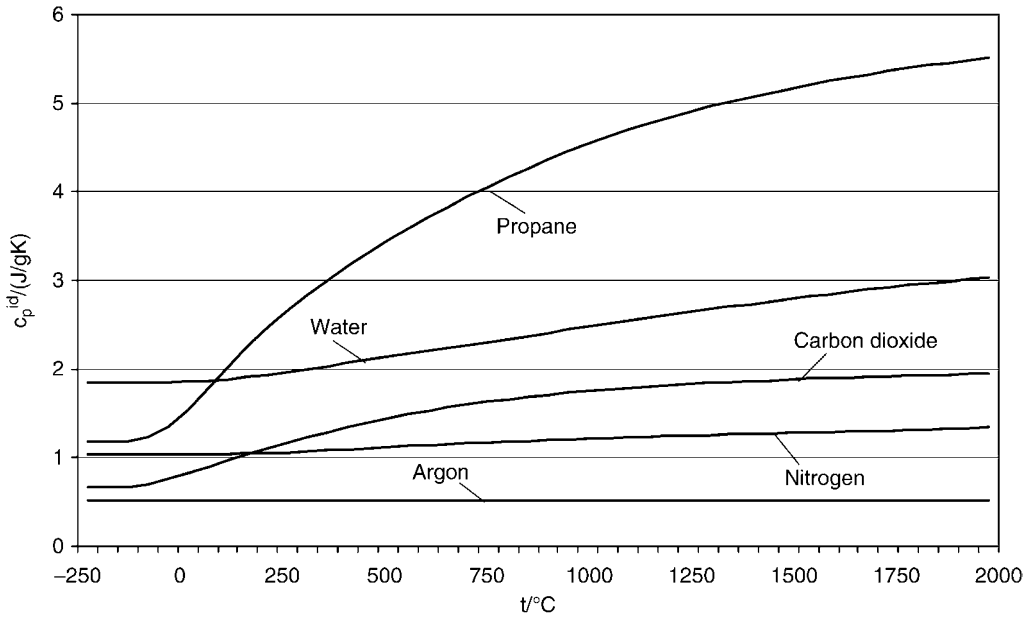
$$\frac{c_p^{id}}{R} = B + (C-B)\left(\frac{T}{A+T}\right)^2 \left[1 - \frac{A}{A+T}\left(D + E\frac{T}{A+T} + F\left(\frac{T}{A+T}\right)^2 + G\left(\frac{T}{A+T}\right)^3\right)\right] \quad (51a)$$

has been widely applied and proved to yield good results. Its disadvantage is the increased number of adjustable parameters. Equation (51a) has been used in Subchap. D3.1 for 275 substances.

Acceptable results can also be obtained with a simpler equation like

$$\frac{c_p^{id}}{\text{J/kg K}} = A + B\frac{T}{K} + C\left(\frac{T}{K}\right)^2 + D\left(\frac{T}{K}\right)^3 + \frac{E}{(T/K)^2} \quad (52)$$

although the extrapolation capability is weak, especially toward low temperatures. However, for most of the process engineering applications the quality of Eq. (52) should be sufficient. The last term is often omitted, leaving a polynomial of degree 3.



D1. Fig. 6. Typical curvatures of the specific isobaric heat capacity of ideal gases.

$$CH_3–COO–CH_2–CH_3$$

D1. Fig. 7. Structural formula of ethyl acetate.

The estimation of the specific isobaric heat capacity of ideal gases can be performed with Joback's group contribution method. The particular group contributions form the coefficients of a 3rd degree polynomial:

$$\frac{\tilde{c}_p^{id}}{\mathrm{J/mol\,K}} = \left(\sum \Delta_A - 37.93\right) + \left(\sum \Delta_B + 0.21\right) \cdot (T/K) + \left(\sum \Delta_C - 3.91 \cdot 10^{-4}\right) \cdot (T/K)^2 + \left(\sum \Delta_D + 2.06 \cdot 10^{-7}\right) \cdot (T/K)^3 \quad (53)$$

The corresponding coefficients for the group contributions are listed in Table 6. Relatively small deviation of approximately 1%. . .2% can be expected. The deviations become larger with increasing complexity of the molecule.

Example 10:
Determine the specific isobaric heat capacity of ethyl acetate in the ideal gas state at $t = 25°C$.
The molecular weight of ethyl acetate is $M = 88.11$ g/mol.
The group assignment of ethyl acetate is:
$2 \times CH_3$
$1 \times CH_2$
$1 \times COO$
The group contributions are:

$$\sum \Delta_A = 2 \cdot (19.5) + 1 \cdot (-0.909) + 1 \cdot (24.5) = 62.591$$

$$\sum \Delta_B = 2 \cdot (-8.08 \cdot 10^{-3}) + 1 \cdot (9.5 \cdot 10^{-2}) + 1 \cdot (4.02 \cdot 10^{-2}) = 0.11904$$

$$\sum \Delta_C = 2 \cdot (1.53 \cdot 10^{-4}) + 1 \cdot (-5.44 \cdot 10^{-5}) + 1 \cdot (4.02 \cdot 10^{-5}) = 2.918 \cdot 10^{-4}$$

$$\sum \Delta_D = 2 \cdot (-9.67 \cdot 10^{-8}) + 1 \cdot (1.19 \cdot 10^{-8}) + 1 \cdot (-4.52 \cdot 10^{-8}) = -2.267 \cdot 10^{-7}$$

The result for c_p^{id} is

$$\frac{\tilde{c}_p^{id}}{\mathrm{J/mol\,K}} = (62.591 - 37.93) + (0.11904 + 0.21) \cdot (298.15) + \left(2.918 \cdot 10^{-4} - 3.91 \cdot 10^{-4}\right) \cdot (298.15)^2 + \left(-2.267 \cdot 10^{-7} + 2.06 \cdot 10^{-7}\right) \cdot (298.15)^3 = 113.397$$

or $c_p^{id} = 1.287$ J/gK, respectively. The true value is considered to be 1.290 J/gK.

The thermodynamically exact mixing rule for mixtures of ideal gases is

$$\tilde{c}_{p,mix}^{id} = \sum_i \tilde{x}_i \tilde{c}_{p,i}^{id} \quad (54)$$

6.3 Real Gas Corrections

With increasing pressure, intermolecular forces play a more and more important role in the calculation of the enthalpy of gases. Usually, these forces are attractive so that energy is needed to increase the distance between the molecules. If this energy is not supplied, the substance cools down during the expansion. A famous example is the liquefaction of air by adiabatic throttling. To take these effects into account, the ideal gas heat capacity on its own is not sufficient.

The difference of enthalpies between the ideal gas state at $p = 0$ and a state at an arbitrary pressure is called the residual part of the enthalpy. It can be evaluated for nonassociating

D1. Table 6. Group contribution for c_p^{id} according to Joback

substances by cubic equations of state. The corresponding expressions are:

Peng-Robinson equation:

$$\Delta h_{\text{Gas}}^{\text{real}} = \widetilde{h}(T,p) - \widetilde{h}(T,p=0) = \widetilde{R}T(Z-1) - \frac{1}{\sqrt{8}b}\left(a - T\frac{\partial a}{\partial T}\right)\ln\left(\frac{v+(1+\sqrt{2})b}{v+(1-\sqrt{2})b}\right) \tag{55}$$

Soave-Redlich-Kwong equation:

$$\Delta h_{\text{Gas}}^{\text{real}} = \widetilde{h}(T,p) - \widetilde{h}(T,p=0) = \widetilde{R}T(Z-1) - \frac{1}{b}\left(a - T\frac{\partial a}{\partial T}\right)\ln\left(\frac{v+b}{v}\right) \tag{56}$$

The residual part of the specific heat capacity of gases can be calculated by the derivatives of Eqs. (55) and (56):

$$\Delta c_{\text{p,Gas}}^{\text{real}} = \left(\frac{\partial \Delta h_{\text{Gas}}^{\text{real}}}{\partial T}\right)_{\text{p}} \tag{57}$$

As it yields a very complicated expression, it is recommended to perform the differentiation in Eq. (57) numerically.

Taking into account the residual part of the enthalpy is important especially for associating substances. Considering only the dimerization of molecules of the same kind, the residual part can be evaluated with the association model described in Sect. 4.2:

$$\Delta h_{\text{Gas,Ass.}}^{\text{real}} = \frac{\widetilde{z}_{\text{D}}\Delta h_{\text{D}}}{\widetilde{z}_{\text{M}} + 2\,\widetilde{z}_{\text{D}}} \tag{58}$$

with

$$\Delta h_{\text{D}} = \widetilde{R} f^0 B \tag{59}$$

where B is the coefficient in Eq. (34). This calculation is quite complicated, as first the true concentrations must be evaluated via Eqs. (36) and (38). The residual part of the specific heat capacity must again be determined by numerical differentiation. For illustration, Fig. 8 shows the specific isobaric heat capacities of acetic acid vapor with and without consideration of the residual part.

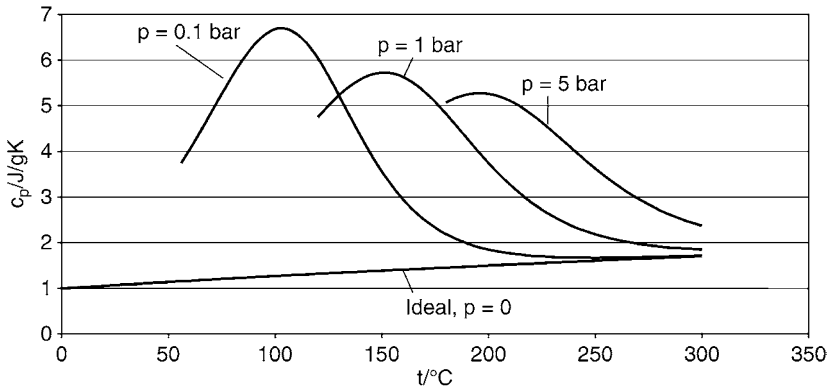
6.4 Specific Heat Capacity of Liquids

The specific isobaric heat capacity of liquids ($c_{\text{p}}^{\text{liq}}$) is a function of temperature. The pressure dependence is usually negligible. Isobaric and isochoric heat capacity differ significantly, as in the isobaric case work has to be spent to increase the distance between the molecules. At low temperatures (approximately up to the normal boiling point), $c_{\text{p}}^{\text{liq}}$ is an almost linear function of temperature. At higher temperatures, the slope increases. In many cases, a flat minimum is formed (Fig. 9). At the critical point, the specific heat capacity of a liquid becomes infinity.

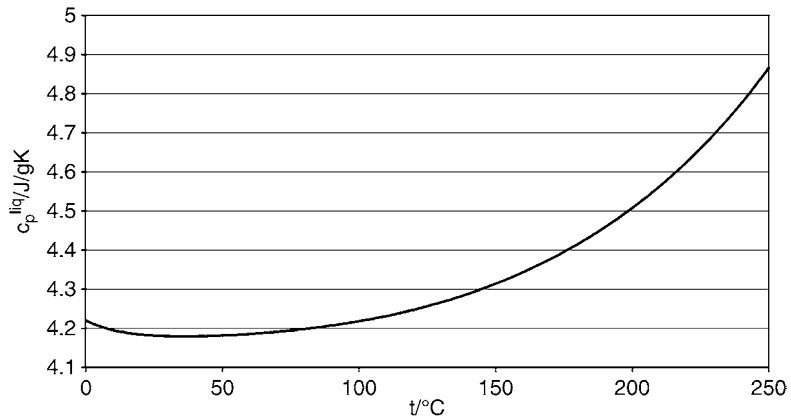
For a boiling liquid, as it often occurs in process engineering, the specific isobaric heat capacity is not a useful quantity, as the heating at constant pressure would result in evaporation and not in temperature increase. For practical applications, a "specific heat capacity along the saturation line" (c_σ) is used, without distinguishing these quantities in the colloquial language. The relationship is

$$\widetilde{c}_\sigma = \widetilde{c}_{\text{p}} + \left[v - T\left(\frac{\partial v}{\partial T}\right)_{\text{p}}\right]\frac{\text{d}p_s}{\text{d}T} \tag{60}$$

The difference between both heat capacities is only relevant for high temperatures. As a rule of thumb, it can be neglected



D1. Fig. 8. Specific isobaric heat capacity of acetic acid vapor at various pressures.



D1. Fig. 9. Specific heat capacity of liquid water as a function of temperature.

for $T < 0.8\ T_c$. The difference can be estimated with the equation

$$\tilde{c}_\sigma = \tilde{c}_p^{liq} - \tilde{R}\ \exp(20.1\ T_r - 17.9) \tag{61}$$

The liquid heat capacity can be correlated with an extended polynomial

$$\frac{c_p^{liq}}{J/kgK} = A + B\frac{T}{K} + C\left(\frac{T}{K}\right)^2 + D\left(\frac{T}{K}\right)^3 + \frac{E}{(T/K)^2} \tag{62}$$

For more precise calculations, the PPDS equation can be used

$$c_p^{liq} = R\left(\frac{A}{\tau} + B + C\tau + D\tau^2 + E\tau^3 + F\tau^4\right) \tag{62a}$$

with

$$\tau = 1 - \frac{T}{T_c} \tag{62b}$$

Eq. (62a) is used in Subchap. D3.1 for the correlation of heat capacities of approximately 275 substances.

There are few substances where all coefficients have to be fitted. In most cases, a quadratic temperature-dependence is sufficient; in case Eq. (62a) is used, the coefficients B, C and D are active. The extrapolation towards the critical point is often not considered to be important, as the quantity becomes more and more difficult to handle due to the increasing difference between c_p and c_σ. For many substances, no data exist above the normal boiling point. Often only a linear temperature-dependence is justified, which leads to an underestimation of c_p when it is extrapolated to high temperatures. To overcome this difficulty, artificial data points can be generated with an estimation method and fitted together with the data available.

For the estimation of c_p^{liq} the method of Rowlinson-Bondi can be used, which is based on the specific heat capacity of ideal gases and the 3-parameter principle of corresponding states:

$$\tilde{c}_p^{fl} = \tilde{c}_p^{id} + 1.45\,\tilde{R} + 0.45\,\tilde{R}\,(1 - T_r)^{-1} + 0.25\,\omega\,\tilde{R}\left[17.11 + 25.2\,(1 - T_r)^{1/3}\,T_r^{-1} + 1.742\,(1 - T_r)^{-1}\right] \tag{63}$$

The deviation to be expected should be approximately 5%.

Example 11:

Estimate the specific heat capacity of liquid methyl ethyl ketone at t = 100°C. The given data are: c_p^{id} (100°C) = 1.655 J/gK, T_c = 535.55 K, ω = 0.323, $\tilde{M}$ = 72.11 g/mol.

From c_p^{id} (100°C) = 120.496 J/molK and T_r = 0.697 it can be calculated

$$\frac{\tilde{c}_p^{liq}}{J/molK} = 119.342 + 1.45 \cdot 8.3143 + 0.45 \cdot 8.3143\,(1-0.697)^{-1} + 0.25 \cdot 0.323 \cdot 8.3143 \left[17.11 + 25.2\,(1-0.697)^{1/3} 0.697^{-1} + 1.742\,(1-0.697)^{-1}\right] = 175.4$$

$$\Rightarrow c_p^{liq} = 2.432\ J/gK$$

The value given in Subchap. D3.1 is 2.430 J/gK.

For mixtures, the specific heat capacity of liquids can be calculated with a linear mixing rule

$$c_{p,mix}^{liq} = \sum_i x_i\, c_{p,i}^{liq} \tag{64}$$

neglecting the influence of the excess enthalpy.

6.5 Routes for Enthalpy Calculation

For process simulation it is necessary that the enthalpy is continuously described in the vapor as well as in the two-phase and in the liquid region. The problem occurs that the particular quantities contributing to the enthalpy are not independent from each other. Depending on the way the enthalpy is calculated (route), there is always one quantity that results from the summation of the other contributions. The most often used routes are described in the following section.

A. Route: Vapor as starting phase

I. **Enthalpy of a vapor**

1. Set the reference point to the standard condition ($T_0 = 298.15$ K, $p_0 = 0$, $h_{0i} = \Delta h_i^{0f}$) for all components.

$$\tilde{h}_i^{id}(T_0, p=0) = \Delta h_i^{0f} \tag{65}$$

Therefore, the enthalpy is consistent regarding chemical reactions.

2. Calculation of the enthalpy of the ideal gas at $p = 0$ for the system temperature T, using c_{pi}^{id} for all components:

$$\tilde{h}_i^{id}(T, p=0) = \Delta h_i^{0f} + \int_{T_0}^{T} \tilde{c}_{pi}^{id}\, dT \tag{66}$$

3. Transition to the mixture at $p = 0$ in the ideal gas state, that is, without an excess enthalpy

$$\tilde{h}_{mix}^{id}(T, p=0, x_i) = \sum \tilde{x}_i \tilde{h}_i^{id}(T, p=0) \tag{67}$$

4. Addition of the residual part in the vapor phase Δh_{Gas}^{real}

$$\Delta h_{Gas}^{real}(T, p, \tilde{x}_i) = \tilde{h}(T, p, \tilde{x}_i) - \tilde{h}^{id}(T, p=0, \tilde{x}_i) \tag{68}$$

until the required state in the vapor phase is obtained:

$$\tilde{h}_{mix}^{real}(T, p, \tilde{x}_i) = h_{mix}^{id}(T, p=0, \tilde{x}_i) + \Delta h_{Gas}^{real}(T, p, \tilde{x}_i) \tag{69}$$

II. **Enthalpy of a liquid**

If the enthalpy of a liquid is calculated (Fig. 10), the steps 1 and 2 are identical to the calculation of a vapor phase enthalpy. The transition to the mixture takes place in the liquid phase. In step 3, the residual part is determined for the pure components to reach the dew point curve at $p = p_{si}$.

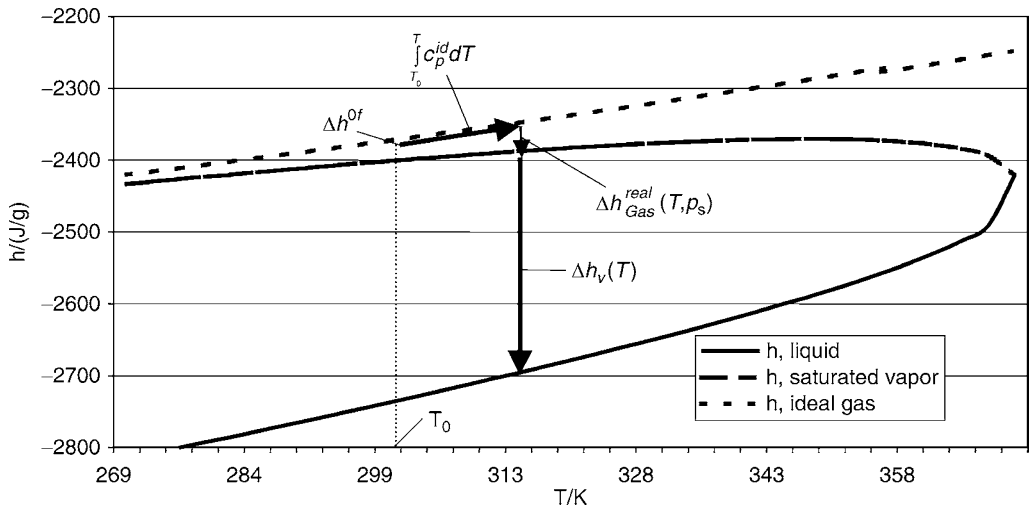
3. Calculation of the dew point curve state

$$\tilde{h}_i''(T) = \Delta h_i^{0f} + \int_{T_0}^{T} \tilde{c}_{pi}^{id}\, dT + \Delta h_{Gas,i}^{real}(T, p_{si}) \tag{70}$$

4. Subtraction of the enthalpy of vaporization at the system temperature T to reach the bubble point curve

$$\tilde{h}_i^{liq}(T) = \Delta h_i^{0f} + \int_{T_0}^{T} \tilde{c}_{pi}^{id}\, dT + \Delta h_{Gas,i}^{real}(T, p_{si}) - \Delta h_{vi}(T) \tag{71}$$

In process simulation, liquids are in general treated as if they are at their bubble point at the system temperature. Enthalpy changes by compression of the liquid are neglected, which is at least at low pressures an acceptable approximation.



D1. Fig. 10. Calculation of the enthalpy of a liquid with the route "vapor as starting phase".

5. Integration of the excess enthalpy

The transition to the mixture takes place in the liquid phase via

$$\widetilde{h}^{\mathrm{liq}}_{\mathrm{mix}}(T,\widetilde{x}_i) = \sum_i \widetilde{x}_i \widetilde{h}^{\mathrm{liq}}_i(T) + \widetilde{h}^{E}(T,\widetilde{x}_i) \qquad (72)$$

The calculation of the excess enthalpy h^{E} itself is explained in Subchap. D5.1.

The main disadvantage of this method is the error in the determination of the liquid heat capacity, which is calculated by deriving the enthalpy with respect to temperature. Even for well-known substances like water or methanol the deviations for $c^{\mathrm{liq}}_{\mathrm{p}}$ are considerable [24], which can hardly be accepted if, for example, liquid–liquid heat exchangers are designed. A procedure has been developed [24] where $c^{\mathrm{liq}}_{\mathrm{p}}$ can be reproduced using "vapor as starting phase."

B. Route: Liquid as starting phase

I. **Enthalpy of a liquid**

1. Enthalpy of a pure liquid

Starting from a reference state in the liquid phase $h_{\mathrm{ref,i}}(T_{\mathrm{ref,i}})$ the enthalpy of the liquid is evaluated by integration of the specific heat capacity of the liquid:

$$\widetilde{h}^{\mathrm{liq}}_i(T) = \int_{T_{\mathrm{ref},i}}^{T} \widetilde{c}^{\mathrm{liq}}_{pi}\mathrm{d}T + \widetilde{h}_{\mathrm{ref},i}(T_{\mathrm{ref},i}) \qquad (73)$$

2. Transition to the mixture

$$\widetilde{h}^{\mathrm{liq}}_{\mathrm{mix}}(T,\widetilde{x}_i) = \sum_i \widetilde{x}_i \widetilde{h}^{\mathrm{liq}}_i(T) + h^{E}(T,\widetilde{x}_i) \qquad (74)$$

analogous to Eq. (72).

II. **Enthalpy of a vapor**

1. Integration of the specific heat capacity to the transition temperature T_{LG}.

$$\widetilde{h}^{\mathrm{liq}}_i(T_{\mathrm{LG},i}) = \int_{T_{\mathrm{ref},i}}^{T_{\mathrm{LG},i}} \widetilde{c}^{\mathrm{liq}}_{\mathrm{pi}}\mathrm{d}T + \widetilde{h}_{\mathrm{ref},i}(T_{\mathrm{ref},i}) \qquad (75)$$

A useful choice for $T_{\mathrm{LG},i}$ is the normal boiling point.

2. Transition to the vapor phase to reach the dew point curve:

$$\widetilde{h}_i{}''(T_{\mathrm{LG},i}) = \widetilde{h}^{\mathrm{liq}}_i(T_{\mathrm{LG},i}) + \Delta h_{\mathrm{v}}(T_{\mathrm{LG},i}) \qquad (76)$$

3. Transition to the ideal gas state

$$\widetilde{h}^{\mathrm{id}}_i(T_{\mathrm{LG},i}, p=0) = \widetilde{h}_i{}''(T_{\mathrm{LG},i}) - \Delta h^{\mathrm{real}}_{\mathrm{Gas},i}(T_{\mathrm{LG},i}, p_{\mathrm{si}}(T_{\mathrm{LG},i})) \qquad (77)$$

4. Integration to the system temperature

$$\widetilde{h}^{\mathrm{id}}_i(T,p=0) = \widetilde{h}^{\mathrm{id}}_i(T_{\mathrm{LG},i},p=0) + \int_{T_{\mathrm{LG},i}}^{T} \widetilde{c}^{\mathrm{id}}_{\mathrm{pi}}\mathrm{d}T \qquad (78)$$

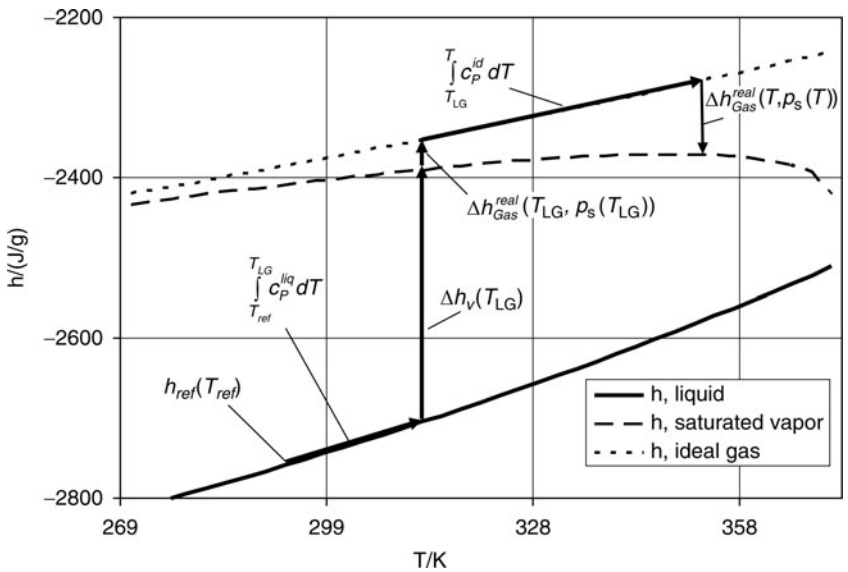
5. Transition to the mixture at $p = 0$ in the ideal gas state, that is, without an excess enthalpy

$$\widetilde{h}^{\mathrm{id}}_{\mathrm{mix}}(T,p=0,\widetilde{x}_i) = \sum_i \widetilde{x}_i \widetilde{h}^{\mathrm{id}}_i(T,p=0) \qquad (79)$$

6. Addition of the residual part to reach the required state in the vapor phase analogously to Eq. (69)

$$\widetilde{h}^{\mathrm{real}}_{\mathrm{mix}}(T,p,\widetilde{x}_i) = \widetilde{h}^{\mathrm{id}}_{\mathrm{mix}}(T,p=0,\widetilde{x}_i) + \Delta h^{\mathrm{real}}_{\mathrm{Gas}}(T,p,\widetilde{x}_i) \qquad (80)$$

$h_{\mathrm{ref},i}(T_{\mathrm{ref},i})$ has to be chosen for each component in a way that the enthalpy for the standard state ($t = 25°\mathrm{C}$, ideal gas state) results in the standard enthalpy of formation $\Delta^{0\mathrm{f}}_{h_i}$. A useful choice for $T_{\mathrm{ref},i}$ is the melting point. The method is illustrated in Fig. 11.



D1. Fig. 11. Calculation of the enthalpy of a saturated vapor with the route "liquid as starting phase".

The specific heat capacity of a liquid is reproduced with this route; nevertheless, it has also its disadvantages. The calculation of the enthalpy of vaporization is indirect and therefore not exact; it does not equal 0 at the critical point. The correlation for c_p^{liq} is often only verified in the temperature region below the normal boiling point and extrapolates poorly, giving large errors in the high-pressure region. Many arrangements (T_{ref}, h_{ref}, T_{LG} for each component) have to be set up.

7 Viscosity

The viscosity is a measure of the momentum transfer in a fluid perpendicular to the flow direction. It is needed especially for the calculation of pressure drops. Furthermore, it is a factor in the Reynolds and in the Grashof number for the determination of the heat transfer coefficient.

It is distinguished between the dynamic viscosity η and the kinematic viscosity ν. They are related via

$$\eta = \nu\,\rho \tag{81}$$

In the following section, only the dynamic viscosity is regarded.

7.1 Dynamic Viscosity of Liquids

Fig. 12 shows the typical curvature of the dynamic viscosity of liquids. In the temperature region above the melting point, it decreases with a large slope. The slope decreases with increasing temperatures, but remains negative. The dynamic viscosity can be roughly correlated with the simple approach

$$\ln\frac{\eta}{\text{Pas}} = A + \frac{B}{T} \tag{82}$$

This equation is appropriate to reproduce the curvature qualitatively. For a precise reproduction, further terms have to be added to Eq. (82), for example,

$$\ln\frac{\eta}{\text{Pas}} = A + \frac{B}{T/K} + C\frac{T}{K} + D\left(\frac{T}{K}\right)^2 + E\left(\frac{T}{K}\right)^3 \tag{83}$$

All of these equations have difficulties when they are extrapolated to high temperatures. It is necessary to check the equation in the temperature range of interest before it is applied. During the recent years, the PPDS equation

$$\frac{\eta}{\text{Pas}} = E\cdot\exp\left[A\left(\frac{C-T}{T-D}\right)^{1/3} + B\left(\frac{C-T}{T-D}\right)^{4/3}\right] \tag{84}$$

has been widely applied. Currently, this equation seems to be the most accurate correlation for liquid viscosities. Furthermore, it seems to extrapolate quite well. When it is programmed, it must be taken care that the term in brackets $(C - T)/(T - D)$ sometimes turns out to be negative, so that it makes sense to write in these cases

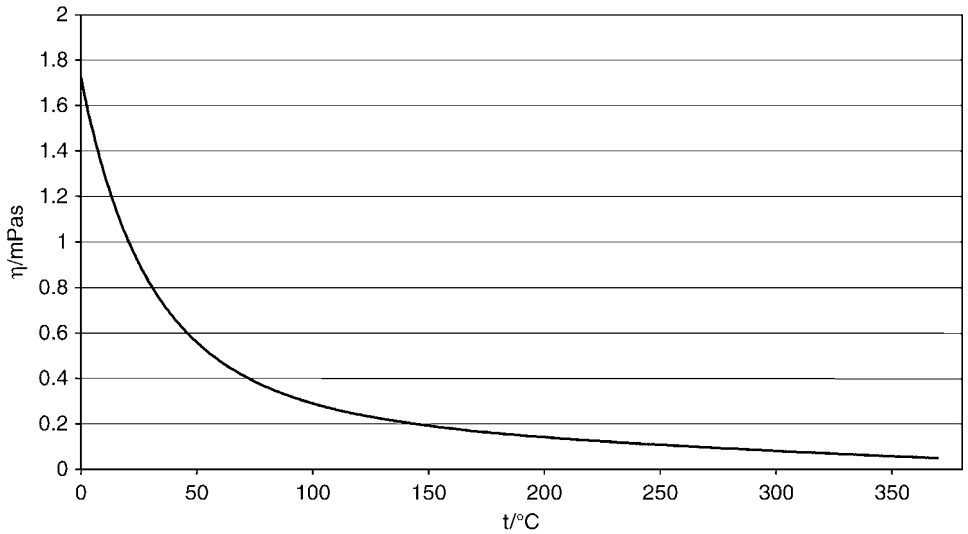
$$\left(\frac{C-T}{T-D}\right)^{1/3} = -\left(\frac{T-C}{T-D}\right)^{1/3} \text{ and}$$

$$\left(\frac{C-T}{T-D}\right)^{4/3} = -\left(\frac{T-C}{T-D}\right)^{1/3}\left(\frac{C-T}{T-D}\right)$$

One of the simplest options to estimate the dynamic viscosity of liquids is the group contribution method of Orrick/Erbar [2]. The calculation equation is

$$\ln\frac{\eta}{\text{mPas}} = \ln\left(\frac{\rho(20^\circ C)}{\text{g/cm}^3}\frac{\tilde{M}}{\text{g/mol}}\right) + \left(\sum\Delta_A + \frac{\sum\Delta_B}{T/K}\right) \tag{85}$$

For substances that are not liquid at $t = 20°C$, the liquid density at the melting point has to be inserted. The group contributions for Δ_A and Δ_B can be taken from Table 7. Partially, the group contributions do not refer to molecular segments but to structural units. First, the molecule has to be checked for aromatic and nonaromatic 5-membered and 6-membered rings. Then, the remaining groups can be assigned. For carbon atoms not recorded so far, a contribution according to the first line in Table 7 is added. Finally, additional corrections for double bonds and the particular kinds of substitution on aromatic rings



D1. Fig. 12. Dynamic viscosity of liquid water as a function of temperature.

D1. Table 7. Group contributions of the Orrick/Erbar method for the calculation of the dynamic viscosity of liquids

n: number of carbon atoms not belonging to the groups shown above

D1. Fig. 13. Structural formula of n-butanol.

(ortho: neighbor C-atoms, para: opposite C-atoms, meta: C-atoms, where one non-substituted C-atom in the ring is between) are made. Components containing nitrogen or sulfur cannot be treated. Deviations of 15% and more should be expected. Better results can be obtained with the group contribution methods of Sastri/Rao [25, 26], van Velzen [27], and, especially, Nannoolal/Rarey [28], where, however, the explanation of the complicated increments would be beyond the scope of this chapter.

Example 12:
Estimate the dynamic viscosity of n-butanol ($C_4H_{10}O$) at $t = 50°C$.

$\rho(20°C) = 810.6$ kg/m^3, $\tilde{M} = 74.12$ g/mol.

The group assignment of n-butanol (Fig. 13) is:

1 OH

4 carbon atoms

The analysis of Table 7 yields the group contributions:

$$\sum \Delta_A = 1 \cdot (-3) + (-6.95 - 0.21 \cdot 4) = -10.79$$
$$\sum \Delta_B = 1 \cdot (1{,}600) + (275 + 99 \cdot 4) = 2{,}271$$

giving a dynamic viscosity of

$$\ln \frac{\eta}{\text{mPas}} = \ln(0.8106 \cdot 74.12) + \left(-10.79 + \frac{2271}{323.15}\right)$$
$$= 0.3334 \Rightarrow \eta = 1.3957 \text{ mPas}$$

The value listed in Subchap. D3.1 is $\eta = 1.418$ mPas.

For $T > 0.7\ T_c$ Sastri [26] recommends the equation

$$\ln \frac{\eta}{\text{mPas}} = \left[\frac{\ln \eta(T_{NBP})}{\ln[\alpha\eta(T_{NBP})]}\right]^{\frac{1 - T/T_c}{1 - T_{NBP}/T_c}} \ln\left(\frac{\alpha\eta(T_{NBP})}{\text{mPas}}\right) \quad (85a)$$

For alcohols, $\alpha = 0.1175$, for other components, $\alpha = 0.248$. Deviations of approximately 10% can be expected.

Example 13:
Determine the dynamic viscosity of n-butane on the saturation line at $t = 100°C$.

$T_{NBP} = 272.65$ K, $T_c = 425.13$ K, $\eta_{NBP} = 0.202$ mPas.

$$\ln \frac{\eta}{\text{mPas}} = \left[\frac{\ln 0.202}{\ln[0.248 \cdot 0.202]}\right]^{\frac{1 - 373.15/425.13}{1 - 272.65/425.13}} \ln(0.248 \cdot 0.202)$$
$$= -2.4177 \Rightarrow \eta = 0.089 \text{ mPas}$$

The actual value is 0.077 mPas.

The liquid viscosity increases with increasing pressure. According to Lucas [29], the effect can be estimated via

$$\eta(T, p) = \eta(T, p_s(T)) \frac{1 + D(\Delta p_r / 2.118)^A}{1 + C\omega\Delta p_r} \quad (86)$$

with

$$\Delta p_r = \frac{p - p_s(T)}{p_c}$$
$$A = 0.9991 - \frac{4.674 \cdot 10^{-4}}{1.0523\ T_r^{-0.03877} - 1.0513}$$
$$D = \frac{0.3257}{\left(1.0039 - T_r^{2.573}\right)^{0.2906}} - 0.2086$$
$$C = -0.07921 + 2.1616\ T_r - 13.404\ T_r^2 + 44.1706\ T_r^3 - 84.8291\ T_r^4 + 96.1209\ T_r^5 - 59.8127\ T_r^6 + 15.6719\ T_r^7 \quad (86a)$$

Errors of approximately 10% should be expected.

Example 14:
Determine the dynamic viscosity of methyl cyclohexane at $T = 300$ K and $p = 500$ bar.

η (300 K, Siedelinie) = 0.661 mPas

p_s (300 K) = 67.56 mbar

$p_c = 34.71$ bar

$T_c = 572.15$ K

$\omega = 0.235$

The results for the particular terms are:

$T_r = 0.5243$

$\Delta p_r = 14.403$

$A = 0.98221$

$D = 0.13717$

$C = 0.06191$

Thus, one gets:

$$\eta(300\,\text{K}, 500\,\text{bar}) = 0.661\ \text{mPas} \frac{1 + 0.13717 \cdot (14.403/2.118)^{0.98221}}{1 + 0.06191 \cdot 0.235 \cdot 14.403}$$
$$= 1.04\,\text{mPas}$$

The experimental value is reported to be 1.09 mPas.

For mixtures, the viscosity can be estimated via

$$\ln\frac{\eta}{\text{Pas}} = \sum_i \widetilde{x}_i \ln\frac{\eta_i}{\text{Pas}} \tag{87}$$

In fact, the prediction of the viscosity of a mixture is much more difficult and Eq. (87) is not very reliable. It can be expected to meet the correct order of magnitude, but hardly more. With the help of an experimental value or the application of group contribution methods, significant improvements can be achieved, however, with a high effort. A detailed compilation of methods of this kind can be found in [2].

Example 15:
Determine the dynamic viscosity of a methanol/water mixture at $t = 40°C$ for $\widetilde{x}_{\text{Methanol}} = 0.5164$.

$$\eta_{\text{Water}} = 0.6652 \text{ mPas}, \quad \eta_{\text{Methanol}} = 0.4421 \text{ mPas}.$$
$$\ln\frac{\eta}{\text{mPas}} = 0.5164 \ln 0.4421 + 0.4836 \ln 0.6652$$
$$= -0.6186 \Rightarrow \eta = 0.5387 \text{ mPas}$$

The actual value is $\eta = 0.9345$ mPas. It is higher than both pure component values, which cannot be reproduced with the mathematical structure of Eq. (87).

7.2 Dynamic Viscosity of Gases

According to the kinetic gas theory, the viscosity of an ideal gas does not depend on the density [22]. This can be explained as follows: There are fewer particles available for the momentum transfer at low densities, but on the other hand they have a larger mean free path so that more momentum can be transferred across the flow direction. Both effects compensate for the ideal gas. For the real gas the viscosity slightly increases with density. There is a strong dependence on temperature, as the mean kinetic energy of the molecules increases with temperature, giving more momentum to be transferred in a collision.

The dynamic viscosity of gases at low pressures can be estimated according to Lucas [30]:

$$\frac{\eta^{\text{id}}}{10^{-7}\text{Pas}} = \frac{F_P^{\text{id}}}{\xi}\left[0.807\ T_r^{0.618} - 0.357\ \exp(-0.449\ T_r) + 0.34\ \exp(-4.058\ T_r) + 0.018\right] \tag{88}$$

where the correction factor F_P^{id} takes into account the influence of the polarity, which is characterized by the reduced dipole moment μ_r

$$\mu_r = 52.46\left(\frac{\mu}{\text{debye}}\right)^2 \frac{p_c}{\text{bar}}\left(\frac{T_c}{\text{K}}\right)^{-2} \tag{89}$$

For a given μ_r, F_P^{id} can be evaluated by

$$\begin{aligned} F_P^{\text{id}} &= 1 && \text{for } 0 \le \mu_r \le 0.022 \\ F_P^{\text{id}} &= 1 + 30.55\,(0.292 - Z_c)^{1.72} && \text{for } 0.022 \le \mu_r \le 0.075 \\ F_P^{\text{id}} &= 1 + 30.55\,(0.292 - Z_c)^{1.72}\,|0.96 + 0.1\,(T_r - 0.7)| && \text{for } \mu_r \ge 0.075 \end{aligned} \tag{90}$$

ξ is the reduced inverse viscosity and can be determined by

$$\xi = 0.176\left(\frac{T_c}{\text{K}}\right)^{1/6}\left(\frac{\widetilde{M}}{\text{g/mol}}\right)^{-1/2}\left(\frac{p_c}{\text{bar}}\right)^{-2/3} \tag{91}$$

For the so-called quantum gases H_2, D_2, and He, there is another correction factor [2]. The average error of the method is reported to be 1%...4% [2]; therefore, this quantity is usually not measured.

The typical curvature of the dynamic viscosity of gases is depicted in Fig. 14. For process simulation, it is sufficient to reproduce it by a simple polynomial

$$\frac{\eta^{\text{id}}}{\text{Pas}} = A + B\frac{T}{\text{K}} + C\left(\frac{T}{\text{K}}\right)^2 + D\left(\frac{T}{\text{K}}\right)^3 + E\left(\frac{T}{\text{K}}\right)^4 \tag{92}$$

Coefficients for Eq. (92) are given in Subchap. D3.1.

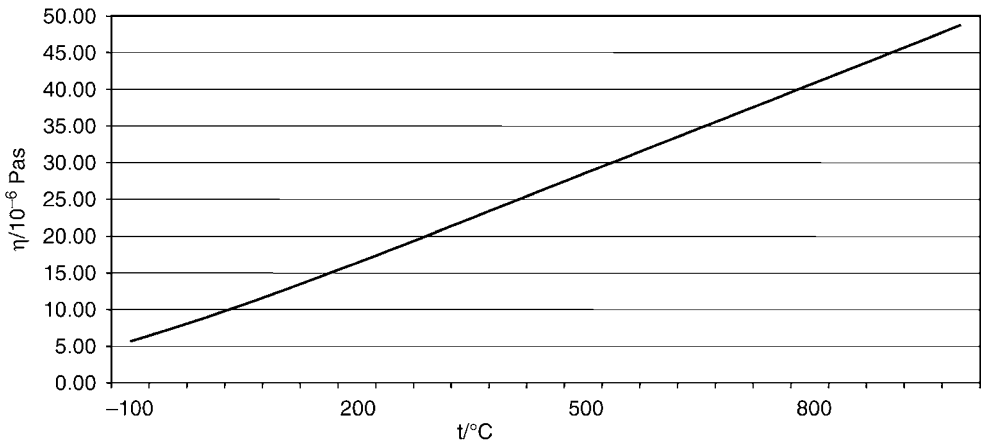
The DIPPR equation

$$\eta^{\text{id}} = \frac{AT^B}{1 + CT^{-1} + DT^{-2}} \tag{92a}$$

shows a better extrapolation behavior but is less flexible.

Example 16:
Estimate the dynamic viscosity of ammonia at $t = 300°C$ and $p = 1$ bar.

The following data are given:
$T_c = 405.5$ K
$p_c = 113.59$ bar



D1. Fig. 14. Dynamic viscosity of gaseous water as a function of temperature at low pressures.

$Z_c = 0.255$
$\mu = 1.5$ debye
$\widetilde{M} = 17.03$ g/mol
We obtain:

$$T_r = 573.15/405.5 = 1.4134$$
$$\mu_r = 52.46 \cdot 1.5^2 \cdot 113.59 \cdot 405.5^{-2} = 0.0815$$
$$\xi = 0.176\ (405.5)^{1/6}\ (17.03)^{-1/2}\ (113.59)^{-2/3} = 0.004947$$
$$F_p^{id} = 1 + 30.55\ (0.292 - 0.255)^{1.72}\ |0.96 + 0.1\ (1.4134 - 0.7)|$$
$$= 1.1086$$

Thus, the viscosity is:

$$\frac{\eta^{id}}{10^{-7}\text{Pas}} = \frac{1.1086}{0.004947}[0.807 \cdot 1.4134^{0.618} - 0.357\ \exp(-0.449 \cdot 1.4134) + 0.34\ \exp(-4.058 \cdot 1.4134) + 0.018]$$
$$= 185.83 \Rightarrow \eta^{id} = 18.58\,\mu\text{Pas}$$

The value from Subchap. D3.1 is η^{id} = 20.1 µPas.

The pressure-dependence of the viscosity of gases can be determined according to Lucas [30] for $1 \le T_r \le 40$ and $0 \le p_r \le 100$:

$$\eta = \eta^{id} Z_2\ F_p \tag{93}$$

with η^{id} from Eq. (88) or (92) and Z_2 via

$$Z_2 = 1 + \frac{A\ p_r^E}{B\ p_r^F + (1 + C p_r^D)^{-1}} \tag{94}$$

with

$$A = \frac{0.001245}{T_r}\exp(5.1726\ T_r^{-0.3286})$$
$$B = A\ (1.6553\ T_r - 1.2723)$$
$$C = \frac{0.4489}{T_r}\exp(3.0578\ T_r^{-37.7332})$$
$$D = \frac{1.7368}{T_r}\exp(2.231\ T_r^{-7.6351}) \tag{94a}$$
$$E = 1.3088$$
$$F = 0.9425\ \exp(-0.1853\ T_r^{0.4489})$$

The correction factor F_p is

$$F_p = \frac{1 + (F_p^{id} - 1)\ Z_2^{-3}}{F_p^{id}} \tag{95}$$

For $T_r < 1$ and $p < p_s(T_r)$ Lucas [30] gives the function

$$\frac{\eta}{10^{-7}\ \text{Pas}} = Z_2 \frac{F_p}{\xi} \tag{96}$$

with

$$Z_2 = 0.6 + 0.76\ p_r^A + (6.99\ p_r^B - 0.6)(1 - T_r)$$
$$A = 3.262 + 14.98\ p_r^{5.508} \tag{96a}$$
$$B = 1.39 + 5.746\ p_r$$

and the correction factor

$$F_p = \frac{1 + (F_p^{id} - 1)\ [Z_2/(\xi \eta^{id}/10^{-7}\ \text{Pas})]^{-3}}{F_p^{id}} \tag{97}$$

As a rule of thumb, an error of approximately 10% should be expected [30] except for the quantum gases, where again additional correction factors are necessary.

Example 17:
Determine the dynamic viscosity of ammonia at T = 420 K and p = 300 bar.
The following data are given:
$T_c = 405.5$ K
$p_c = 113.59$ bar
$Z_c = 0.255$
$\mu = 1.5$ debye
$\widetilde{M} = 17.03$g/mol
η^{id} (420 K, 1 bar) = 14.57 µPas
$\xi = 0.004947$
$\mu_r = 0.0815$
With $T_r = 1.0358$ and $p_r = 2.6411$ one gets:
$A = 0.1998$
$B = 0.08834$
$C = 0.9764$
$D = 9.2349$
$E = 1.3088$
$F = 0.7808$
and

$$Z_2 = 1 + \frac{A\ p_r^E}{B\ p_r^F + (1 + C p_r^D)^{-1}} = 4.77398$$

Furthermore, one obtains:

$$F_p^{id} = 1 + 30.55\ (0.292 - 0.255)^{1.72}\ |0.96 + 0.1\ (1.0358 - 0.7)|$$
$$= 1.1046$$
$$F_p = \frac{1 + (1.1046 - 1)\ \cdot 4.77398^{-3}}{1.1046} = 0.9062$$

The result for the dynamic viscosity is:

$$\eta = 14.57\ \mu Pas \cdot 4.77398 \cdot 0.9062 = 63.03\ \mu Pas$$

The reference value [31] is η = 56.6 µPas.

For the calculation of the viscosity of gas mixtures the Wilke mixing rule [32] can be applied at low pressures:

$$\eta^{Gem} = \sum_i \frac{\widetilde{y}_i \eta_i}{\sum_j \widetilde{y}_i F_{ij}} \tag{98}$$

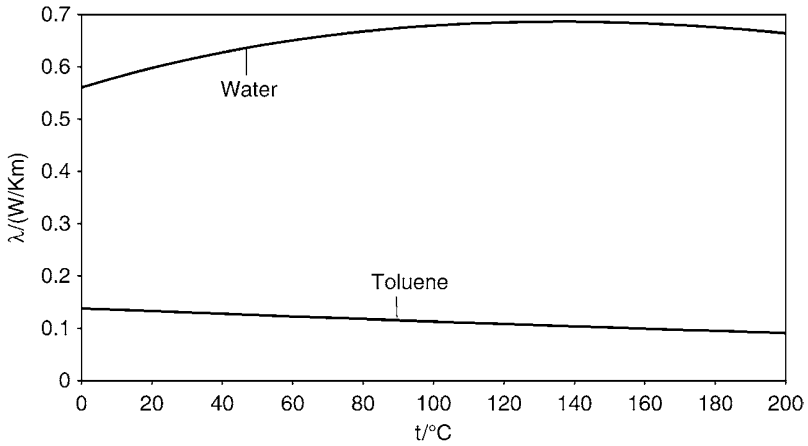
with

$$F_{ij} = \frac{\left[1 + (\eta_i/\eta_j)^{1/2}\ (\widetilde{M}_j/\widetilde{M}_i)^{1/4}\right]^2}{\sqrt{8\ (1 + \widetilde{M}_i/\widetilde{M}_j)}} \tag{98a}$$

At high pressures, mixing rules based on the corresponding-states principle are available [2].

8 Thermal Conductivity

The thermal conductivity is often the decisive quantity in heat transfer processes. Its order of magnitude is λ = 0.1... 0.2 W/Km for most liquids. Exceptions are water ($\lambda \approx$ 0.6... 0.7 W/Km) and some oligoethers. For gases, an order of magnitude of $\lambda \approx$ 0.01... 0.03 W/Km can be expected. The quantum gases hydrogen ($\lambda \approx$ 0.2 W/Km) and helium ($\lambda \approx$ 0.14 W/Km) behave differently.



D1. Fig. 15. Curvatures of the liquid thermal conductivity as a function of temperature for water and toluene.

8.1 Thermal Conductivity of Liquids

The thermal conductivity of liquids can be described with a 4th degree polynomial

$$\frac{\lambda_{\mathrm{fl}}}{\mathrm{W/Km}} = A + B\frac{T}{\mathrm{K}} + C\left(\frac{T}{\mathrm{K}}\right)^2 + D\left(\frac{T}{\mathrm{K}}\right)^3 + E\left(\frac{T}{\mathrm{K}}\right)^4 \qquad (99)$$

or with the Jamieson [33] equation

$$\lambda_{\mathrm{L}} = A\,(1 + B\tau^{1/3} + C\tau^{2/3} + D\tau) \qquad (99a)$$

with

$$\tau = 1 - \frac{T}{T_{\mathrm{c}}} \qquad (99b)$$

Values for the coefficients of Eq. (99) are given in Subchap. D3.1. The thermal conductivity decreases almost linearly with the temperature over a wide range, so that a polynomial of the 1st degree is often sufficient, especially if only data below the normal boiling point are available. The other coefficients are also necessary, if either data at higher temperatures are given or if a maximum has to be described, as is the case for water. The curvatures for the liquid thermal conductivity for water and toluene as a typical organic substance are depicted in Fig. 15.

As the thermal conductivities are in the same order of magnitude for most substances, the estimation is comparably simple. The method of Sato-Riedel [34] is well established:

$$\frac{\lambda_{\mathrm{fl}}}{\mathrm{W/Km}} = 1.11\left(\frac{\widetilde{M}}{\mathrm{g/mol}}\right)^{-1/2} \frac{3 + 20\,(1 - T_{\mathrm{r}})^{2/3}}{3 + 20\,\left(1 - T_{\mathrm{NBP,r}}\right)^{2/3}} \qquad (100)$$

Example 18:
Determine the thermal conductivity of liquid acetone at $t = -50°\mathrm{C}$.
The given values are:
$t_{\mathrm{c}} = 234.95°\mathrm{C}$
$t_{\mathrm{NBP}} = 56.08°\mathrm{C}$
$\widetilde{M} = 58.08\,\mathrm{g/mol}$

$$\frac{\lambda_{fl}}{\mathrm{W/Km}} = 1.11(58.08)^{-1/2}\,\frac{3+20\,(1-223.15/508.1)^{2/3}}{3+20\,(1-329.23/508.1)^{2/3}} = 0.1864$$

The value given in Subchap. D3.1 is $\lambda = 0.193$ W/Km.

D1. Table 8. Values for Q in Eq. (101)

T_{r}	p_{r}					
	1	5	10	50	100	200
0.8	0.036	0.038	0.038	0.038	0.038	0.038
0.7	0.018	0.025	0.027	0.031	0.032	0.032
0.6	0.015	0.02	0.022	0.024	0.025	0.025
0.5	0.012	0.0165	0.017	0.019	0.02	0.02

The pressure dependence of thermal conductivity for liquids is almost negligible. At very high pressures, it has a certain influence, which can be estimated with the Missenard method

$$\frac{\lambda(p_{\mathrm{r}}, T)}{\lambda(p_{\mathrm{s}}, T)} = 1 + Q\,p_{\mathrm{r}}^{0.7} \qquad (101)$$

Values for Q are listed in Table 8.

Example 19:
Determine the thermal conductivity of toluene at $T = 304$ K and $p = 6{,}330$ bar.
The given values are:
λ (304 K, 1 bar) = 0.1309 W/Km
$p_{\mathrm{c}} = 41.26$ bar
$T_{\mathrm{c}} = 591.75$ K
With $T_{\mathrm{r}} = 0.5137$ and $p_{\mathrm{r}} = 153.42$ one gets $Q = 0.0207$ from Table 8 by interpolation. Thus, it is

$$\lambda(p_{\mathrm{r}}, T) = \lambda(p_{\mathrm{s}}, T) \cdot \left(1 + Q\,p_{\mathrm{r}}^{0.7}\right) = 0.1309\,\mathrm{W/Km}.$$
$$\left(1 + 0.0207 \cdot 153.42^{0.7}\right) = 0.2227\,\mathrm{W/Km}$$

The experimental value [2] is 0.228 W/Km.

As a mixing rule for the thermal conductivity of liquids, the method of Li [35] is appropriate, as it can also be extended to multicomponent mixtures:

$$\lambda_{\mathrm{mix}} = \sum_{i=1}^{n}\sum_{j=1}^{n} \frac{2\Phi_i\Phi_j}{\lambda_i^{-1} + \lambda_j^{-1}} \qquad (102)$$

with

$$\Phi_i = \frac{\widetilde{x}_i v_{\mathrm{liq},i}}{\sum_{j=1}^{n} \widetilde{x}_j v_{\mathrm{liq},j}} \qquad (102a)$$

Example 20:
Determine the thermal conductivity of a liquid mixture of benzene and methanol with $x_{benzene} = 0.381$ at $T = 273$ K.
The following data at $T = 273$ K are given:
$\lambda_{benzene} = 0.151$ W/Km (extrapolated below melting point)
$\lambda_{methanol} = 0.207$ W/Km

$\widetilde{M}_{benzene} = 78.11$g/mol
$\widetilde{M}_{methanol} = 32.04$g/mol

$\rho_{benzene} = 897.6$ kg/m^3 => $\nu_{benzene} = 8.702 \cdot 10^{-5}$ m^3/mol (extrapolated below melting point)
$\rho_{methanol} = 810.7$ kg/m^3 => $\nu_{methanol} = 3.952 \cdot 10^{-5}$ m^3/mol

$$\Phi_{benzene} = \frac{0.381 \cdot 8.702 \cdot 10^{-5}}{0.381 \cdot 8.702 \cdot 10^{-5} + 0.619 \cdot 3.952 \cdot 10^{-5}} = 0.5754$$

$$\Phi_{methanol} = 1 - \Phi_{benzene} = 0.4246$$

$$\frac{\lambda_{mix}}{\mathrm{W/Km}} = \frac{2 \cdot 0.5754^2}{2 \cdot 0.151^{-1}} + 2 \cdot \frac{2 \cdot 0.5754 \cdot 0.4246}{0.151^{-1} + 0.207^{-1}} + \frac{2 \cdot 0.4246^2}{2 \cdot 0.207^{-1}} = 0.1726$$

The experimental value [2] is $\lambda = 0.17$ W/Km.

8.2 Thermal Conductivity of Gases

The thermal conductivity of gases can be derived from the kinetic gas theory analogously to the viscosity. Instead of the momentum transfer, the transfer of kinetic energy has to be regarded [22]. Similar to viscosity, the thermal conductivity increases with increasing temperature. At low to moderate pressures (approximately 0.1...10 bar), it does not depend on the pressure. The thermal conductivity of gases can be correlated with a 4th degree polynomial:

$$\frac{\lambda^{id}}{\mathrm{W/Km}} = A + B\frac{T}{\mathrm{K}} + C\left(\frac{T}{\mathrm{K}}\right)^2 + D\left(\frac{T}{\mathrm{K}}\right)^3 + E\left(\frac{T}{\mathrm{K}}\right)^4 \quad (103)$$

The typical, almost linear curvature is depicted in Fig. 16.

The thermal conductivity of gases at low pressures can be estimated according to Chung [36] via

$$\lambda = \frac{3.75 \Psi \eta \widetilde{R}}{\widetilde{M}} \quad (104)$$

with

$$\Psi = 1 + \alpha \frac{0.215 + 0.28288\,\alpha - 1.061\,\beta + 0.26665\,\gamma}{0.6366 + \beta\gamma + 1.061\,\alpha\beta} \quad (104a)$$

and

$$\alpha = \widetilde{c}_p/\widetilde{R} - 2.5$$
$$\beta = 0.7862 - 0.7109\,\omega + 1.3168\,\omega^2 \quad (104b)$$
$$\gamma = 2 + 10.5\,T_r^2$$

For nonpolar substances, deviations of about 5%...10% might be expected. For polar compounds, the error is often higher. In these cases, the group contribution method of Roy/Thodos [2] is recommended.

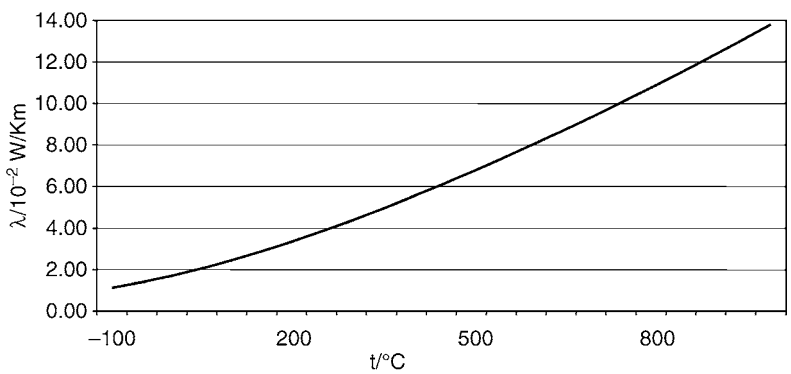
Example 21:
Determine the thermal conductivity of 2-methylpentane at $t = 100°C$ and 1 bar.
The given data are:
$\widetilde{M} = 86.16$ g/mol
$\omega = 0.280$
$T_c = 497.7$ K
$c_p = 2.008$ J/gK
$\eta = 8.2$ µPas
One gets:

$$\alpha = \frac{2.016 \cdot 86.16}{8.3143} - 2.5 = 18.308$$
$$\beta = 0.7862 - 0.7109 \cdot 0.280 + 1.3168 \cdot 0.280^2 = 0.6904$$
$$\gamma = 2 + 10.5 \cdot (373.15/497.7)^2 = 7.9023$$
$$\Psi = 1 + \alpha \frac{0.215 + 0.28288\,\alpha - 1.061\,\beta + 0.26665\,\gamma}{0.6366 + \beta\gamma + 1.061\,\alpha\beta} = 7.3538$$
$$\lambda = \frac{3.75 \cdot 7.3538 \cdot 8.2 \cdot 10^{-6} \cdot 8.3143}{86.16 \cdot 10^{-3}} \frac{\mathrm{W}}{\mathrm{Km}} = 0.0218\,\mathrm{W/Km}$$

The value listed in Subchap. D3.1 is 0.0206 W/Km.

The thermal conductivity of gases depends on the pressure in an unusual way. At very low pressures ($p < 10^{-3}$ mbar), when the mean free path is large in comparison with the vessel dimensions, the thermal conductivity is proportional to the pressure and to the distance d between the limiting walls in the direction of the heat flux:

$$\lambda = \frac{3}{8} p d \sqrt{\frac{3\widetilde{R}}{\widetilde{M}T}} \quad (105)$$



D1. Fig. 16. Thermal conductivity of gaseous water as a function of temperature.

At normal pressures (p = 0.001 bar ... 10 bar), it is almost independent of the pressure. At high pressures, the thermal conductivity can be estimated according to Stiel and Thodos [37]:

$$\begin{aligned}
\lambda &= \lambda^{id} + 0.0122\,\Gamma^{-1}Z_c^{-5}\times \\
&\quad [\exp(0.535\,\rho/\rho_c) - 1] \qquad \text{for} \quad \rho/\rho_c < 0.5 \\
\lambda &= \lambda^{id} + 0.0114\,\Gamma^{-1}Z_c^{-5}\times \\
&\quad [\exp(0.67\,\rho/\rho_c) - 1.069] \qquad \text{for} \quad 0.5 < \rho/\rho_c < 2 \\
\lambda &= \lambda^{id} + 0.0026\,\Gamma^{-1}Z_c^{-5}\times \\
&\quad [\exp(1.155\,\rho/\rho_c) + 2.016] \qquad \text{for} \quad 2 < \rho/\rho_c < 2.8
\end{aligned} \tag{106}$$

Γ is given by

$$\frac{\Gamma}{(\mathrm{W/Km})^{-1}} = 210\left(\frac{T_c}{\mathrm{K}}\right)^{1/6}\left(\frac{\widetilde{M}}{\mathrm{g/mol}}\right)^{1/2}\left(\frac{p_c}{\mathrm{bar}}\right)^{-2/3} \tag{107}$$

The method is not considered to be very accurate, deviations of 10%. . .20% are usual. For polar compounds, this method is not appropriate. There are other, more difficult methods available [2], which are more accurate. However, none of them can really handle polar compounds.

Example 22:
Determine the thermal conductivity of nitrous oxide at t = 105°C and p = 138 bar.
The given values are:

λ^{id} = 0.02375 W/Km
p_c = 72.45 bar
T_c = 309.52 K
ρ_c = 454 kg/m^3
ρ (105°C, 138 bar) = 303.978 kg/m^3
$\widetilde{M}$ = 44.01g/mol
For Γ, one gets:

$$\frac{\Gamma}{(\mathrm{W/Km})^{-1}} = 210 \cdot 309.52^{1/6} \cdot 44.01^{1/2} \cdot 72.45^{-2/3} = 208.49$$

$$\rho/\rho_c = 0.66956$$

$$Z_c = \frac{72.45 \cdot 10^5 \cdot 44.01 \cdot 10^{-3}}{454 \cdot 8.3143 \cdot 309.52} = 0.2729$$

which yields

$$\frac{\lambda}{\mathrm{W/Km}} = 0.02375 + 0.0114 \cdot 208.49^{-1} \cdot 0.2729^{-5}$$
$$[\exp(0.67 \cdot 0.66956) - 1.069] = 0.0417$$

The experimental value is 0.039 W/Km.

For the calculation of the thermal conductivity of gaseous mixtures, the mixing rule of Wassiljeva, Mason, and Saxena [2] can be applied analogously to the mixing rule of Wilke for viscosity:

$$\lambda^{mix} = \sum_i \frac{\widetilde{y}_i \lambda_i}{\sum_j y_j F_{ij}} \tag{108}$$

with

$$F_{ij} = \frac{\left[1 + (\eta_i/\eta_j)^{1/2}\,(\widetilde{M}_j/\widetilde{M}_i)^{1/4}\right]^2}{\sqrt{8\,(1 + \widetilde{M}_i/\widetilde{M}_j)}} \tag{108a}$$

Example 23:
Determine the thermal conductivity of a gaseous mixture consisting of 25 mol% benzene and 75 mol% argon at t = 100.6°C and p = 1 bar.
The following values are given:
$\widetilde{M}_{benzene}$ = 78.11 g/mol
$\widetilde{M}_{argon}$ = 39.95 g/mol
$\eta_{benzene}$ = 9.465 µPas
η_{argon} = 27.05 µPas
$\lambda_{benzene}$ = 0.01694 W/Km
λ_{argon} = 0.02089 W/Km
We get:

$$F_{12} = \frac{\left[1 + (9.465/27.05)^{1/2}\,(39.95/78.11)^{1/4}\right]^2}{\sqrt{8\,(1 + 78.11/39.95)}} = 0.4629$$

$$F_{21} = \frac{\left[1 + (27.05/9.465)^{1/2}\,(78.11/39.95)^{1/4}\right]^2}{\sqrt{8\,(1 + 39.95/78.11)}} = 2.58655$$

$$F_{11} = F_{22} = 1$$

The thermal conductivity of the mixture is calculated to be:

$$\frac{\lambda^{mix}}{\mathrm{W/Km}} = \frac{0.25 \cdot 0.01694}{0.25 \cdot 1 + 0.75 \cdot 0.4629} + \frac{0.75 \cdot 0.02089}{0.25 \cdot 2.58655 + 0.75 \cdot 1}$$
$$= 0.0183$$

The experimental value is λ = 0.0192 W/Km.

9 Surface Tension

The surface tension is a quantity which decides whether a liquid is prone to form droplets or not. For pure substances, it decreases with increasing temperature and becomes 0 at the critical point (Fig. 17), where vapor and liquid are identical. It is essentially determined by intermolecular forces, especially by the differences of the attractive forces acting on the molecules located in the surface, one from the vapor side and one from the liquid side. The surface tension can be correlated by

$$\frac{\sigma}{\mathrm{N/m}} = A\,(1 - T_r)^{B + CT_r + DT_r^2 + ET_r^3} \tag{109}$$

where the coefficients C, D, and E can either be set to 0 or be fitted according to demand. Coefficients for Eq. (109) are given in Subchap. D3.1.

The surface tension can be estimated according to Brock/Bird/Miller [2], based on the 3-parameter corresponding states principle:

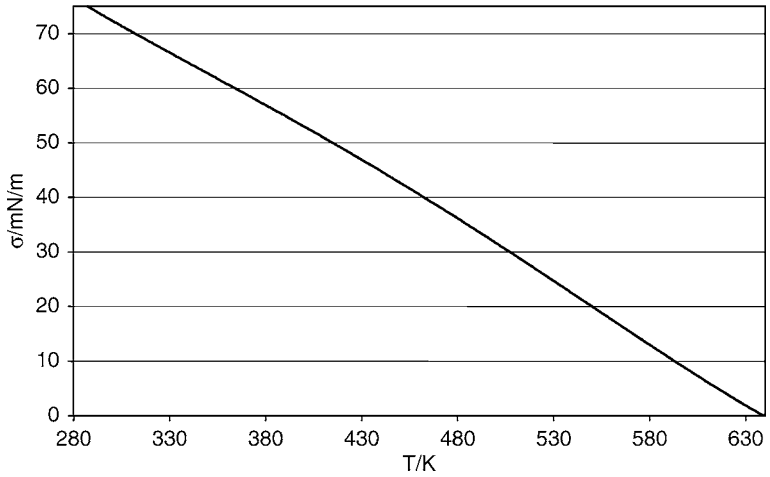
$$\frac{\sigma}{\mathrm{mN/m}} = \left(\frac{p_c}{\mathrm{bar}}\right)^{2/3}\left(\frac{T_c}{\mathrm{K}}\right)^{1/3} Q(1 - T_r)^{11/9} \tag{110}$$

with

$$Q = 0.1196\left[1 + \frac{\frac{T_{NBP}}{T_c}\ln\frac{p_c}{1.01325\,\mathrm{bar}}}{1 - T_{NBP}/T_c}\right] - 0.279 \tag{110a}$$

For substances which are not strongly polar, the deviations are usually less than 5%.

Example 24:
Estimate the surface tension of bromobenzene at t = 50°C.
The given data are:
T_{NBP} = 429.15 K



D1. Fig. 17. Surface tension of water as a function of temperature.

$T_c = 670.20$ K
$p_c = 45.19$ bar
With

$$Q = 0.1196\left[1 + \frac{\frac{429.15}{670.20}\ln\frac{45.19}{1.01325}}{1 - 429.15/670.20}\right] - 0.279 = 0.6492$$

we get

$$\frac{\sigma}{\text{mN/m}} = 45.19^{2/3} \cdot 670.20^{1/3} \cdot 0.6492 \cdot (1 - 323.15/670.2)^{11/9} = 32.25$$

The value listed in Subchap. D3.1 is 33 mN/m.

As a mixing rule, the equation

$$\frac{\sigma_{\text{mix}}}{\text{mN/m}} = \left(P^{\text{liq}}_{\text{mix}} \frac{\widetilde{\rho}^{\text{mix}}_{liq}}{\text{mol/cm}^3} - P^{\text{vap}}_{\text{mix}} \frac{\widetilde{\rho}^{\text{mix}}_{\text{vap}}}{\text{mol/cm}^3}\right)^4 \qquad (111)$$

is suggested, where the terms for the gas phase can be neglected at low pressures. P is the parachor

$$P = \left(\frac{\widetilde{\rho}}{\text{mol/cm}^3}\right)^{-1}\left(\frac{\sigma}{\text{mN/m}}\right)^{1/4} \qquad (112)$$

which can be averaged via

$$P_{mix} = \sum_i \sum_j \widetilde{x}_i \widetilde{x}_j \frac{P_i + P_j}{2} \qquad (113)$$

More accurate methods, especially for aqueous systems, are listed in Poling/Prausnitz/O'Connell [2].

Example 25:
Estimate the surface tension of a mixture of diethyl ether (1) and benzene (2) with a mole fraction $x_1 = 0.423$ at $T = 298$ K. The influence of the vapor in Eq. (107) can be neglected due to the low pressure.
The given data are:
$\widetilde{M}_1 = 74.12$g/mol
$\widetilde{M}_2 = 78.11$g/mol
$\sigma_1 = 16.429$ mN/m
$\sigma_2 = 28.214$ mN/m
$\rho_1 = 707.8$ kg/m^3 = 0.009549 mol/cm^3
$\rho_2 = 872.80$ kg/m^3 = 0.011174 mol/cm^3
One gets:

$$P_1 = 0.009549^{-1} \cdot 16.429^{1/4} = 210.84$$
$$P_2 = 0.011174^{-1} \cdot 28.214^{1/4} = 206.26$$
$$P_{\text{mix}} = 0.423^2 \cdot 210.84 + 2 \cdot 0.423 \cdot 0.577 \frac{210.84 + 206.26}{2} + 0.577^2 \cdot 206.26 = 208.20$$
$$\rho^{\text{mix}}_{\text{liq}} = \left(\widetilde{x}_1 \widetilde{\rho}^{-1}_{\text{liq},1} + \widetilde{x}_2 \widetilde{\rho}^{-1}_{\text{liq},2}\right)^{-1} = \left(\frac{0.423}{0.009549} + \frac{0.577}{0.011174}\right)^{-1} \frac{\text{mol}}{\text{cm}^3} = 0.0104237 \text{ mol/cm}^3$$
$$\sigma_{\text{mix}} = (208.20 \cdot 0.0104237)^4 \text{ mN/m} = 22.18 \text{ mN/m}$$

The experimental value [34] is 21.81 mN/m.

10 Diffusion Coefficient

The binary diffusion coefficient D_{12} is needed for all calculations where mass transfer is involved. In this chapter, it is defined as

$$j_{12} = -\rho_{\text{mix}} D_{12}\left(\frac{dx}{dz}\right) \qquad (114)$$

with j_{12} as mass flux density and z as coordinate direction. The diffusion coefficient is symmetric, that is, $D_{12} = D_{21}$. It is essentially determined by intermolecular forces. For its evaluation, experimental values are difficult to measure and hardly available. In almost all cases, it has to be relied on estimation methods.

10.1 Diffusion Coefficients in Gases

In addition for its role in viscosity and thermal conductivity, the kinetic gas theory [22] is the basis for the estimation methods for diffusion coefficients in the gas phase. It depends not only on temperature but also on pressure. At pressures up to $p = 10$ bar,

it is inversely proportional to the pressure. It is almost independent from the concentration. At low pressures, the binary diffusion coefficient for gases can be estimated according to Fuller [38] with a remarkable accuracy. The calculation equation is given by:

$$\frac{D_{12}}{\mathrm{cm^2/s}} = \frac{0.00143\left(\frac{T}{\mathrm{K}}\right)^{1.75}\left[\left(\frac{\widetilde{M}_1}{\mathrm{g/mol}}\right)^{-1} + \left(\frac{\widetilde{M}_2}{\mathrm{g/mol}}\right)^{-1}\right]^{1/2}}{\frac{p}{\mathrm{bar}}\sqrt{2}\left[\left(\sum \Delta_{v_1}\right)^{1/3} + \left(\sum \Delta_{v_2}\right)^{1/3}\right]^2} \quad (115)$$

Δ_v is the so-called diffusion volume, which can be determined with the group contributions from Table 9. The accuracy of the Fuller method is approximately 4% [2].

Example 26:

Determine the binary diffusion coefficient of a mixture of ammonia (NH_3) and diethyl ether ($C_4H_{10}O$) at $T = 288$ K and $p = 2$ bar. The molecular weights are $M_{NH3} = 17.03$ g/mol and $M_{C4H10O} = 74.12$ g/mol.

The diffusion volumes for both components can be evaluated as:

$$\left(\sum \Delta_{v_1}\right) = 20.7$$

$$\left(\sum \Delta_{v_2}\right) = 4 \cdot 15.9 + 10 \cdot 2.31 + 6.11 = 92.81$$

After inserting the diffusion volumes into Eq. (115), one gets:

$$D_{12} = \frac{0.00143(288)^{1.75}\left[(17.03)^{-1} + (74.12)^{-1}\right]^{1/2}}{2\sqrt{2}\left[(20.7)^{1/3} + (92.81)^{1/3}\right]^2}\,\mathrm{cm^2/s}$$

$$= 0.0517\,\mathrm{cm^2/s}$$

The value taken from the literature [2] is $D_{12} = 0.0505$ cm^2/s.

D1. Table 9. Group contributions for the diffusion volumes in the Fuller method

Atom and structure contributions			
C	15.9	Br	21.9
H	2.31	I	29.8
O	6.11	S	22.9
N	4.54	Aromatic ring	–18.3
F	14.7	Heterocyclic ring	–18.3
Cl	21		
Simple molecules			
He	2.67	CO	18.0
Ne	5.98	CO_2	26.9
Ar	16.2	N_2O	35.9
Kr	24.5	NH_3	20.7
Xe	32.7	H2O	13.1
H_2	6.12	SF_6	71.3
D_2	6.84	Cl_2	38.4
N_2	18.5	Br_2	69.0
O_2	16.3	SO_2	41.8
Air	19.7		

The influence of the pressure can be evaluated with the equation of Riazi and Whitson [2]:

$$\frac{(\rho D_{12})}{(\rho D_{12})^{\mathrm{id}}} = 1.07\left(\frac{\eta}{\eta^{\mathrm{id}}}\right)^{B + C\,p/p_c} \quad (116)$$

with

$$B = -0.27 - 0.38\,\omega \quad (116a)$$

and

$$C = -0.05 + 0.1\,\omega \quad (116b)$$

For mixtures, ω and p_c can be calculated with a linear mixing rule:

$$\omega = \sum_i \widetilde{y}_i \omega_i \quad (117)$$

$$p_c = \sum_i \widetilde{y}_i p_{ci} \quad (118)$$

The disadvantage of this relationship is that it requires the dynamic viscosity of the vapor mixture, which has to be estimated itself. Therefore, approximately 15% deviation for the estimation of vapor diffusion coefficients at high pressures should be expected.

10.2 Diffusion Coefficients in Liquids

The binary diffusion coefficient in liquid mixtures is a complicated function of the concentration and furthermore depends on temperature and pressure. A reliable estimation method is not available. For most of the related engineering problems it is sufficient to meet the correct order of magnitude. It is distinguished between the limiting case of the ideally diluted solution and the case with arbitrary concentrations.

For the limiting case of infinite dilution of the solute A in the solvent B the diffusion coefficient can be estimated using several methods [2]. They are all characterized by individual rules for special components, limited ranges of applicability, or input parameters which are difficult to access. A reasonable compromise between accuracy and applicability is the simplified version of the method of Tyn/Calus [2]:

$$\frac{D_{AB}^{\infty}}{\mathrm{cm^2/s}} = 8.93 \cdot 10^{-8}\left(\frac{v_B(T_{NBP})}{\mathrm{cm^3/mol}}\right)^{-1/3}\left(\frac{v_A(T_{NBP})}{\mathrm{cm^3/mol}}\right)^{1/6}\left(\frac{P_B}{P_A}\right)^{0.6}\frac{T}{K}\left(\frac{\eta_B}{\mathrm{mPas}}\right)^{-1} \quad (119)$$

with P as the parachor, which can be estimated to be

$$P_i = \frac{v_i(T)}{\mathrm{cm^3/mol}}\left(\frac{\sigma_i}{\mathrm{mN/m}}\right)^{0.25} \quad (120)$$

There is also a group contribution method available [2], which, however, only covers a small part of all possible applications.

The special rules of the Tyn/Calus equation are:

- The dynamic viscosity of the solvent should be less than 20...30 mPas.
- If the solute is water, v_A and P_A should be set to $v_A = 37.4$ cm^3/mol and $P_A = 105.2$.

- If the solute is an organic acid, the values for v_A and P_A should be doubled. Exceptions are made if the solvent is water, methanol, or n-butanol.
- If the solvent is an alcohol and the solute is nonpolar, the values for v_A and P_A should be multiplied with a factor corresponding to $8\eta_B$/mPas.

The deviations of the Tyn/Calus equation that should be expected are approximately 10%.

The temperature dependence of Eq. (119) is only an approximation. The actual functional relationship is not finally clarified. Moreover, the pressure dependence is not well defined. It is only known that the liquid diffusion coefficient decreases with increasing pressure at very high pressures.

The model of the ideally diluted solution is applicable if the concentration of the solute does not exceed 5%. . .10%. For the transition of the ideally diluted solution to the general case with arbitrary concentrations the Vignes correlation can be used:

$$D_{AB} = (D_{AB}^{\infty})^{\widetilde{x}_B}(D_{BA}^{\infty})^{\widetilde{x}_A}\left(\frac{\partial \ln(\widetilde{x}_A\gamma_A)}{\partial \ln \widetilde{x}_A}\right)_{T,p} \qquad (121)$$

where γ is the activity coefficient (see Subchap. D5.1). Because of the validity of the Gibbs-Duhem equation it does not matter which component is used for the differential quotient.

Example 27:
Determine the binary diffusion coefficient in a liquid mixture of benzene (A) and toluene (B) at T = 298 K for x_A = 0.4. Approximately, it is an ideal mixture so that the activity coefficients can be regarded to be unity.

The given values are:
$v_A(T_{NBP})$ = 95.84 cm^3/mol
$v_B(T_{NBP})$ = 118.31 cm^3/mol
v_A(T) = 89.49 cm^3/mol
v_B(T) = 106.79 cm^3/mol
σ_A(T) = 28.21 mN/m
σ_B(T) = 27.94 mN/m
η_A(T) = 0.601 mPas
η_B(T) = 0.553 mPas
The parachors can be determined to be:
P_A = 206.24
P_B = 245.52
Thus, the diffusion coefficients in the ideally diluted state are:

$$D_{AB}^{\infty} = 8.93 \cdot 10^{-8}(118.31)^{-1/3}(95.84)^{1/6}\left(\frac{245.52}{206.24}\right)^{0.6} \cdot 298 \cdot (0.553)^{-1}\,\mathrm{cm^2/s} = 2.33 \cdot 10^{-5}\,\mathrm{cm^2/s}$$

$$D_{BA}^{\infty} = 8.93 \cdot 10^{-8}(95.84)^{-1/3}(118.31)^{1/6}\left(\frac{206.24}{245.52}\right)^{0.6} \cdot 298 \cdot (0.601)^{-1}\,\mathrm{cm^2/s} = 1.93 \cdot 10^{-5}\,\mathrm{cm^2/s}$$

There is only one experimental value available [2] (D_{BA}^{∞} = 1.85·10^{-5} cm^2/s), which is met very well.

For the actual concentration, the diffusion coefficient is determined with the Vignes correlation

$$D_{AB} = (2.33 \cdot 10^{-5})^{0.6}(1.93 \cdot 10^{-5})^{0.4}\,\mathrm{cm^2/s} = 2.16 \cdot 10^{-5}\,\mathrm{cm^2/s}$$

10.3 Diffusion in Multicomponent Mixtures

In multicomponent mixtures, the diffusion flow depends not only on its own but also on the interaction of all concentration gradients. In extreme cases, a component can even diffuse in the opposite direction of its own concentration gradient [39]. The calculation of such processes is very complex and beyond the scope of this chapter.

11 Symbols

a	parameter in RKS and PR equation of state (Pa m^6 mol^{-2})
b	parameter in RKS and PR equation of state (m^3 mol^{-1})
A, B, C, D, E, F	coefficients
c_σ	specific heat capacity along the saturation line (J kg^{-1} K^{-1})
D	diffusion coefficient (m^2 s^{-1})
f	fugacity (Pa)
F_{ij}	weighting factor
F_P	factor for pressure correction
j	mole flux density (mol m^{-2} s^{-1})
k_{ij}	interaction parameter in cubic equations of state
K	equilibrium constant (Pa^{-1})
n	degree of association
n_A	number of atoms in a molecule
P	parachor
q	electric charge (C)
r	distance (m)
t	Celsius temperature (°C)
v	specific volume (m^3 mol^{-1})
z	coordinate (m)
$\widetilde{z}$	true concentration (association) (mol mol^{-1})
Z	compressibility factor
Z_2	correction factor
α	coefficient
γ	activity coefficient
Δ_G	group contribution for standard Gibbs energy of formation
Δ_H	group contribution for standard enthalpy of formation
Δ_T	group contribution for critical temperature
Δ_p	group contribution for critical pressure
Δ_{NBP}	group contribution for normal boiling point
Δ_v	group contribution for critical volume
Δg^{0f}	standard Gibbs energy of formation (J mol^{-1})
Δh^{0f}	standard enthalpy of formation (J mol^{-1})
Δh_{Gas}^{real}	residual part of vapor enthalpy (J mol^{-1})
Δh_{in}	enthalpy of association (J mol^{-1}) (component i, degree of association n)
Δh_m	enthalpy of fusion (J mol^{-1})
Δh_v	enthalpy of vaporization (J mol^{-1})
μ	dipole moment (debye)
ν	kinematic viscosity (m^{2}s^{-1})
ξ	reduced inverse viscosity

$\Sigma\Delta_v$	diffusion volume
φ	fugacity coefficient
Φ	parameter in thermal conductivity mixing rule
ω	acentric factor

Indices

D	dimer
E	excess quantity
Gas	Gas
id	ideal gas
LG	transition liquid–gas
liq	liquid
m	melting point
M	monomer
mix	mixture
NBP	normal boiling point
ref	reference state
s	saturation state
SRK	Soave-Redlich-Kwong
$'$	boiling liquid
$''$	saturated vapor
∞	state of infinite dilution

D2.1 Properties of Water and Steam

Wolfgang Wagner[1] · *Hans-Joachim Kretzschmar*[2]
[1]Ruhr-Universität Bochum, Bochum, Germany
[2]Hochschule Zittau/Görlitz, University of Applied Sciences, Zittau, Germany

1 Introduction

The International Association for the Properties of Water and Steam (IAPWS) adopted two international standards for the thermodynamic properties of water substance.

The scientific equation of state was adopted in 1995 and is called "The IAPWS Formulation 1995 for the Thermodynamic Properties of Ordinary Water Substance for General and Scientific Use" [1] or just IAPWS-95 for short. The formulation is valid in the entire stable fluid region of H_2O from the melting curve to 1,000°C at pressures up to 10,000 bar; the lowest temperature on the melting curve is $t = -21.985$°C (at 2099 bar). In this entire region, IAPWS-95 represents the most accurate experimental data within their uncertainties. This formulation can be reasonably extrapolated far beyond its range of validity. A comprehensive article [2] describes all details about this formulation.

The industrial standard for the thermodynamic properties of water and steam was adopted in 1997 and is called "IAPWS Industrial Formulation 1997 for the Thermodynamic Properties of Water and Steam" [3] or "IAPWS-IF97" for short. IAPWS-IF97 consists of a set of equations for different regions that covers the following range of validity:

$$0°C \le t \le 800°C \qquad p \le 1000 \text{ bar}$$
$$800°C < t \le 2000°C \qquad p \le 500 \text{ bar}$$

This industrial standard has been coupled to the scientific standard IAPWS-95 by fitting the basic equations of IAPWS-IF97 to values of several thermodynamic properties calculated from IAPWS-95. The Industrial Formulation IAPWS-IF97 is comprehensively described in the book "International Steam Tables" [4].

2 Tables of Thermophysical Properties

The values of the thermophysical properties listed in the following tables were calculated from the Industrial Formulation IAPWS-IF97 [3, 4], except for the temperature range $t < 0$°C of Table 1. The tabulated values of the transport properties were calculated from the current IAPWS equations for the thermal conductivity [5] and the dynamic viscosity [6], each in the version for industrial use. These equations are also given in the latest International Steam Tables [4]. Apart from the basic equations of IAPWS-IF97, this book contains all backward equations that have been developed in the past years. These backward equations allow quick calculations of properties for input values other than (p,T), for example, (p,h), (p,s), and (h,s) without iterations. The book also contains the representation of 25 properties in pressure-temperature diagrams. The property values in Tables 1–14 were calculated with the CD providing the interactive program "IAPWS-IF97 Electronic Steam Tables" that accompanies the International Steam Tables [4]. This software allows the calculation of "personal" steam tables for arbitrary values of pressure and temperature.

Tables 1–14 cover the following properties:

t – Celsius temperature	α_v – Isobaric cubic expansion coefficient, $\alpha_v = (1/v)(\partial v/\partial T)_p$
T – Thermodynamic temperature	
p – Pressure	λ – Thermal conductivity
ρ – Density	η – Dynamic viscosity
v – Specific volume	ν – Kinematic viscosity, $\nu = \eta/\rho$
Z – Compression factor, $Z = p/(\rho RT)$	a – Thermal diffusivity, $a = \lambda/(c_p\,\rho)$
h – Specific enthalpy	Pr – Prandtl number, $\Pr = \eta\, c_p/\lambda$
s – Specific entropy	σ – Surface tension
c_p – Specific isobaric heat capacity	b – Laplace coefficient, $b = \{\sigma/[g(\rho' - \rho'')]\}^{0.5}$, where g is the acceleration of gravity, $g = 9.80655$ m s^{-2}

Further properties are tabulated in the International Steam Tables [4].

The characteristic properties of water are:

Molar mass $\tilde{M} = 18.015\,275$ g mol^{-1}	Triple point: $T_t = 273.16$ K or $t_t = 0.01$°C $p_t = 6.116\,57$ mbar
Specific gas constant $R = 0.461\,526$ kJ kg^{-1} K^{-1}	
Critical point: $T_c = 647.096$ K or $t_c = 373.946$°C $p_c = 220.64$ bar $\rho_c = 322$ kg m^{-3}	Normal boiling point ($p = 1.013\,25$ bar): $T_b = 373.124$ K or $t_b = 99.974$°C

[a]The values for the properties at $t \leq 0°C$ and $p = 1$ bar correspond to the (metastable) subcooled liquid; in the stable state at these t-p values, water is in the solid phase (ice). The values were calculated with the scientific standard equation of state IAPWS-95 [1, 2] that can be extrapolated up to these for $t < 0°C$ temperatures. The equation for λ [4, 5] cannot be extrapolated to temperatures $t < 0°C$; thus, the properties a and Pr cannot be calculated, either.
[b]Temperature at the saturated-liquid line.
t, Temperature; ρ, Density; h, Specific enthalpy; s, Specific entropy; c_p, Specific isobaric heat capacity; α_v, Isobaric cubic expansion coefficient; λ, Thermal conductivity; η, Dynamic viscosity; ν, Kinematic viscosity; a, Thermal diffusivity; Pr, Prandtl number.

D2.1. Table 2. Thermodynamic properties of water in the saturation state from the triple point to the critical point

[a]The values at $t = 0°C$ were determined by extrapolating the saturation curves from $t = 0.01°C$ (triple-point temperature) to $t = 0°C$.
[b]Triple-point temperature.
[c]Critical temperature.
[d]The industrial equations for λ [4, 5] and η [4, 6] do not represent the critical enhancement in the near-critical region. If more accurate values are needed in this region, the scientific equations for λ [5] and η [6] should be used.
[e]In the near-critical region, the use of IAPWS-IF97 for c_p and the use of the industrial equations for λ [4, 5] and η [4, 6] do not yield accurate values for Pr.
t, Temperature; p_s; Saturation pressure; λ, Thermal conductivity; η, Dynamic viscosity; ν, Kinematic viscosity; Pr, Prandtl number; σ, Surface tension; b, Laplace coefficient; ′, Saturated liquid; ″, Saturated vapor.

[a]The bold horizontal lines in the columns indicate the transition from the liquid phase to the gas phase.

[b]The values for the properties at $t = 0$°C and $p = 1$ bar correspond to the (metastable) subcooled liquid; in the stable state at these t-p values, water is in the solid phase (ice).

D2.1. Table 9. Isobaric cubic expansion coefficient $\alpha_v/(10^{-3}\ K^{-1})$ of water for given values of pressure and temperature[a]

[a]The bold horizontal lines in the columns indicate the transition from the liquid phase to the gas phase.
[b]The values for the properties at $t = 0$°C and $p = 1$ bar correspond to the (metastable) subcooled liquid; in the stable state at these t-p values, water is in the solid phase (ice).
[c]The λ values below the dashed lines are beyond the range of validity of the λ equation for industrial use [4, 5]; for details of this extrapolation, see [4]. If more accurate λ values are needed in this range, the λ equation for scientific use [5] should be used.

D2.1. Table 11. Dynamic viscosity $\eta/(10^{-6}$ Pa s) of water for given values of pressure and temperature[a]

[a]The bold horizontal lines in the columns indicate the transition from the liquid phase to the gas phase.
[b]The values for the properties at $t = 0$°C and $p = 1$ bar correspond to the (metastable) subcooled liquid; in the stable state at these t-p values, water is in the solid phase (ice).
[c]The a values below the dashed lines were calculated with λ values from the λ equation for industrial use [4, 5] beyond its range of validity; for details of this extrapolation, see [4]. If more accurate a values are needed in this range, the λ equation for scientific use [5] should be used.

[a]The bold horizontal lines in the columns indicate the transition from the liquid phase to the gas phase.
[b]The values for the properties at $t = 0°C$ and $p = 1$ bar correspond to the (metastable) subcooled liquid; in the stable state at these t-p values, water is in the solid phase (ice).
[c]The Pr values below the dashed lines were calculated with λ values from the λ equation for industrial use [4, 5] beyond its range of validity; for details of this extrapolation, see [4]. If more accurate Pr values are needed in this range, the λ equation for scientific use [5] should be used.

As usual for water, the reference state for the caloric properties was set by choosing the specific internal energy and the specific entropy of the saturated liquid to be zero at the triple point, i.e., $u_t'(T_t) = 0$ and $s_t'(T_t) = 0$. As a consequence of this zero-point setting, the specific enthalpy of the saturated liquid at the triple point is given by $h_t'(T_t) = 0.000\,611\,783$ kJ kg^{-1}.

D2.2 Properties of Dry Air

Roland Span
Ruhr-Universität Bochum, Bochum, Germany

1 Composition of Dry Air

Substance	Mole fraction	Molecular mass g/mol	Mass fraction
N_2	0.7812	28.013	0.75570
Ar	0.0092	39.948	0.01269
O_2	0.2096	31.999	0.23161

Molecular mass of the mixture: $\widetilde{M}$ = 28.9583 g/mol

Specific gas constant of the mixture: R = 0.28712 kJ/(kg K)

Deviations caused by neglecting the CO_2 fraction in air always remain smaller than the uncertainty of the equations used to calculate the tabulated properties. The impact of all other trace components is smaller than the impact of CO_2. Humidity has to be considered separately.

To calculate the properties tabulated in the following pages, the "pseudo pure-component" equations from the cited references were used. According to the authors, these equations are slightly more accurate than the mixture models published in the same articles.

Z	Compression factor $Z = p/(\rho RT)$	β	Isobaric expansion coefficient in 10^{-3}/K $\beta = v^{-1}\,(\partial_v/\partial T)_p$
Pr	Prandtl number Pr = $\eta\, c_p/\lambda$	c_p	Specific isobaric heat capacity in kJ/(kg K)
		w_s	Isentropic speed of sound in m/s

p	Pressure in bar	v	Specific volume in m^3/kg
ρ	Density in kg/m^3	λ	Thermal conductivity in mW/(m K)
ϑ	Temperature in °C	ν	Kinematic viscosity ν in 10^{-7} m^2/s
h	Specific enthalpy in kJ/kg	η	Dynamic viscosity in 10^{-6} Pa·s
s	Specific entropy in kJ/(kg K)	a	Thermal diffusivity in 10^{-7} m^2/s

2 Critical Parameters of Dry Air

	Temperatures	Pressures	Densities
Critical	132.531 K	3.7860 MPa	11.8308 mol/dm^3
	−140.619 °C	37.860 bar	342.599 kg/m^3
Maxcondentherm	132.631 K	3.7850 MPa	10.4477 mol/dm^3
	−140.519 °C	37.850 bar	302.547 kg/m^3
Maxcondenbar	132.604 K	3.7891 MPa	11.0948 mol/dm^3
	−140.547 °C	37.891 bar	321.286 kg/m^3

2.1 Reference States of Enthalpy and Entropy

h = 0 kJ/kg, s = 0 kJ/(kg K) at T = 298.15 K (ϑ) = 25°C), p = 1.01325 bar for the pure components

D2.2. Table 1. Properties of dry air at $p = 1$ bar

ϑ °C	ρ kg/m³	h kJ/kg	s kJ/(kg K)	c_p kJ/(kg K)	β 10^{-3}/K	λ mW/(m K)	η μ Pa*s	ν 10^{-7} m²/s	a 10^{-7} m²/s	Pr –	w_s m/s

D2.3 Properties of Nitrogen

Roland Span[1] · *Rolf Krauss*[2]
[1]Ruhr-Universität Bochum, Bochum, Germany
[2]Universität Stuttgart, Stuttgart, Germany

1 Properties of Nitrogen

Tables with thermodynamic properties of nitrogen were calculated with the reference equation of state established by Span et al. [1], see also Span et al. [2].

The thermal conductivity and viscosity of nitrogen were calculated with the corresponding equations by Stephan and Krauss [3]. The densities required as input for the equations by Stephan and Krauss were calculated using the equation by Span et al.

p	Pressure in bar	v	Specific volume in m^3/kg
ρ	Density in kg/m^3	λ	Thermal conductivity in mW/(m K)
ϑ	Temperature in °C	ν	Kinematic viscosity ν in $10^{-7} m^2/s$
h	Specific enthalpy in kJ/kg	η	Dynamic viscosity in 10^{-6} Pa·s
s	Specific entropy in kJ/(kg K)	a	Thermal diffusivity in 10^{-7} m^2/s
Z	Compression factor $Z = p/(\rho RT)$	β	Isobaric expansion coefficient in 10^{-3}/K $\beta = v^{-1}\cdot(\partial v/\partial T)_p$
Pr	Prandtl number $Pr = \eta\, c_p/\lambda$	c_p	Specific isobaric heat capacity in kJ/(kg K)
w_s	Isentropic speed of sound in m/s	c_v	Specific isochoric heat capacity in kJ/(kg K)

2 Characteristic Quantities

Molecular mass $\widetilde{M}$ = 28.01348 g/mol, specific gas constant R = 296.8039 J/(kg K)

3 Critical Point [1]

p_c = 33.958 bar, T_c = 126.192 K (ϑ_c = −146.958°C), ρ_c = 313.3 kg/m^3

4 Triple Point [1]

T_t = 63.151 K (ϑ_t = −209.999°C)

5 Reference States of Enthalpy and Entropy [1]

h = 309.494 kJ/kg, s = 6.8360 kJ/(kg K) at T = 298.15 K (ϑ = 25°C), p = 1.01325 bar corresponding to h = 0 kJ/kg, s = 0 kJ/(kg K) for a perfect crystal at T = 0 K

D2.4 Properties of Carbon Dioxide

Roland Span[1] · *Rolf Krauss*[2]
[1]Ruhr-Universität Bochum, Bochum, Germany
[2]Universität Stuttgart, Stuttgart, Germany

1 Properties of Carbon Dioxide

Tables with thermodynamic properties of carbon dioxide were calculated with the reference equation of state established by Span and Wagner [1].

The thermal conductivity and viscosity of carbon dioxide were calculated with the corresponding equations by Vesovic et al. [2]. The densities required as input to the equations by Vesovic et al. were calculated using the equation by Span and Wagner. The critical enhancement was considered for the thermal conductivity, where it significantly affects a rather large region around the critical point.

p	Pressure in bar	ν	Specific volume in m^3/kg
ρ	Density in kg/m^3	λ	Thermal conductivity in mW/(m K)
ϑ	Temperature in °C	ν	Kinematic viscosity ν in $10^{-7} m^2/s$
h	Specific enthalpy in kJ/kg	η	Dynamic viscosity in 10^{-6} Pa·s
s	Specific entropy in kJ/(kg K)	a	Thermal diffusivity in 10^{-7} m^2/s
Z	Compression factor $Z = p/(\rho RT)$	β	Isobaric expansion coefficient in 10^{-3}/K $\beta = \nu^{-1}\cdot(\partial\nu/\partial T)_p$
Pr	Prandtl number $Pr = \eta\, c_p/\lambda$	c_p	Specific isobaric heat capacity in kJ/(kg K)
w_s	Isentropic speed of sound in m/s	c_v	Specific isochoric heat capacity in kJ/(kg K)

2 Characteristic Quantities

Molecular mass $\tilde{M}$ = 44.0098 g/mol, specific gas constant R = 188.9241 J/(kg K).

3 Critical Point [1]

p_c = 73.773 bar, T_c = 304.1282 K (ϑ_c = 30.9782°C), ρ_c = 467.6 kg/m^3.

4 Triple Point [1]

p_t = 5.1795 bar, T_t =216.592 K (ϑ_t = −56.558°C).

5 Reference States of Enthalpy and Entropy

h = 506.78 kJ/kg, s = 2.739 kJ/(kg K) at T = 298.15 K (ϑ = 25°C), p = 1.01325 bar corresponding to h' = 200 kJ/kg, s' = 1 kJ/(kg K) for saturated liquid at ϑ = 0°C.

D2.4. Table 1. Properties of carbon dioxide at $p = 1$ bar

D2.5 Properties of Oxygen

Roland Span[1] · *Rolf Krauss*[2]
[1]Ruhr-Universität Bochum, Bochum, Germany
[2]Universität Stuttgart, Stuttgart, Germany

The tables with thermodynamic properties of oxygen were calculated using the fundamental equation of state by Schmidt and Wagner [1], see also Wagner and de Reuck [2]. This equation formally is valid for temperatures up to 300 K (26.85°C). However, it allows for reasonable extrapolation to much higher temperatures [2], even far beyond the limit of 100°C chosen for the tables in this section.

p	Pressure in bar	β	Isobaric expansion coefficient in 10^{-3}/K $\beta = v^{-1}\cdot(\partial v/\partial T)_p$
ρ	Density in kg/m^3	w_s	Isentropic speed of sound in m/s
ϑ	Temperature in °C	λ	Thermal conductivity in mW/(m K)
Z	Compression factor $Z = p/(\rho RT)$	η	Dynamic viscosity in 10^{-6} Pa·s
h	Specific enthalpy in kJ/kg	ν	Kinematic viscosity ν in 10^{-7} m^2/s
s	Specific entropy in kJ/(kg K)	a	Thermal diffusivity in 10^{-7} m^2/s
c_p	Specific isobaric heat capacity in kJ/(kg K)	Pr	Prandtl number Pr = $\eta\, c_p/\lambda$
c_v	Specific isochoric heat capacity in kJ/(kg K)	v	Specific volume in m^3/kg

The correlations by Laesecke et al. [3] were used to calculate the thermal conductivity and viscosities. The required densities were calculated using the fundamental equation [1, 2].

1 Characteristic Quantities

Molecular mass $\tilde{M}$ = 31.9988 g/mol, specific gas constant R = 259.832869 J/(kg K).

2 Critical Point [1]

p_c = 50.460 bar, T_c = 154.599 K (ϑ_c = −118.551°C), ρ_c = 417 kg/m^3.

3 Triple Point [1]

p_t = 0.0014633 bar, T_t = 54.361 K (ϑ_t = −218.789°C).

4 Reference States of Enthalpy and Entropy

h = 0 kJ/kg, s = 0 kJ/(kg K) at T = 298.15 K (ϑ = 25°C), p = 1 bar for the ideal gas.

D2.5. Table 1. Properties of oxygen at $p = 1$ bar

D2.6 Properties of Ammonia

Roland Span[1] · *Rolf Krauss*[2]
[1]Ruhr-Universität Bochum, Bochum, Germany
[2]Universität Stuttgart, Stuttgart, Germany

Tables with thermodynamic properties of ammonia were calculated using the reference equation of state established by Tillner-Roth et al. [1, 2].

Tabulated thermal conductivities were calculated using the equation by Tufeu et al. [3]. Viscosities were calculated using the equation by Fenghour et al. [4]. The densities required as input to these correlations were calculated using the reference equation of state.

p	Pressure in bar	v	Specific volume in m^3/kg
ρ	Density in kg/m^3	β	Isobaric expansion coefficient in $10^{-3}/K$ $\beta = v^{-1}\cdot(\partial v/\partial T)_p$
ϑ	Temperature in °C	w_s	Isentropic speed of sound in m/s
Z	Compression factor $Z = p/(\rho RT)$	λ	Thermal conductivity in mW/(m K)
h	Specific enthalpy in kJ/kg	η	Dynamic viscosity in 10^{-6} Pa·s
s	Specific entropy in kJ/(kg K)	ν	Kinematic viscosity ν in 10^{-7} m^2/s
c_p	Specific isobaric heat capacity in kJ/(kg K)	a	Thermal diffusivity in 10^{-7} m^2/s
c_v	Specific isochoric heat capacity in kJ/(kg K)	Pr	Prandtl number $Pr = \eta\, c_p/\lambda$

1 Characteristic Quantities

Molecular mass $\tilde{M}$ = 17.0305 g/mol, specific gas constant R = 488.2175 J/(kg K).

2 Critical Point [2]

p_c = 113.39 bar, T_c = 405.4 K (ϑ_c = 132.25 °C), ρ_c = 225 kg/m^3.

3 Triple Point [2]

T_t = 195.5 K (ϑ_t = −77.65 °C).

4 Reference States of Enthalpy and Entropy

h' = 200 kJ/kg and s' = 1 kJ/(kg K) for saturated liquid at ϑ = 0 °C.

D2.6. Table 1. Properties of ammonia at $p = 1$ bar

D2.7 Properties of R134a (1,1,1,2-tetrafluoromethane)

Roland Span[1] · *Rolf Krauss*[2]
[1]Ruhr-Universität Bochum, Bochum, Germany
[2]Universität Stuttgart, Stuttgart, Germany

Tables with thermodynamic properties of R134a (1,1,1,2-Tetrafluoroethan) were calculated with the reference equation of state established by Tillner-Roth and Baehr [1, 2].

The thermal conductivity and viscosity of R134a were calculated with the corresponding equations by Krauss et al. [3]. The densities required as input to these equations were calculated using the equation by Tillner-Roth and Baehr.

p	Pressure in bar	β	Isobaric expansion coefficient in 10^{-3}/K $\beta = v^{-1}\,(\partial v/\partial T)_p$
ρ	Density in kg/m^3	w_s	Isentropic speed of sound in m/s
ϑ	Temperature in °C	λ	Thermal conductivity in mW/m K
Z	Compression factor $Z = p/(\rho RT)$	η	Dynamic viscosity in 10^{-6} Pa·s
h	Specific enthalpy in kJ/kg	ν	Kinematic viscosity ν in 10^{-7} m^2/s
s	Specific entropy in kJ/(kg K)	a	Thermal diffusivity in 10^{-7} m^2/s
c_p	Specific isobaric heat capacity in kJ/(kg K)	Pr	Prandtl number Pr = $\eta\, c_p/\lambda$
c_v	Specific isochoric heat capacity in kJ/(kg K)	v	Specific volume in m^3/kg

1 Characteristic Quantities

Molecular mass $\widetilde{M}$ = 102.032 g/mol, specific gas constant R = 81.488856 J/(kg K).

2 Critical Point [1]

p_c = 40.56 bar, T_c = 374.18 K (ϑ_c = 101.03°C), ρ_c = 508 kg/m^3.

3 Triple Point [1]

p_t = 0.00391 bar, T_t = 169.85 K (ϑ_t = −103.3°C), ρ'_t = 1591kg/m^3.

4 Reference States of Enthalpy and Entropy

h' = 200 kJ/kg and s' = 1 kJ/(kg K) for saturated liquid at ϑ = 0 °C.

D3.1 Liquids and Gases

Michael Kleiber[1] · *Ralph Joh*[2]
[1]Uhde GmbH, Bad Soden, Germany
[2]Siemens AG, Frankfurt, Germany

In the previous edition, this section containing thermophysical data of 275 compounds had been supplemented by correlations for temperature-dependent properties in order to give a better opportunity for interpolation and, with the appropriate caution, extrapolation. With the help of these correlations, the user can make use of the data in process simulation programs.

Most of the data points given in the tables have been obtained by regression of experimental data from the literature or the relevant databanks. During this regression, a careful evaluation of the data has been performed, and outliers have been removed from the database. The equations listed below have been used for this regression. The final correlations are at least valid in the temperature range where data points are given in the tables. Although the correlations are usually suitable for extrapolation, one should be careful to go beyond this range. Especially when polynoms are used, a plausible curvature should be maintained (see Chap. D1).

In comparison to the previous German edition of the VDI Heat Atlas, for the liquid density, the liquid viscosity, the enthalpy of vaporization and the specific heat capacities of liquids and ideal gases the new PPDS equations have been used. Currently, these equations seem to be the most accurate ones and show a reasonable extrapolation behavior. For the vapor pressure, the 2.5-5-form of the Wagner equation is used, which performs slightly better than the well established 3-6-form.

Whenever it was possible, high-precision equations of state have been used to obtain artificial data points as the basis for the regression. On the other hand, many values for transport properties, especially for gases, have been obtained by the estimation methods described in Chap. D1.

In general, all the values and correlations are not the absolutely correct ones but refer to the best possible data according to the knowledge of the authors. Like all data collections, also this one cannot claim completeness or absolute reliability. The authors are grateful for hints on mistakes and general improvements of this chapter.

The correlation equations for the temperature-dependent properties are:

Liquid density

$$\frac{\rho_{\mathrm{liq}}}{\mathrm{kg/m^3}} = \frac{\rho_c}{\mathrm{kg/m^3}} + A\left(1-\frac{T}{T_c}\right)^{0.35} + B\left(1-\frac{T}{T_c}\right)^{2/3} + C\left(1-\frac{T}{T_c}\right) + D\left(1-\frac{T}{T_c}\right)^{4/3} \tag{1}$$

Dynamic viscosity of liquids

$$\frac{\eta}{\mathrm{Pa\,s}} = E\cdot\exp\left[A\left(\frac{C-T}{T-D}\right)^{1/3} + B\left(\frac{C-T}{T-D}\right)^{4/3}\right] \tag{2}$$

When Eq. (2) is programmed, it must be taken care that the term in brackets $(C-T)/(T-D)$ sometimes turns out to be negative, so that it makes sense to write in these cases

$$\left(\frac{C-T}{T-D}\right)^{1/3} = -\left(\frac{T-C}{T-D}\right)^{1/3}$$

and

$$\left(\frac{C-T}{T-D}\right)^{4/3} = -\left(\frac{T-C}{T-D}\right)^{1/3}\left(\frac{C-T}{T-D}\right) \tag{2a}$$

Dynamic viscosity of gases

$$\frac{\eta}{\mathrm{Pa\,s}} = A + B\frac{T}{K} + C\left(\frac{T}{K}\right)^2 + D\left(\frac{T}{K}\right)^3 + E\left(\frac{T}{K}\right)^4 \tag{3}$$

Thermal conductivity of liquids

$$\frac{\lambda}{\mathrm{W/mK}} = A + B\frac{T}{K} + C\left(\frac{T}{K}\right)^2 + D\left(\frac{T}{K}\right)^3 + E\left(\frac{T}{K}\right)^4 \tag{4}$$

Thermal conductivity of gases

$$\frac{\lambda}{\mathrm{W/mK}} = A + B\frac{T}{K} + C\left(\frac{T}{K}\right)^2 + D\left(\frac{T}{K}\right)^3 + E\left(\frac{T}{K}\right)^4 \tag{5}$$

Surface tension

$$\frac{\sigma}{\mathrm{N/m}} = A\left(1-\frac{T}{T_c}\right)^{B+C(T/T_c)+D(T/T_c)^2+E(T/T_c)^3} \tag{6}$$

Vapor pressure

$$\ln\frac{p_s}{p_c} = \frac{T_c}{T}\left[A\left(1-\frac{T}{T_c}\right) + B\left(1-\frac{T}{T_c}\right)^{1.5} + C\left(1-\frac{T}{T_c}\right)^{2.5} + D\left(1-\frac{T}{T_c}\right)^{5}\right] \tag{7}$$

Specific heat capacity of liquids

$$c_p^{\mathrm{liq}} = R\left(\frac{A}{1-\frac{T}{T_c}} + B + C\left(1-\frac{T}{T_c}\right) + D\left(1-\frac{T}{T_c}\right)^2 + E\left(1-\frac{T}{T_c}\right)^3 + F\left(1-\frac{T}{T_c}\right)^4\right) \tag{8}$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_12,

Equation (8) reduces to a polynomial if the first parameter A is set to 0. For many substances, only few data points are known so that it is not justified to fit all the parameters.
In these cases, extrapolation beyond the range of validity should be avoided.

Enthalpy of vaporization

$$\Delta h_v = RT_c\left[A\left(1-\frac{T}{T_c}\right)^{1/3}+B\left(1-\frac{T}{T_c}\right)^{2/3}+C\left(1-\frac{T}{T_c}\right)+D\left(1-\frac{T}{T_c}\right)^{2}+E\left(1-\frac{T}{T_c}\right)^{6}\right] \quad (9)$$

Specific heat capacity of ideal gases

$$\frac{c_p^{id}}{R} = B+(C-B)\left(\frac{T}{A+T}\right)^2\left[1-\frac{A}{A+T}\left(D+E\frac{T}{A+T}+F\left(\frac{T}{A+T}\right)^2+G\left(\frac{T}{A+T}\right)^3\right)\right] \quad (10)$$

The symbols are explained in Chap. D1. If the data points are recalculated from the parameters, small deviations due to approximation errors of the parameters might occur.

D3.2 Properties at Saturation

Roland Span
Ruhr-Universität Bochum, Bochum, Germany

The tables in this chapter contain values of thermal, caloric, and transport properties of the saturated liquid and vapor of the corresponding fluids. Originally, these tables were adapted from the Heat Exchanger Design Handbook (*R. N. Maddox*, Hemisphere Publishing Corporation, 1983). However, most tables were recalculated by now. References are included to enable access to more detailed information. An alphabetic list of references is given at the end of Subchap. D3.2.

At a given temperature, properties of the saturated vapor (except for the saturated vapor density) can be used for the homogeneous gas region as a first-order approximation. In the same sense, data for the saturated liquid can be used for the homogeneous liquid at a given temperature. However, when approaching the critical temperature this approximation results in an increasing systematic error. Wherever possible, the cited equations of state should be used to directly calculate properties at homogeneous states.

Since critical parameters are required for many relations used to calculate properties on the phase boundary and since they are important parameters of the correlations used to calculate the given tables, values of the critical temperature, T_c, the critical pressure, p_c, and the critical density, ρ_c, are given for each of the fluids. The values given in this chapter are parameters of the used correlations and are as such independent of the values reported in Chap. D1.

The following properties are reported in the tables of this section:

T_s	Saturation temperature in K
p_s	Vapor pressure in kPa
h	Specific enthalpy in kJ/kg
Δh_v	Specific enthalpy of evaporation in kJ/kg
c_p	Specific isobaric heat capacity in kJ/(kg K)
η	Dynamic viscosity in kg/(m s)
λ	Thermal conductivity in W/(m K)
Pr	Prandtl number
σ	Surface tension in N/m
β'	volumetric expansion coefficient of the liquid in K^{-1} with $\beta' = \frac{(v_2 - v_1)}{v_1(T_2 - T_1)}$

Properties marked with $'$ denote saturated liquid states. Properties marked with $''$ denote saturated vapor states.

In most cases, "typical" uncertainties exist for properties of the saturated liquid or of the saturated vapor at temperatures ranging from the normal-boiling temperature to about 90% of the critical temperature. In most cases, the uncertainty of all properties except for the vapor pressure significantly increases at temperatures above 90% of the critical temperature. Between triple-point temperature and normal-boiling temperature particularly, relative uncertainties of vapor pressure and saturated vapor density increase. However, depending on the data situation the uncertainty of properties may very well vary significantly with temperature even in the range where by principle no problems would be expected. Thus, reducing a discussion of uncertainties to a single value always is a critical simplification. On the other hand, information on the uncertainty of properties is essential for the user. Therefore, it has been tried to characterize the "typical" relative uncertainty of the data presented in the tables by classifying them into groups a to f:

a	$\Delta y/y \leq \pm 0.2\%$
b	$\Delta y/y \leq \pm 0.5\%$
c	$\Delta y/y \leq \pm 1\%$
d	$\Delta y/y \leq \pm 2\%$
e	$\Delta y/y \leq \pm 5\%$
f	$\Delta y/y \leq \pm 10\%$
g	$\Delta y/y > \pm 10\%$
h	Insufficient information for classification

Typically, the category h is found where data were adapted from other compilations.

Interpolation between the values given in the tables is permitted. However, due to large temperature steps in the tables simple linear interpolation may result in errors up to 10% even at moderate temperatures sufficiently far away from the critical temperature. The magnitude of the error caused by interpolation strongly depends on the algorithm used for interpolation and on characteristics of the property. Based on the general formula for interpolation,

$$y = y_1 + \frac{\tau - \tau_1}{\tau_2 - \tau_1}\,(y_2 - y_1),$$

we recommend the following algorithms.

Linear interpolation over temperature ($\tau = T$) for enthalpies of the saturated liquid ($y = h'$) and the saturated vapor ($y = h''$) and for the thermal conductivity of the saturated liquid ($y = \lambda'$).

Linear interpolation in the logarithmic distance to the critical temperature ($\tau = \ln(T_c - T)$) for the dynamic viscosity ($y = \eta''$) and the thermal conductivity ($y = \lambda''$) of the saturated vapor.

Tables are given for the following fluids:

Logarithmic interpolation in the logarithmic distance to the critical temperature ($\tau = \ln(T_c - T)$) for the saturated liquid density ($y = \ln(\rho')$), the enthalpy of evaporation ($y = \ln(\Delta h_v)$), the isobaric heat capacity of the saturated liquid ($y = \ln(c_p')$) and the saturated vapor ($y = \ln(c_p'')$), the Prandtl number of the saturated liquid ($y = \ln(\mathrm{Pr}')$) and of the saturated vapor ($y = \ln(\mathrm{Pr}'')$), the surface tension ($y = \ln(\sigma)$) and the volumetric expansion coefficient of the liquid ($y = \ln(\beta')$).

Linear interpolation in the inverse temperature ($\tau = T^{-1}$) for the dynamic viscosity of the saturated liquid ($y = \eta'$).

Logarithmic interpolation in the inverse temperature ($\tau = T^{-1}$) for the vapor pressure ($y = \ln(p_s)$) and the saturated vapor density ($y = \ln(\rho'')$).

Even when these algorithms are used, additional uncertainties between ±0.2% and ±1% have to be considered for interpolated values. This becomes particularly relevant for properties with the uncertainty class a or b – the "typical" uncertainties given in the tables do not include errors due to interpolation. Interpolation errors up to ±3% occur for the Prandtl number of the saturated vapor. Interpolation between the last two columns of the table (for temperatures close to the critical temperature) may result in significantly larger errors.

D4.1 Refrigerants: Regulations

Ewald Preisegger · Felix Flohr
Solvay Fluor GmbH, Hannover, Germany

1 Introduction

The refrigerants used in vapor compression refrigeration systems in the European Community (EC) today are

- Hydrochlorofluorocarbons (HCFCs), e.g., R22
- Hydrofluorocarbons (HFCs), e.g., R134a
- Ammonia (R717)
- Carbon dioxide (R744)
- Hydrocarbons (HCs), e.g., propane

The still mainly used halogenated refrigerants belonging to the group of HCFCs and HFCs are subject to comprehensive international legislation due to their ozone-depleting properties (in case of HCFCs), respectively, their potential effect on the climate (in case of HFCs) if released into the atmosphere.

The basic international instruments are

- The *Montreal Protocol* of 1987 regulating production and consumption of ozone-depleting substances (ODS) [1]
- The *Kyoto Protocol* of 1997 requiring measures to reduce greenhouse gas (GHG) emissions [2]

All subsequent regulations concerning production, placing on the market, and use of halogenated refrigerants are based on these international protocols with the aim to implement the requirements set in these protocols into national law of the signatory states.

1.1 Legislation for Ozone-Depleting Substances

1.1.1 Montreal Protocol

It regulates production and consumption of ODS, e.g., chlorofluorocarbons (CFCs) globally. Its basic requirements for industrialized and developing countries are described in brief in Table 1a.

EC Regulation 1005/2009 [3]

The EC implemented the Montreal Protocol with a detailed regulation going far beyond the requirements of the Montreal Protocol. The latest version is the recently published regulation EC 1005/2009 that replaced the previous regulation EC 2037/2000 by January 01, 2010. Since fully halogenated CFCs already had been phased out completely in the EC, special provisions have to be made in this new regulation on ODS only for HCFCs, as far as refrigeration and air conditioning (AC) applications are concerned.

This EC regulation is immediately applicable law in all Member States and does not require national implementations!

Some requirements are especially important for refrigeration systems still running with HCFC refrigerants:

Placing on the market and use

- The placing on the market and the use of controlled substances shall be prohibited (Art 5(1))
- Until December 31, 2014, only reclaimed and recycled HCFCs may be used for the maintenance or servicing of existing refrigeration, AC, and heat pump equipment with further restrictions according to Art 11(3 and 4)

Labeling and recording

- Cylinders containing reclaimed and recycled HCFCs as well as refrigeration, AC, and heat pump equipment have to be labeled according to Art 11(3 and 6)
- Operators of equipment have to keep records on HCFCs used for maintenance and servicing; service contractors are required to keep records on the sources of HCFCs used for servicing (Art 11(7))

Exports

- Exports of products and equipment containing HCFCs have to be authorized by the Commission on request of the competent authority of a Member State (Art 17(3))

Recovery of controlled substances

- Controlled substances contained in equipment shall be recovered for destruction, recycling, or reclamation (Art 22(1))

Leakage checks

- Companies shall take all precautionary measures practicable to prevent and minimize any leakages and emissions of controlled substances. Refrigeration, AC and heat pump

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_13,

D4.1. Table 1a. *Montreal Protocol* (latest version 2008) regulates worldwide production and use ("consumption") of ODS

Basis	100% ODP-weighted HCFC consumption in 1989 + 2.8% ODP-weighted CFC consumption in 1989	
	Industrialized nations	Developing countries
CFCs	Phase-out 1996	Phase-out 2010
HCFCs	Freeze 2004	Freeze 2013 based on average 2009/2010 consumption
	2010: 75% reduction	2015: 10% reduction
	2015: 90% reduction	2020: 35% reduction
	2020: 99.5% reduction	2025: 67.5% reduction
	2030: phase out	2030: 97.5% reduction
		2040: phase out

D4.1. Table 1b. *Kyoto Protocol*

Basis	UN framework convention on climate change (UNFCCC)	
Target	Emission reduction of the GHGs	
	CO_2, CH_4, and N_2O (natural GHGs)	
	HFCs, PFCs, and SF_6 (industrial GHGs)	
Emission reduction targets	EC	−8%
	USA	−7%
	Japan	−6%
	Global average	−5.2%
Commitment period	2008–2012	
Baseline	For CO_2, CH_4, and N_2O: emissions in 1990	
	For HFCs, PFCs, and SF_6: emissions in 1995 (optional 1990)	
Entry into force: February 16, 2005		

equipment with a refrigerant charge of more than 3 kg has to be frequently checked for leakages with a checking frequency depending on the refrigerant charge. For each system records shall be maintained on the leakage checks as well as on the refrigerant charge and any quantities added or removed during maintenance or servicing (Art 23).

National Regulations

Some EC Member States may have implemented national regulations, e.g., for defining the minimum qualification requirements for the personnel carrying out, e.g., leak checking activities and refrigerant recovery, as it is the case, e.g., with the German "Chemikalien-Ozonschicht-Verordnung" [4].

European countries outside the EC, where the regulation 1005/2009 is not to be applied, need their own national legislation for ODS. As an example, the "Verordnung über umweltgefaehrdende Stoffe" [5] in Switzerland may be mentioned.

In both cases it therefore will be necessary to get acquainted with individual national regulations for each of these countries before starting activities at HCFC containing refrigeration, AC, and heat pump systems.

1.2 Legislation for Greenhouse Gases

1.2.1 Kyoto Protocol

It requires measures on a global basis to reduce emissions of the most important GHGs, carbon dioxide (CO_2), methane (CH_4), nitrogen oxide (N_2O) as well as emissions of the group of fluorinated gases. This group consists of HFCs, perfluorocarbons (PFCs), and sulfur hexafluoride (SF_6).

Its basic requirements for industrialized and developing countries are described in brief in Table 1b.

EC Regulation 842/2006 [6]

On July 4, 2006, the "Regulation EC 842/2006 of the European Parliament and of the Council on certain fluorinated greenhouse gases" [6] entered into force and therefore—as an immediately applicable law—has to be complied with by all 27 EC Member States. It represents the implementation of the Kyoto Protocol in the EC with regard to fluorinated gases.

Certain requirements of this regulation are concerning the persons and companies involved in operating and servicing of refrigeration, AC, and heat pump systems with HFC and PFC

refrigerants. In detail, the following legally binding measures have to be observed:

General requirements for emission reduction (Art 3(1))

Operators of refrigeration, AC, and heat pump systems containing HFC or PFC refrigerants generally have to take all measures which are technically and economically feasible

- To prevent leakage of these gases
- To repair any detected leakage as soon as possible

Requirements for leak testing (Art 3(2))

Art 3(2) lays down the following procedure for leak testing of refrigeration and AC systems:

- Systems with a HFC or PFC charge of 3 kg or more:
  - At least once every 12 months (does not apply to hermetically sealed systems labeled as such and containing less than 6 kg HFC or PFC)
- Systems with a HFC or PFC charge of 30 kg or more:
  - At least once every 6 months
- Systems with a HFC or PFC charge of 300 kg or more:
  - At least once every 3 months
  - For these applications leakage detection systems shall be installed and checked every 12 months to ensure their proper functioning.
  - *Basically valid*: Where a properly functioning leakage detection system is in place, the frequency of the leak checks shall be halved. After a leak has been repaired, the system shall be checked again within 1 month.

Logbook (Art 3(6))

This chapter imposes the operators of refrigeration and AC systems with more than 3 kg HFC or PFC refrigerant charge to keep records on the following data:

- Type and location of the system
- Type of HFC or PFC refrigerant used
- Refrigerant charge (nominal charge)
- Date and result of leak checks; name and employer of the testing person
- Date of servicing and maintenance; name and employer of the serviceman
- Quantity of HFC or PFC refrigerant added during servicing
- Quantity of HFC or PFC refrigerant recovered during servicing, maintenance, and final disposal of the system

Recovery (Art 4)

Operators of refrigeration and AC systems are responsible for the proper recovery of HFC and PFC refrigerants in order to ensure their recycling, reclamation, or destruction. Similarly this applies for the users of transport and storage containers for fluorinated GHGs like HFC refrigerants prior to scrapping.

Labeling (Art 7)

All refrigeration, AC, and heat pump systems with HFC or PFC refrigerants (as well as other products and equipment containing fluorinated gases covered by this regulation) only may be placed on the EC market if they carry a label with the chemical designation (accepted industry nomenclature, e.g., R134a), the nominal charge and a remark that it contains a fluorinated GHG covered by the Kyoto Protocol.

Training and certification (Art 5)

Activities mentioned in "Requirements for leak testing" and "Recovery" only shall be carried out by appropriately trained and certified personnel. The EC Commission has set minimum requirements [7] as the basis for corresponding measures that Member States had to implement until July 04, 2008. From July 04, 2009, only certified personnel involved in servicing of equipment or refrigerant recovery is allowed to take delivery of fluorinated GHGs!

Besides this, the Commission has published standard requirements regarding the methodology for leak testing as well as the labeling of products, equipment, and containers [8,9].

National Regulations

Some EC Member States may have implemented national regulations, e.g., for specifying in detail the criteria to be applied for leak checking activities or for setting necessary qualification standards for personnel involved in certain activities. An example is the German "Chemikalien-Klimaschutz-Verordnung" [10].

The EC Member States Austria and Denmark have additional national regulations on fluorinated GHGs in force which are partially stricter than the EC regulation 842/2006 [11–13].

European countries outside the EC, where the regulation 842/2006 is not applicable, have established own national legislation for fluorinated GHGs. As an example, the "Verordnung über umweltgefaehrdende Stoffe" [14] in Switzerland may be mentioned.

It will therefore be necessary to get acquainted with individual national regulations in each of these countries before starting activities at refrigeration, AC, and heat pump systems containing HFC or PFC refrigerants.

1.3 Legislation for Nonhalogenated Refrigerants

Since the refrigerants ammonia, carbon dioxide, and HCs are not ODS and their global warming potential is very low compared with HFCs and PFCs, no environment-related international or national regulations comparable with those in force for fluorinated gases are restricting their use. However, due to their safety-related properties regarding flammability and/or toxicity, comprehensive safety precautions have to be applied when using these gases as refrigerants.

The necessary requirements are laid down in the European Standard EN 378 (1-4) [15], which additionally contains provisions to protect the aquatic environment when handling ammonia.

Beyond this, the operation of refrigeration systems with ammonia and HCs is subject to various additional regionally differing requirements in the EC. The publication [16] provides an overview about the most important directives, regulations, and standards to be considered when planning and building an ammonia refrigeration plant in Germany (Tables 2a and 2b).

D4.1. Table 2a. Thermophysical properties of refrigerants

Refrigerant	Formula (ma.%)	Molar mass (kg/kmol)	Melting temperature or triple point temperature[a] (°C)	Normal boiling point (°C)	Temperature t_{crit} (°C)	Pressure p_{crit} (bar)	Boiling pressure		Pressure ratio	Specific volume of sat. vapor	Theoretical swept volume for 1 kWh (−15°C /30°C) (m^3/kWh)	Circulated refrigerant mass per kW (kg/min kW)	Circulated mass of sat. liquid per kW	Coefficient of performance[b]	Volumetric refrigeration capacity[b] (kJ/m^3)	Isentropic compressing end temperature[b]
							At −15°C (bar)	At +30°C (bar)	p_s (30°C)/p_s (−15°C) (–)	at −15°C (m^3/kg)			at 30°C (dm^3/min)	(−15°C/30°C) (–)		(−15°C/30°C) (°C)

D4.2 Cryostatic Bath Fluids, Aqueous Solutions, and Glycols

Gernot Krakat
FRAGOL Schmierstoffe GmbH & Co., Mülheim (Ruhr), Germany

Following synoptical tables (Table 1–6) will give an overview on current cryostatic bath fluids, aqueous heat transfer fluids, and glycols including their data. Most of the data are taken from manufacturer's product overviews and brochures based on recent informations.

They passed without obligation in comply with our best knowledge and experiences and the same to existing third person trade mark rights.

The trade names are mostly registered trade marks by the companies, so this explicit advice replace the identification of the circumstances.

D4.2. Table 1. Cryostatic bath fluids

Substance	Chemical formula	Melting point Boiling point (°C)	Range of application (°C)	Vapor pressure (bar)	Min/max		
					Density (kg/m³)	Specific heat capacity (kJ/kg K)	Kinematic viscosity (10^6 m²/s)
Methanol	CH_3OH	−97.65	−90	–	904	2.14	9.62
		64.65	60		755	2.69	0.46
Ethanol	C_2H_5OH	−114.05	−100	–	892	1.90	52.7
		78.35	78.3	1.01			
			100		716	3.45	0.46
Methylglycol	CH_3OCH_2–	−85	−80	–			120
	CH_2OH	122–127	−40		1,020		
			20			2.236	
			+50	0.06	935		17.0
Tetrachlormethane	CCl_4	−22.9	−20	–	1,672	0.834	1.20
		76.55	70	0.8	1,574	0.876	0.25
Trichlorethylene	C_2HCl_3	−86	−85	–	1,730	0.879	1.31
		87.25	80	99			
			100		1,340	1.005	0.26

D4.2. Table 5a. Organic charge materials for aqueous solutions (overview)

Substance	Chemical formula	Contents at min. temperature (kg/kg^c)	Melting point ambient temperature (°C)	Density (kg/m^3)	Specific heat capacity (kJ/kg K)	Kinematic viscosity (10^{-6} m^2/s)	pH value
Methanol	CH_3OH	1	−97.65	904	2.14	9.62	
			20	792	2.495	0.737	
Ethanol	C_2H_5OH	1	−114.05	892	1.90	52.7	
			20	789	2.394	1.53	
Monoethylenglycol[a]	$C_2H_4(OH)_2$	0.65	−50				
			20	1,134	2.3	27	7.8–8.2
1.2 Propylenglycol[a]	$C_3H_6(OH)_2$	0.6	−40	1,100	2.3		
			20	1,050	2.5	71.4	7–9
Glycerin	$C_3H_6(OH)_3$	0.63	−40	1,190	2.53	840	
			20	1,162	3.00	11.2	
Potassium formiate-based (acc. safety data sheet Pekasol 2000) [7]	HCOOK	1	−56				
			−50	1,313	3.00	123	
			0	1,297	3.14	6.70	
			20	1,290	3.19	3.18	11.5–12

Substance	Chemical formula	Corrosiveness	Physiological number	Remarks
Methanol	CH_3OH	High corrosive	$LD_{50}{}^b$ = 0.34 g/kg MAK 200 ppm	
Ethanol	C_2H_5OH	High corrosive	MAK 1,000 ppm	
Monoethylenglycol[a]	$C_2H_4(OH)_2$	More corrosive as pure water; less corrosive when inhibited	$LD_{50}{}^b$ = 5.8 g/kg	For example, Antifrost B (AVIA) Antifrogen N (Clariant) Glythermin NF (BASF) Dowcal 10 (Dow) Tyfocor (Tyforop) Glykosol N (Prokühlsole) Fragoltherm W-EGA (Fragol) Fragoltherm W-EBS (Fragol)
Monoethylenglycol[a]	$C_2H_4(OH)_2$	Less corrosive when inhibited	Free of nitrite, amine, phosphate $LD_{50}{}^b > 2.0$ g/kg	For example, Zitrec M (Arteco)
1,2 Propylenglycol[a]	$C_3H_6(OH)_2$	Less corrosive when inhibited	$LD_{50}{}^b$ = 15 g/kg	For example, Antifrogen L (Clariant) Glythermin P 44 (BASF) Dowcal 20 (Dow) Dowcal N FDA-approved Tyfocor L (Tyforop) Pekasol L (Prokühlsole) Fragoltherm W-PGA (Fragol) Zitrec F (Arteco) NSF approved
1,2 Propylenglycol[a]	$C_3H_6(OH)_2$	Less corrosive when inhibited	Free of nitrite, amine, phosphate $LD_{50}{}^b$ = 15 g/kg	For example, Zitrec L (Arteco)
Potassium acetate	CH_3COOK	Low tested acc. ASTM D 1384; wastage rate <0.01 mm/year regarding the guidelines	$LD_{50}{}^b > 2.0$ g/kg MAK 200 ppm	based on potassium acetate which is approved as a food additive
Potassium acetate-potassium formiate-mix	CH_3COOK-HCOOK	Low tested acc. EMPA-SOP Nr. 1536: steel 0, carbon steel 0 g/m^2 weight loss; low, when inhibited	Free of nitrite, amine, phosphate $LD_{50}{}^b > 2.0$ g/kg MAK 200 ppm	[9] Institut Fresenius: contents components which are approved as food additives

D4.2. Table 5a. (continued)

Substance	Chemical formula	Corrosiveness	Physiological number	Remarks
potassium formiate-sodium propionate-mix	HCOOK- C_2H_5 COONa-mixture	Low, tested acc. ASTM D 1384; wastage rate <0.01 mm/year regarding the guidelines	Free of nitrite, amine, phosphate LD_{50}[b] > 2.0 g/kg	For example, Zitrec S (Arteco)
potassium formiate	HCOOK	Low, tested acc. ASTM D 1384; wastage rate <0.01 mm/year regarding the guidelines	Free of nitrite, amine, phosphate LD_{50}[b] > 2.0 g/kg MAK 200 ppm	Based on potassium acetate which is approved as a food additive

[a]Commercial coolants, anti corrosion inhibited
[b]LD_{50} (oral, rat)
[c]Contents kg substance/kg solution

D4.2. Table 5b. Organic charge materials for aqueous solutions (overview)

Substance	Chemical formula	Application concentration % (volume)	Application range (°C)	Density at 20°C (kg/m³)	Specific heat capacity at 20°C (kJ/kg K)
Methanol	CH_3OH	10–100	−90 to +20	792	2.945
Ethanol	C_2H_5OH	10–100	−100 to +20	798	2.394
Monoethylenglycol[a]	$C_2H_4(OH)_2$	5–90	−40 to +130	1,114	2.35
1,2 Propylenglycol[a]	$C_3H_6(OH)_2$	5–90	−30 to +130	1,036	2.50
Potassium acetate	CH_3COOK	60–90	−55 to +80[c]	1,100–1,240	3.55–2.95
Potassium acetate-potassium formiate-mixture	CH_3COOK–HCOOK	30–100	−60 to +60	1,289	2.668
Potassium formiate-sodium propionate-mixture	HCOOK–C_2H_5 COONa–Gemisch	Ready made	−55 to +80	1.089–1.312	3.63–2.5
Potassium formiate	HCOOK	Ready made	−60 to +80[c]	1,222–1,394	3.20–2.52

Substance	Chemical formula	Kinematic viscosity at 20°C (10^{-6} m²/s)	Corrosiveness (versus metals)	Physiological figures	Examples of commercial products with corrosion protection
Methanol	CH_3OH	0.737	In aqueous solutions High corrosive	LD_0 = 0.34 g/kg (oral, human) MAK: 200 ppm	
Ethanol	C_2H_5OH	1.53	In aqueous solutions High corrosive	LD_{50}[b] = 7.06 g/kg (oral, rat) MAK: 1,000 ppm	
Monoethylenglycol[a]	$C_2H_4(OH)_2$	19	Low, when anti-corrosive inhibited	LD_{50}[b] = 5.8 g/kg (oral, rat)	For example, Antifrost B (AVIA) Antifrogen N (Clariant) Glythermin NF (BASF) Tyfocor (Tyforop) Dowcal 10 (Dow) Glykosol N (Prokühlsole) Fragoltherm W-EGA (Fragol) Zitrec M (Arteco)

D4.2. Table 5b. (continued)

Substance	Chemical formula	Kinematic viscosity at 20°C (10^{-6} m²/s)	Corrosiveness (versus metals)	Physiological figures	Examples of commercial products with corrosion protection
1,2 Propyleneglycol[a]	$C_3H_6(OH)_2$	56	Low, when anti-corrosive inhibited	LD_{50}[b] = 15 g/kg (oral, rat)	For example, Antifrogen L (Clariant) Glythermin P 44 (BASF) Tyfocor L (Tyforop) Dowcal 20 (Dow) Dowcal N FDA approved Pekasol L (Prokühlsole) Fragoltherm W-PGA (Fragol) Zitrec L (Arteco) Zitrec F (Arteco)NSF approved
Potassium acetate	CH_3COOK	1.67 to −10	Low considering the guidelines	LD_{50}[b] > 2.0 g/kg MAK 200 ppm	Tyfoxit (Tyforop)
Potassium acetate-potassium formiate-mixture	CH_3COOK-HCOOK	1.29 to −9.8 2.95 to −60	Low considering the guidelines	Free of nitrite, amine, phosphate LD_{50}[b] > 2.0 g/kg MAK 200 ppm	Pekasol 2000 (Prokühlsole)
Potassium formiate-sodium propionate-mixture	HCOOK-C_2H_5 COONa		Low considering the guidelines	Free of nitrite, amine, phosphate	For example, Zitrec S (Arteco)
Potassium formiate	HCOOK	1.67 to −15 2.88 to −60	Low considering the guidelines	Free of nitrite, amine, phosphate	Tyfoxit F15–F60: ready made (Tyforop) Antifrogen KF (Clariant) Freezium (Kemira)

[a]Commercial coolants, anti-corrosion inhibited
[b]LD_{50} (oral, rat)
[c]Considering the guidelines

D4.3 Oil-based and Synthetic Heat Transfer Media

Andreas Glück[1] · *Dietmar Hunold*[2]
[1]HTT Vertriebsbüro Süd GmbH, Ebersbach, Germany
[2]HTT Energy Systems GmbH, Herford, Germany

1 Introduction

The following synoptical tables with the most common heat transfer media currently available in the market including their properties shall offer the user a quick orientation. The predominant part of this compilation consists of producer information and procedure documentations. They correspond to the best knowledge and experiences and are passed in this sense – without being able to give the grade of exactness and without bindingness – also in regard to the existing proprietary rights of third parties. The trade names for the most part are registered as trademarks of companies. By this general remark, the designation of the fact is replaced.

Moreover, from basic considerations, heat transfer media known from the literature were included regardless the binding health and safety regulations in the meantime. Generally, it is to check for each heat transfer medium if the intended use is allowed according to the latest status.

To identify the optimum heat transfer medium for each application, indications of thermostability and the product life to be expected are to be inquired besides the price, which can vary strongly depending on delivery quantity and region. It is recommended to contact manufactorers of heat transfer plants with long-term experience besides the manufactorers of heat transfer fluids and its sales or distributing organisations. These companies can ensure a product-independent consultation and also specify various possibilities of a service life prolonging plant dimensioning and equipment.

At production and operation of plants with heat transfer media different acts, regulations, rules, standards, and directives depending on the location are to be observed. So for example, in Germany, there are to name among others the Immission Control Acts, Health and Safety Regulations, the Equipment Safety Statute or the Directive BGV D3 of the chemical industry (former VGB 64). As specific standard for heat transfer plants, the following have been established worldwide:

- DIN 4754: Heat transfer medium plants with other heat transfer media than water
- Directive VDI 3033: Heat transfer medium plants with other heat transfer media than water; design, operation, and maintenance
- Pressure Equipment Directive 97/23/EC
- AD-Merkblaetter of the workship "pressure vessels"
- Safety data sheet according to Directive 91/155/EEC for the heat transfer medium in use

Particularly, Anglo-Saxon influenced countries (British/Latin American) often use the following:

- American Society of Mechanical Engineers (ASME) Codes and Standards

The property collection corresponds in its coverage and content to one of the up-to-date German versions of the *VDI Wärmeatlas* (10. edition) and shall offer the reader a quick survey over the heat transfer media on mineral oil basis and/or synthetic heat transfer media basically suitable for his or her purpose.

At this point, it may be indicated explicitly that there are a number of additional heat transfer media with comparable properties available on the market. The VDI Heat Atlas, however, does not claim to offer a complete list of all products.

Due to the required space for it, the tables dispense with the indication of the usual Anglo-Saxon units. Instead, the essential conversion factors and formulas were prefixed in tabular form (Table 1).

The special field of the heat transfer technology was further ensured by the following standards:

DIN ISO 6743 Part 12 classification; family Q (heat transfer media)
DIN 51 522 Heat transfer media Q; specifications, checking
DIN 51 528 Determination of the thermostability of unused heat transfer media
DIN 51 529 Testing and assessment of used heat transfer media

Finally, it is pointed out to a *Wagner*-based property collection [1, 2], which also contains the appropriate safety data sheets.

Since the survey data named by the producers do not agree with extrapolations from the tabulated properties in all cases, the newest data should be obtained before making decisions.

2 Characteristics of Heat Transfer Media

To assess mineral-oil-based and synthetic heat transfer media the following characteristics are compared [1, 3]:

- *Aging.* All organic heat transfer substances are decomposed under the time influence of temperature, pressure, and

D4.3. Table 1. Conversion factors and formulas between metric and British/American units

Property	Brit./Am. unit	Metric unit	Metric unit	Brit./Am. unit
Temperature	x [°F]	5/9 · (x−32) [°C]	x [°C]	9/5 · (x + 18.5) [°F]
Pressure	1 psi	0.069 bar	1 bar	14.504 psi
Density	1 lb/ft^3	16.031 kg/m^3	1 kg/m^3	0.0624 lb/ft^3
Specific thermal capacity	1 Btu/(lb·°F)	4.179 kJ/(kg·K)	1 kJ/(kg·K)	0.239 Btu/(lb·°F)
Kinematic viscosity	1 lb/(ft·h)	0.403 mm^2/s	1 mm^2/s	2.482 lb/(ft·h)
Thermal conductivity	1 Btu/(ft·h·°F)	1.730 W/(m·K)	1 W/(m·K)	0.578 Btu/(ft·h·°F)
Enthalpy	1 Btu/lb	2.3235 kJ/kg	1 kJ/kg	0.4301 Btu/lb

oxygen; this decomposition rating can be reduced at best by targeted measures. Depending on the application, it is to distinguish between thermostability as the consistency of the molecules compared to the temperature free from oxygen and the oxidation stability as the consistency of the molecules compared to oxygen. The superordinated term of the disproportionation differs generally from the substance decomposition or substance conversion to products less suitable as heat transfer medium. Organic heat transfer media react with the oxygen of the ambient air at higher temperatures unless no inertization is planned. The oxidation products (e.g., organic acids or polymerization products) cause mostly an increase of viscosity as long as they remain in the solution. When the molar mass of these substances however exceeds a definite value, the oxidation products are deposited as mud. By the materials used at production of the heat transfer plant or by impurities in the plants, the oxidative aging can be advanced. When the specified temperature limits are observed as well as suitable materials and an inert gas superposition (e.g., N2) are used, an early oxidative damage to the substance can be avoided.

- "Aging is according to definition a production of substances that are not available in unused oil. The substances are created by the influence of atmospheric oxygen, heat, as well as excavation of metals and sealing materials" Zufall [4].
- At normal use of the heat transfer oils, the atmospheric oxygen supply in the plants according to DIN 4754 is either not possible due to inertization or planned only in the open but "cold" expansion vessel. The latter has no important influence on the aging.
- The already mentioned increase in viscosity mostly occurs at mineral oil fillings and only when inadmissible atmospheric air supply in larger quantities is possible. The main cause for this in most cases can be found in an expansion vessel, which is warmed up and open to the atmosphere. The inadmissible atmospheric air supply is mostly connected also with the formation of acid substances in such a large quantity that an appreciable neutralization value or similar can be measured.
- Cracking is the fission of the heat transfer medium molecules primarily in the boundary layer of the heating surface of the heater.
- This procedure can be minimized when the proceeding is according to DIN 4754 and the producer information to the admissible film temperature of the heat transfer medium at the design are observed.
- As an additional consequence of the thermal load, many heat transfer media form also small quantities of low boiling, benzine-like substances that have to be removed from the circuit by "boiling out" to avoid a critical lowering of the flash point and problems by cavitation.
- Polymerized substances (so-called heavy boiler) resulting from "cracking" are comparable in its effects on the plant to the above mentioned increase in viscosity and can lead to serious problems by deposits on the heating surfaces (fouling) or even choking. Therefore, special attention is to be paid to them when designing the plant and also at the annual checking of the heat transfer medium. Among others, the chronological course of the Conradson value is thereby of particular importance as a measure for the solid, not vaporable residues. At noticeable increase, it can signalize the beginning of formation of deposits. In each case, the careful and regular checking of the heat transfer medium is urgently recommended to the operator of a heat transfer plant. To avoid misinterpretation, a correct sampling is to be considered.
- *Thermostability and service life.* As an essential criteria for this feature, it is to state that the heat transfer medium flow temperature, which is to be expected under normal operating conditions, has a distance as large as possible to the maximum admissible flow temperature given by each producer. The following formulation may apply as rough guide value: A flow temperature reduced by 10 K leads to a doubling of the service life, particularly the usability of the heat transfer medium.
- *Corrosion.* Within the specified stated temperature limits, the ferrous materials are generally not affected.
- *Physiological properties.* In general, heat transfer media are not toxic. Arising decomposition products can, however, cause irritations to the respiratory tracts and mucous membranes; therefore, the regulations of the producer for handling are to be strictly observed. At toxicological effect, the maximum allowable concentration values will be determined by asking the producer in case of doubt. Maximum allowable concentration values are not included systematically.
- *Properties and methods of test.* Declaration of the properties listed in survey Tables 2a and 3a:

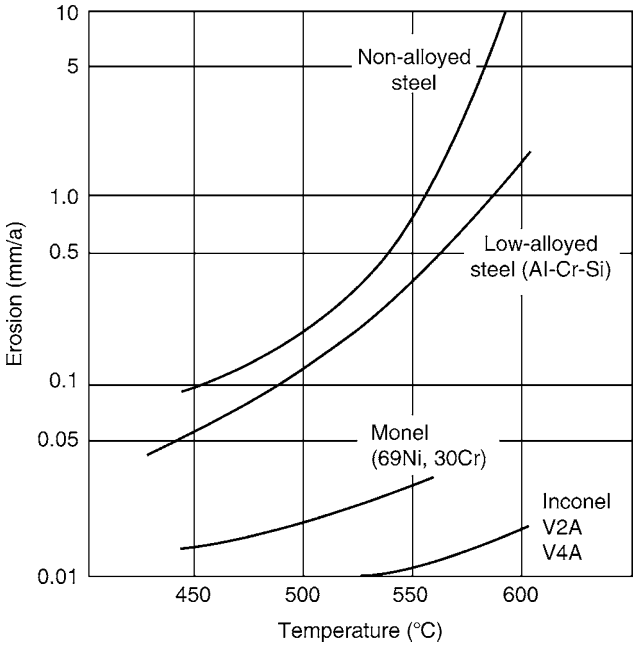
D4.3. Table 6a. High temperature salts (HTS)

Substance (trade name):	Durferrit ASD heat transfer salt
Substance structure:	Eutectic melting, ternary mixture from alkali-nitrates and nitrites, in the literature designated as HTS-melting
Producer:	Houghton Durferrit GmbH; D-63408 Hanau
Melting range: max.	138°C up to 142°C
Application temperature:	620°C, reaction conversion too large, also corrosion-limited
Chemical main reaction:	In the salt melting reaction proceeds in the presence of air to the right only:
	$2NaNO_2 + O_2 \rightarrow NaNO_3$
	hermetically sealed:
	$5NaNo_2 \rightarrow NaNO_3 + Na_2O + N_2$
	In both cases decrease of nitrite volume, increase of the nitrate volume. N_2-superposition delayed, does however not avoid alteration
Temperature criteria:	$t \leq 450$°C, melting practical thermally stable
	$t < 450$°C, also for a short time, results in nitrite decomposition causing increase of the melting point; hardly any change of thermal transfer properties
	$t < 500$°C, HTS melting starts to convert with iron
	$t < 620$°C, conversion distinctive: $\vartheta_{max} = 620$°C
Chemical side reaction:	Absorption of carbon dioxide under formation of alkali carbonates, which fail when exceeding the solubility
Service life:	Producer informs on the basis of sent in HTS samples; from the operating data of the melting the decomposition rate can be predestinated
Regeneration salt:	Durferrit ASD regeneration salt; in most cases a reconstitution of the original salt properties is more advantageous than the exchange of the complete amount of salt
Materials:	Corrosion behavior of different materials at temperatures up to 600°C; (Fig. 1). Materials with less than 0.1 mm/a are considered to be constant. Up to 450°C unalloyed or alloy-treated steels will do if no local superheating occurs. Risk of intercrystalline corrosion. Copper, silver, cast iron, magnesium alloys as well as aluminium and its alloys may not be used. When using aluminium and magnesium explosive reactions can occur.
See the original brochure for further details, in particular precautions (toxicity, flammability, fire fighting, and information about melting down); make a request for safety data sheet.	



D4.3. Fig. 1. Material excavation in Durferrit ASD.

Column 5 top: Turbidity point, particularly yielding point according to DIN ISO 3016 (pour point) in °C.
Column 5 bottom: Boiling point to be established from the boiling progress, which is determined either according to DIN 51 751 at normal pressure (preferably at synthetic heat transfer media) or according to DIN 51 356 under reduced pressure and conversion to 1.013 bar (at mineral oils).

Boiling point is the first dropping off condensation drop in the test apparatus, which serves also to determine the boiling progress under normal pressure (DIN 51 751). According to the actual running progresses, this should be denominated rather as distillation point and distillation progress [4].
Column 6: Upper and lower category temperature for the application range; exclusively producer's indications.
Column 9: Indication of the true specific thermal capacity, demand of the middle specific thermal capacity [2, 3].
Column 12: Lower application temperatures according to *Wagner* [1]. It is about temperatures at which the kinematic viscosity has the following values:
Filling and start-up at maximum $300 \cdot 10^{-6}$ m^2/s,
Economical pump operation at maximum $5 \cdot 10^{-6}$ m^2/s.
Column 13: Maximum film temperature, admissible locally for a short time only in the boundary layer of the heating surface (remark else as column 6, upper category temperature), recalculation in heated tube according to DIN 4754, enclosure A1.
Column 14: Flash point: It is the lowest temperature based on 1.013 bar at which the vapors developed by the heat transfer medium flame up in presence of a pilot flame.
Methods of determination:

- Flash point according to DIN ISO 2592, determination in open cup according to Cleveland (COC);
- Flash point according to DIN 51 758, determination in closed cup according to *Pensky-Martens*. This method is used at heat transfer media since it is easier to prove low boilers in used oil.

According to DIN 51 522 "Heat transfer oils Q," the determination of the flash point according to DIN 51 758 is prescribed to check mineral oils and other combustible fluids. Provided that these values are available, they will be mentioned additionally in the tables. A decrease of the flash point is an indication of

D4.3. Table 6b. Physical properties

HTS melting	Temperature (°C)	Density (kg/m³)	Specific heat capacity (kJ/kg K)	Thermal conductivity (W/m K)	Dynamic viscosity (10^{-3} Ns/m²)	Kinematic viscosity (10^{-6} m²/s)	Thermal diffusivity (10^{-8} m²/s)	Prandtl number
Durferrit ASD	145	–	1.392	≈0.5	–	–	–	–
	150	1,972	1.395	≈0.5	18.68	9.47	18.2	52.1
	200	1,935	1.425	≈0.5	11.64	6.02	18.1	33.2
	300	1,860	1.486	≈0.5	5.98	3.21	18.1	17.8

	400	1,786	1.547	≈0.5	(3.73)[a]	2.09	18.1	11.5
	450	1,748	1.577	≈0.5	(3.07)[a]	1.76	18.1	9.68
	500	1,711	1.607	≈0.5	(2.59)[a]	1.51	18.2	8.32

[a]Values in ( ) have been extrapolated

D4.3. Table 6c. Physical properties, supplementation. The properties depend on the aging grade, which varies from the property for new salt and for example, at a four-years period of use a melting aged to 20% $NaNO_2$

Density of layer:	1,150 to 1,200 kg/m³ according to DIN 53 912
Density of the HTS melting:	ρ = [1,972−0.745 (ϑ−150)/K] kg/m³, with ϑ as celsius temperature of the HTS melting
Melting temperature:	142°C of the pure ternary, eutectic melting salt mixture. With increasing water content k_{H2O} (in % of the mass) the melting point of the salt mixture drops along the liquid saturation temperature ϑ_{liq} (Fig. 2).
	ϑ_{liq} = 140.24 exp (−0.081 k_{H2O}), with ϑ in °C
Linear expansion coefficient:	$\beta = 4.95 \cdot 10^{-5}$ K^{-1} for the solid
Cubic expansion coefficient:	α = 0.745/[1972−0.745(ϑ−150)] K^{-1}, with ϑ as celsius temperature
Medium specific heat capacity:	c m [J/(kg K)] = 1303.9 + 0.60666 θ [°C]; 145°C < θ < 500°C
Melting heat:	approx. 84 kJ/kg
Thermal conductivity melting:	approx. 0.5 W/(mK)
Dynamic viscosity for new salt:	$\eta = 69.8958\ \vartheta^{-1.642}$
	η in Pa s, ϑ celsius temperature, measured in range 145°C < ϑ <350°C, (Fig. 3).
Specific electric resistance:	θ = 150°C: ρ = 19.0 x 10^8 Ω square mm/m

decomposition products and combustible gases that resulted from the cracking of the heat transfer medium.

Column 15: The autoignition temperature according to DIN 51 794 is the temperature at which the heat transfer medium autoignites without external ignition source at 1.013 bar.

"These temperature values are less interesting for the practical operation, they can partly be dangerous since they are much too high. More important is the remark that heat transfer oils on mineral oil basis can lead to autoignition at 100°C and higher when they have wetted insulating materials such as glass or mineral wool. In this case it is not important how strong the air flow is in this insulating materials" [4].

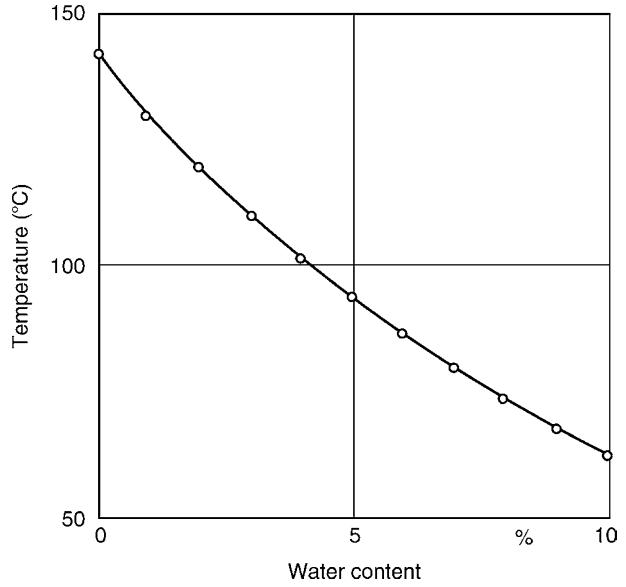
Table 3a and Table 4a still contain

Column 19: Explosive limit in % volume content l.: lower, u.: upper.

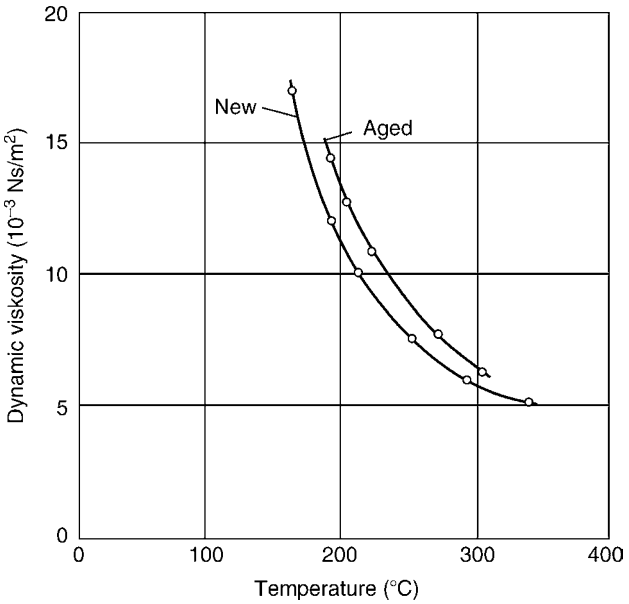
Indication of the system temperature t in °C, at which the limit concentration in the vapor phase just adjusts itself, for example, Table 4a, no. 6 Marlotherm L: 123 ≙ 0.9 means: at 123°C the lower explosive limit is attained in the vapor phase with 0.9% volume content.

Column 21: Application possibilities of the heat transfer medium:

Group A: The heat transfer medium decomposes (disproportionate) below or until the beginning of the boiling point at 1



D4.3. Fig. 2. Liquid saturation temperature in dependence of water content.



D4.3. Fig. 3. Temperature dependence of the dynamic viscosity of Durferrit ASD.

D4.3. Table 7. Aspects and criteria for selection of heat transfer media (summary)

1. Operational criteria for selection
– Toxicity and handling (maximum allowable concentration, etc.)
– Environmental compatibility: odor, biodegradable, costs for disposal of used product, taking back by the supplier, etc.
– Operation risks and operational safety
Hazard category
Combustibility and combustion behavior
Enthalpy of reaction (calorific value)
Auto Ignition behavior and self-ignition in air (of the vapors)
Reactions with existing operating fluids
Risk at leakages, leaking of product in the ambience or in counter circuits. When liquid enters, for example, in absorbing insulating materials, self-igniting explosive mixtures can be formed with air due to wicking action. For this reason not-absorbing insulation materials are to be used.
– Thermostability
– Security of supply regarding prices, quantities stored, and delivery periods
– Reference list about heat transfer plants in operation, collected operational experience, and recommendations of producers of the heat transfer plants.
2. Special criteria for selection
– Admissible temperature range, min./max. application temperatures, max. film temperature
– Low pour point
– High boiling temperature or late boiling point
– Small increase of vapor pressure with the temperature
– High specific thermal capacity
– Low viscosity at deep temperatures: criteria for start-up and filling as well as for economical pump operation according to *Wagner* [1]
– High thermal conductivity
– No unrequested formation of layer on the heat-exchanging surfaces that means no fouling factor that causes additional energy demand, flow reduction, and cleaning costs
– Aging and oxidation resistance; insensitive to catalytic acting foreign substances, for example, acids, salts, water, air humidity, metal shavings, rust or mounting fats (oils), in particular after the start-up
– Production of no corrosion signs
– Small volume dilatation when heating
– Requirement for regeneration for the heat transfer medium as low as possible

bar by separating mostly light parts. When exceeding ϑ_{max} the characteristics of the heat transfer medium changes constantly.

Group B: The use of the heat transfer medium at temperatures above the boiling point is possible when an inert-gas superposition is available to avoid evaporation. Arising vapors are not to be condensed to the actual substance anymore. The heat transfer medium changes constantly.

Group C: The heat transfer media do not change by evaporation and condensation; the original characteristics remain. The heat transfer media are therefore applicable for isothermal heating by condensing vapor.

In the following text, the most popular heat transfer oils are listed under the main criterion "applicable temperature range" (up to 300°C/larger 300°C) as well as the classic heat transfer media for heating–cooling–chilling processes without the claim to be complete.

D5.1 Calculation of Vapor–Liquid Equilibria

Andreas Pfennig
RWTH Aachen, Aachen, Germany

1 Introduction

For the design of processes, the knowledge of the vapor–liquid equilibrium (VLE) is essential in many cases, either to be able to detect the formation of a second phase or to quantitatively describe the properties of the coexisting phases in a two-phase process. The VLE of any given system depends strongly on composition as well as on temperature or pressure.

In this short chapter, only some basic fundamentals are presented. The principal thermodynamic relations forming the basis for VLE description are independent of the specifics of the substances dealt with. On the other hand, for models describing the substance-specific thermodynamic properties a variety of approaches are available and still under development. Here, only comparably simple systems can be dealt with, excluding e.g., polymers, electrolytes, surfactants, and biomolecules. The interested reader is referred to textbooks and specialized literature for further reading [1–6].

The model parameters are optimally based on experimental data for any system of interest. Extensive data sets can be found either in the original literature or in data collections [7–15], which are usually also available in digital form [16, 17]. Since experiments are often not available during the first steps of process and equipment design, today several prediction methods have been developed of which some are included in this chapter.

2 Phase Equilibria and Phase Diagrams

2.1 Composition in Multicomponent Systems

The composition of multicomponent systems can be described with different concentration measures. Typical measures are mass fraction, which is often used in technical applications, and molar concentrations, which are mostly used for chemical calculations and are also relevant for the description of mass transfer. In thermodynamic calculations, mol fractions are the measure of choice in most of the applications. Thermodynamics can in principle be built on any concentration measure. In most of the thermodynamic calculations the molar scale is relevant, taking the molecular picture into account which generally leads to a description that is physically more sound and thus, often more accurate. Mass fraction, often erroneously called weight fraction, is applied only for components that have no defined molar mass like polymers. Molar concentrations are used where the particles per volume are relevant for the microscopic description as e.g., in electrolyte solutions. The different concentration measures can be converted using density and/or molar mass. The details of the alternative descriptions can be found in the standard textbooks mentioned earlier. Here, only the most common description based on molar scale is presented.

The mol fraction x_i of component i is defined as

$$x_i = \frac{N_i}{N}, \tag{1}$$

where N_i is the amount of substance of component i, N the amount of substance in the system with

$$N = \sum_{i=1}^{K} N_i \tag{2}$$

and K the number of components. The convention is often followed that x_i denotes mol fraction of a liquid, y_i that of a vapor or gas, and z_i denotes an explicitly unknown state or the overall mol fraction in a multiphase system. From the definition of the x_i follows that

$$\sum_{i=1}^{K} x_i = 1 \tag{3}$$

i.e., in a mixture only $K - 1$ mol fractions can be chosen independently, the mol fraction of the Kth component results from Eq. (3).

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_14,

2.2 Equilibrium Conditions and Phase Rule

If a system consists of π coexisting phases in equilibrium, the pressure p and temperature T in all phases have to be identical, constituting mechanical and thermal equilibrium. Additionally, for establishing material equilibrium, the chemical potentials μ_i of each component have to be identical in all phases, i.e.,

$$\mu_i^{\alpha} = \mu_i^{\beta} = \cdots = \mu_i^{\pi} \tag{4}$$

for all i. In deriving these conditions it is assumed that no external fields exist and the influence of interfaces can be neglected. Also, chemical reactions are not accounted for. It should be noted here that generally the indices are chosen to increase with decreasing volatility. Thus, usually component 1 is the one with the highest vapor pressure and component K, with the lowest.

If the independent variables describing the multiphase system in equilibrium, i.e., the compositions of all phases, pressure, and temperature are to be determined from these equilibrium conditions, it turns out that a certain number of conditions have to be specified in order to unequivocally determine the system state. This number of freedoms F is given by the Gibbs phase rule:

$$F = K - \pi + 2. \tag{5}$$

2.3 Useful Variables

For the description of VLE, some useful intermediate variables are often introduced. The partition coefficient or distribution ratio K_i describes the ratio of the mol fractions between the phases:

$$K_i = \frac{y_i}{x_i}. \tag{6}$$

The relative volatility $\alpha_{i,j}$ describes the ratio of the partition coefficients between the components regarded:

$$\alpha_{i,j} = \frac{K_i}{K_j}. \tag{7}$$

For a binary system, the relative volatility can be used to connect the vapor and the liquid equilibrium compositions:

$$y_1 = \frac{\alpha_{1,2} x_1}{\alpha_{1,2} x_1 + 1 - x_1}. \tag{8}$$

2.4 Ideal Systems

If the system regarded shows ideal behavior in the vapor as well as in the liquid phase, the chemical potentials of vapor (v) and liquid (l) are

$$\mu_i^{\mathrm{v}} - \mu_i^0 = \tilde{R} T \ln(y_i p) \tag{9}$$

and

$$\mu_i^{\mathrm{l}} - \mu_i^0 = \tilde{R} T \ln(x_i p_i^{\mathrm{s}}) \tag{10}$$

where the reference state is referred to by μ_i^0, which is chosen identical for both phases. Introducing these expressions for the chemical potentials into Eq. (4) results in Raoult's law:

$$y_i p^{\mathrm{s}} = x_i p_i^{\mathrm{s}}, \tag{11}$$

where superscript s indicates saturated conditions. p_i^{s} refers to the pure-component vapor pressure at the desired temperature T, and p^{s} to the vapor pressure of the mixed system at T, with the equilibrium compositions x_i in the liquid and y_i in the vapor. Since Eq. (3) applies for y_i as well:

$$p^{\mathrm{s}} = \sum_{i=1}^{K} x_i p_i^{\mathrm{s}}. \tag{12}$$

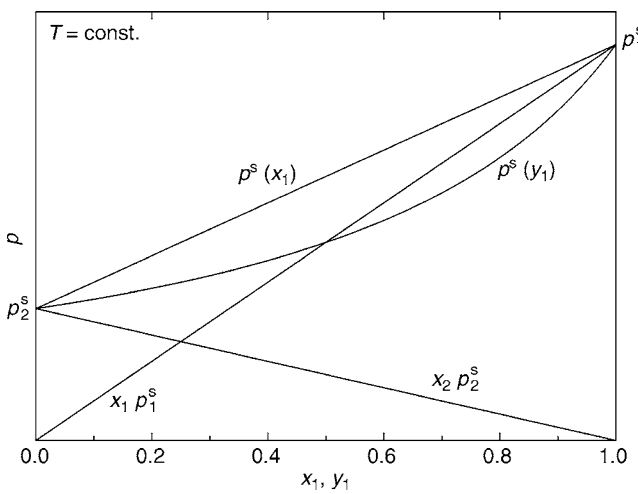
The principal behavior of an ideal binary system is depicted in Fig. 1, where the pressure is plotted against mol fraction. The individual contributions are shown, which are straight lines proportional to x_i running through p_i^{s} at the appropriate side of the diagram, according to the right-hand side of Eq. (11). The sum of both contributions obviously is a straight line connecting the pure-component vapor pressures. The y_i can then be obtained from Eq. (8), where for the ideal system follows

$$K_i = \frac{p_i^{\mathrm{s}}}{p^{\mathrm{s}}} \tag{13}$$

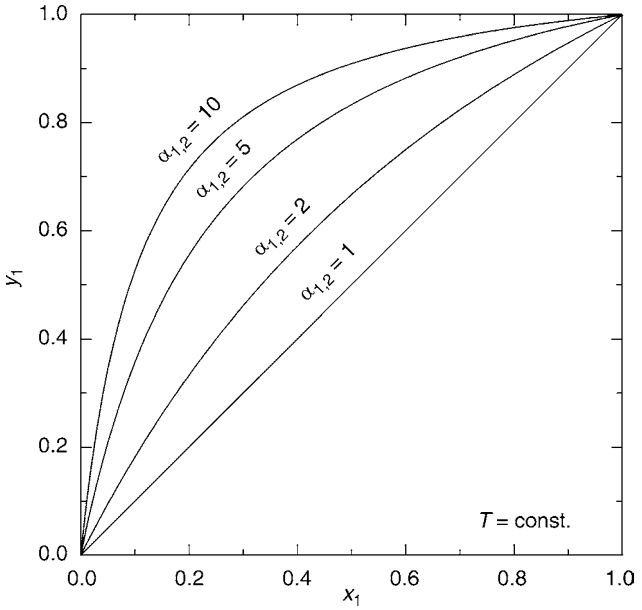
and

$$\alpha_{i,j} = \frac{p_i^{\mathrm{s}}}{p_j^{\mathrm{s}}}. \tag{14}$$

In Fig. 1 the dependence $p^{\mathrm{s}}(y_1)$ obtained with Eq. (8) also is shown. Figure 2 shows the corresponding $y_i = f(x_i)$ for different values of $\alpha_{1,2}$ as e.g., used for the construction of the McCabe–Thiele diagram in distillation.



D5.1. Fig. 1. Pressure contributions and Raoult's law for an ideal system.



D5.1. Fig. 2. *yx*-diagram for varied relative volatility.

2.5 Graphical Representation of Nonideal Systems

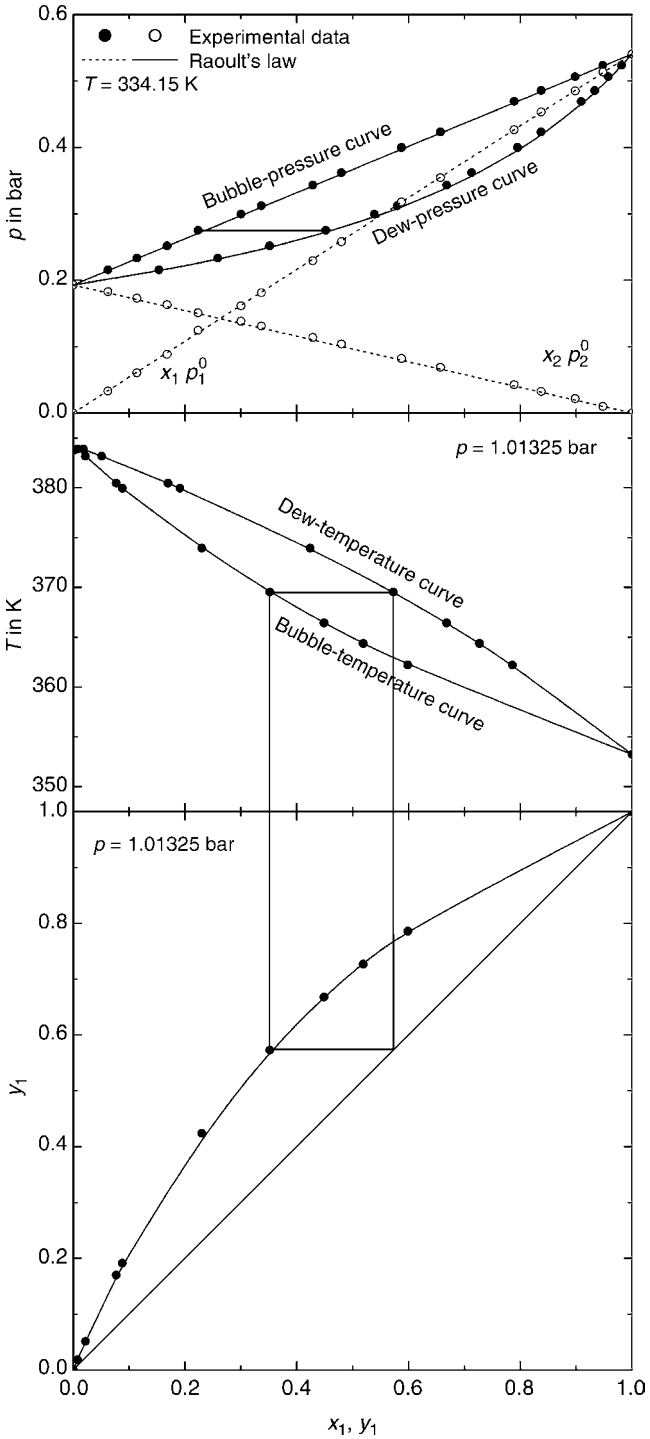
VLE for a typical system with only little deviation from ideality is shown in Fig. 3 in three diagrams. The boiling-point and dew-point curves are specified as well as an example of tie lines connecting the representation of two phases in equilibrium which in this case are horizontal. Also it is shown how the *yx*-diagram can be constructed from the boiling-point and dew-point curves.

In Fig. 4, a binary azeotropic system is shown. At the azeotrope vapor and liquid compositions become identical,

$$x_{i,az} = y_{i,az} \tag{15}$$

and the slope of bubble-point and dew-point curves are horizontal, i.e., have an extreme point. Thus, both curves touch each other at their maximum or minimum. Maximum or minimum pressure or temperature azeotropes are possible, depending on the molecular interactions in the mixture as compared to the pure components. The isothermal and isobaric diagrams are linked such that a vapor–pressure maximum corresponds to a boiling-temperature minimum and vice versa. In the *yx*-diagram the equilibrium curve intersects the diagonal. The azeotrope depends on the conditions chosen, e.g., on the system pressure or temperature. Since distillation does not allow to overcome azeotropic compositions, extensive data collections exist for azeotropic data [10, 14, 15]. The azeotropic data for some selected systems are given in Table 1.

For systems displaying a miscibility gap a heteroazeotrope is frequently encountered. For systems of narrow or strongly asymmetric miscibility gap the azeotrope can be to the side of the miscibility gap. In the majority of cases, the azeotrope lies within the miscibility gap as shown in Fig. 5, which is called heteroazeotrope. If the miscibility gap is very wide, i.e., the components are only very slightly miscible as is the case in



D5.1. Fig. 3. Isothermal and isobaric vapor–liquid equilibrium diagrams for the binary system benzene (1) and toluene (2). Comparison of experimental data with values determined with Raoult's law. Data are taken from [7].

many aqueous-organic systems, the vapor pressure of a binary heteroazeotrope can be approximated by

$$p_{az}^s = p_1^s + p_2^s \tag{16}$$

and the vapor composition of the heteroazeotrope by

$$y_{i,az} = \frac{p_i^s}{p_{az}^s}. \tag{17}$$

3 Modeling Vapor–Liquid Equilibria

To evaluate the equilibrium conditions for specific systems, two approaches are generally applied, one relying on equations of state (EOS), the other building on models for the excess Gibbs energy. Both approaches are briefly presented in the following.

3.1 Equations of State

EOS stem from the fundamental equation for the free (Helmholtz) energy of a system:

$$\tilde{a} = \tilde{a}(T, \tilde{v}, x_i), \tag{18}$$

where $\tilde{v}$ is the molar volume of the system. From this fundamental equation, the pressure and the chemical potential can be derived:

$$p(T, \tilde{v}, x_i) = -\left(\frac{\partial \tilde{a}(T, \tilde{v}, x_i)}{\partial v}\right)_{T, x_i} \tag{19}$$

and

$$\mu_i(T, \tilde{v}, x_k) = \left(\frac{\partial N\tilde{a}(T, \tilde{v}, x_k)}{\partial N_i}\right)_{T, N\tilde{v}, N_{j\neq i}}. \tag{20}$$

Other thermodynamic properties can be derived from the fundamental equation as well, as described in the standard text books. If the EOS is given as $p(T, \tilde{v}, x_i)$, Eq. (19) can be used to obtain $\tilde{a}(T, \tilde{v}, x_i)$ by integration. It should be noted that in practice not $\tilde{a}$ but rather the deviation from ideal-gas behavior is relevant for which the integration is generally possible even if it may be tedious.

When working with EOS, usually fugacities f_i of component i are introduced and defined by

$$\mu_i = \tilde{R}T \ln f_i. \tag{21}$$

Fugacity can be regarded as a partial pressure of component i in a mixture corrected for the deviation of the real component from the ideal-gas behavior. Fugacities thus have units of pressure. It is also customary to introduce fugacity coefficients φ_i with

$$f_i = \varphi_i x_i p, \tag{22}$$

which expresses this interpretation more explicitly. The fugacity coefficient can be derived directly from

$$\ln \varphi_i = \left(\frac{\partial N \frac{\tilde{a} - \tilde{a}^{ig}}{\tilde{R}T}}{\partial N_i}\right)_{T, N\tilde{v}, N_{j\neq i}} - \ln Z, \tag{23}$$

where the index ig refers to the ideal gas and Z is the compressibility factor

$$Z = \frac{p\tilde{v}}{\tilde{R}T}. \tag{24}$$

It is obvious that for an ideal gas with

$$Z = 1 \tag{25}$$

also

$$\varphi_i = 1 \tag{26}$$

and

$$f_i = y_i p = p_i, \tag{27}$$

where p_i is the partial pressure of component i. Since all components approach ideal-gas behavior at sufficiently low density, Eq. (25) has to be approached for any substance in this limit. This also has to hold for all EOS model equations properly describing the system behavior.

Substituting Eq. (21) into Eq. (4) it is easily realized that with fugacities VLE can be obtained from

$$f_i^{\mathrm{v}} = f_i^{\mathrm{l}} \tag{28}$$

which has to be satisfied for all components i simultaneously. With Eq. (22) follows

$$K_i = \frac{\varphi_i^{\mathrm{l}}}{\varphi_i^{\mathrm{v}}}. \tag{29}$$

D5.1. Table 1. Azeotropic data for some selected systems at 1.01325 bar [14, 15]. For extensive data sets, see [10, 14, 15]

Component 1	Component 2	Substance	Saturation temperature (°C)	Temperature of azeotrope (°C)	Azeotropic mol fraction

D5.1. Fig. 5. Isobaric vapor–liquid equilibrium data for the binary system water (1) and 1-pentanol (2) displaying a heteroazeotrope. Comparison of experimental values with the results of the NRTL model. Data are taken from [7].

These equilibrium conditions have to be evaluated numerically, where some algorithms can e.g., be found in [18, 19]. To give an example, a simple algorithm for bubble-pressure calculation is presented in Fig. 6.

In the following, some selected EOS are presented that allow for the calculation of the fugacities and fugacity coefficients. Since a variety of EOS are able to describe liquid as well as vapor phase, a single EOS can be used to calculate VLE consistently based on one single substance-specific mathematical equation. Another advantage is that most EOS allow for the description of the system behavior up to and also above the critical point. Thus, equilibria can be described in an extremely wide range of conditions including VL-critical behavior as well as supercritical phase equilibria between fluid phases.

A common disadvantage that will become obvious in the following lies in the simplicity of the correlations introducing the mixture effects for most EOS. This leads to significant problems if substances are to be modeled with EOS for which the molecular interactions differ significantly between pure components and in the mixture. Thus, EOS are generally applied for only moderately nonideal systems.

3.1.1 The Virial Equation

A very simple EOS is the virial equation which is a Taylor-series expansion in molar density ρ of the nonideal system behavior about the ideal-gas equation, which for technical application is generally truncated after the second term:

$$Z = 1 + \tilde{B}\tilde{\rho}, \tag{30}$$

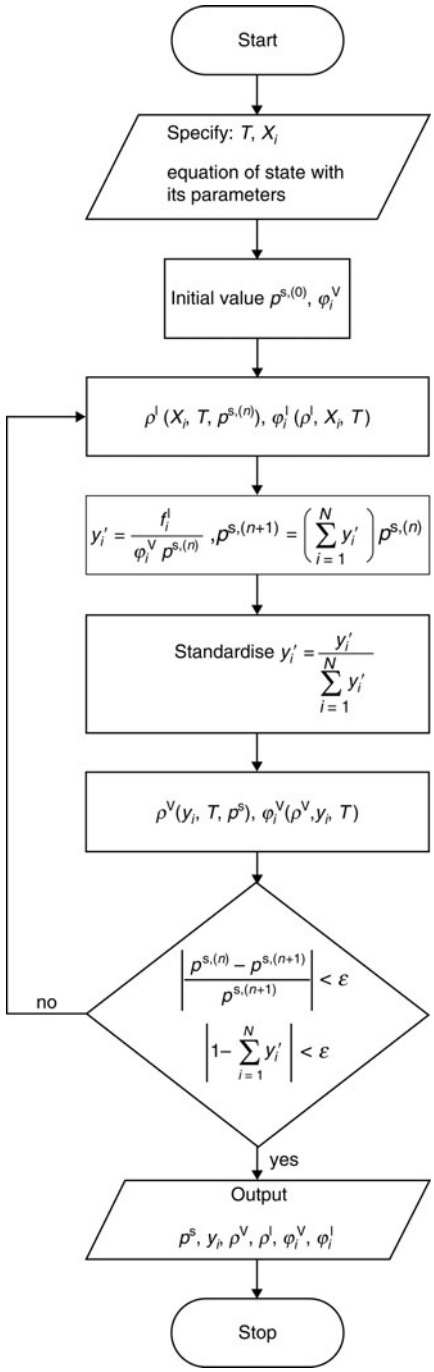
where $\tilde{B}$ is the second virial coefficient, which depends only on temperature and composition, and

$$\tilde{\rho} = \tilde{v}^{-1}. \tag{31}$$

The virial equation can only describe the vapor or gas state. It is generally recommended that Eq. (30) should be used only up to roughly one third of the critical density, since above that the deviations may become unacceptably large. Special care should be taken for systems with carboxylic acids which can form dimers even in the vapor state, an effect that has to be accounted for explicitly. In a mixture $\tilde{B}$ is described by

$$\tilde{B} = \sum_{i=1}^{K}\sum_{j=1}^{K} y_i y_j \tilde{B}_{i,j}, \tag{32}$$

where the virial cross coefficient $\tilde{B}_{i,j} = \tilde{B}_{j,i}$ accounts for the interactions between components i and j. $\tilde{B}_{i,i}$ is the second virial coefficient of pure component i. With the virial equation the fugacity coefficient becomes



D5.1. Fig. 6. A simple algorithm for the calculation of bubble pressure with equations of state.

$$\ln \varphi_i = 2\rho \sum_{j=1}^{K} y_j \tilde{B}_{i,j} - \ln Z. \tag{33}$$

The second virial coefficients for many components are available in data banks and have been published, e.g., by Dymond and Smith [9]. If the second virial coefficients have to be estimated the method of Tsonopoulos [20–23] who derived a correlation based on the principle of corresponding states, is often applied for pure components, i.e., by taking reference to the critical point (c):

$$\frac{\tilde{B}_{ii} p_c}{\tilde{R} T_c} = f^{(0)} + \omega f^{(1)} + f^{(2)}, \tag{34}$$

where ω is the acentric or Pitzer factor

$$\omega = -\log \frac{p^s(T_r = 0.7)}{p_c} - 1 \tag{35}$$

with the reduced temperature

$$T_r = \frac{T}{T_c} \tag{36}$$

and the f-functions for nonpolar contributions given by

$$f^{(0)} = 0.1445 - \frac{0.330}{T_r} - \frac{0.1385}{T_r^2} - \frac{0.0121}{T_r^3} - \frac{0.000607}{T_r^8}, \tag{37}$$

$$f^{(1)} = 0.0637 + \frac{0.331}{T_r^2} - \frac{0.423}{T_r^3} - \frac{0.008}{T_r^8} \tag{38}$$

$f^{(2)}$ accounts for polar interactions. For components without hydrogen bonds

$$f^{(2)} = \frac{a}{T_r^s}. \tag{39}$$

For ketones, aldehydes, nitriles, and ethers a can be approximated with the reduced dipole moment μ_r

$$a = -2.14 \cdot 10^{-4} \mu_r - 4.308 \cdot 10^{-21} \mu_r^8 \tag{40}$$

with

$$\mu_r = \frac{\mu^2 p_c}{1.01325 \frac{\mathrm{Pa} D^2}{K^2} T_c^2}, \tag{41}$$

where μ is the dipole moment e.g., in Debye.

For polar components with hydrogen bonds

$$f^{(2)} = \frac{a}{T_r^6} - \frac{b}{T_r^8} \tag{42}$$

with $a = 0.0878$ for all alcohols and $a = 0.0279$ for water. For methanol $b = 0.0560$, for unbranched alcohols from C_2 to C_4 $b = 0.00908 + 0.0006957\mu_r$, and for water $b = 0.0229$.

If information is missing for the cross virial coefficients, their absolute value can be approximated by the Lorentz combining rule

$$|\tilde{B}_{i,j}| = \frac{1}{8}\left[\left(|\tilde{B}_{i,i}|\right)^{1/3} + \left(|\tilde{B}_{j,j}|\right)^{1/3}\right]^3. \tag{43}$$

This is a very rough approximation though, since $\tilde{B}_{i,j}$ can in principle lie outside the range between $\tilde{B}_{i,i}$ and $\tilde{B}_{j,j}$. If the signs of the pure-component virial coefficients are not identical, some arithmetic mean has to be chosen. For the correlation of Tsonopoulos, it is recommended to apply mixing rules for the critical properties and evaluate the correlations given earlier with those [24].

3.1.2 Cubic Equations of State

The so-called cubic EOS are capable of also describing the behavior of the liquid phase, thus allowing for the calculation of VLE

based on only one material equation. Two frequently used EOS are presented here, which are based on the EOS of van der Waals who was the first to suggest this principal model structure.

The Soave modification of the Redlich–Kwong EOS [25, 26], often abbreviated as SRK EOS or RKS EOS, is given by

$$p = \frac{\tilde{R}T}{\tilde{v} - b} - \frac{a(T)}{\tilde{v}(\tilde{v} + b)} \tag{44}$$

with the mixing rules for the parameters

$$a = \sum_{i=1}^{K} \sum_{j=1}^{K} z_i z_j a_{i,j}, \tag{45}$$

$$b = \sum_{i=1}^{K} z_i b_i. \tag{46}$$

The combining rule for $i \neq j$ is

$$a_{i,j} = (1 - k_{i,j}) \sqrt{a_{i,i} a_{j,j}}, \tag{47}$$

where $k_{i,j}$ is a binary parameter, usually close to zero, to be fitted to experimental data.

The pure-component parameters can be determined from the following correlation

$$a_{i,i}(T) = a_{c,i} \alpha_i(T), \tag{48}$$

$$\alpha_i(T) = \left[1 + m_i \left(1 - \sqrt{T_{r,i}}\right)\right]^2, \tag{49}$$

$$m_i = 0.480 + 1.574\omega_i - 0.176\omega_i^2. \tag{50}$$

From the conditions of the critical point, i.e., the critical isotherm having a saddle point, the following relations can be derived

$$a_{c,i} = \frac{1}{9(2^{1/3} - 1)} \frac{\tilde{R}^2 T_{c,i}^2}{p_{c,i}} \tag{51}$$

and

$$b_i = \frac{(2^{1/3} - 1)}{3} \frac{\tilde{R} T_{c,i}}{p_{c,i}}. \tag{52}$$

For the fugacity coefficient results

$$\ln \varphi_i = \frac{b_i}{b}(Z - 1) - \ln\left[Z\left(1 - \frac{b}{\tilde{v}}\right)\right] + \frac{1}{b\tilde{R}T}\left[\frac{ab_i}{b} - 2\sqrt{aa_i}\right] \ln\left(1 + \frac{b}{\tilde{v}}\right). \tag{53}$$

Equation (44) is called a cubic EOS because if T and p and the composition of the mixture are specified, a cubic equation results for the determination of the molar volume. In case this determining equation has three real roots larger than b, the lowest value corresponds to the liquid molar volume and the highest to the vapor molar volume. The intermediate value corresponds to an unstable state. Above the critical isotherm only one real root larger than b is found.

A second cubic EOS often applied is the Peng–Robinson EOS (PR EOS) [27], which is given by

$$p = \frac{\tilde{R}T}{\tilde{v} - b} - \frac{a(T)}{\tilde{v}^2 + 2b\tilde{v} - b^2} \tag{54}$$

with mixing and combining rules as well as the defining equations for $a_{i,i}(T)$ and $\alpha_i(T)$ being identical to that of the SRK EOS. m_i is given by

$$m_i = 0.37464 + 1.54226\omega - 0.26992\omega^2. \tag{55}$$

The pure-component parameters can be determined from the critical coordinates of a component by

$$a_{c,i} = 0.45724 \frac{\tilde{R}^2 T_{c,i}^2}{p_{c,i}} \tag{56}$$

and

$$b_i = 0.077796 \frac{\tilde{R} T_{c,i}}{p_{c,i}}. \tag{57}$$

For the fugacity coefficient results

$$\ln \varphi_i = \frac{b_i}{b}(Z - 1) - \ln\left[Z\left(1 - \frac{b}{\tilde{v}}\right)\right] + \frac{1}{b\tilde{R}T}\left[\frac{\sqrt{2}ab_i}{4b} - \sqrt{\frac{aa_i}{2}}\right] \ln\left(\frac{1 + \frac{b}{\tilde{v}}(1 + \sqrt{2})}{1 + \frac{b}{\tilde{v}}(1 - \sqrt{2})}\right). \tag{58}$$

In the 1970s and 1980s, many variations and generalizations of these equations have been proposed, most of which are hardly applied today.

For these cubic EOS, the binary parameters have been fitted and are published in the corresponding volumes of the DECHEMA Data Series [7].

3.1.3 Noncubic Equations of State

A variety of noncubic EOS are available in the literature. With noncubic EOS the densities for given $T, p,$ and z_i do not result from a cubic equation but rather have to be determined iteratively. A variety of algorithms have been proposed to quickly and safely find the roots of the EOS even in the very close vicinity of the critical point.

One class of noncubic EOS is the extended virial EOS. The Benedict–Webb–Rubin EOS (BWR EOS) [28, 29] or the Bender EOS [30] can e.g., be used to describe mixtures of components with very small molar mass like in natural gas. Other even generalized forms of this type of equation are available, e.g., by Lee and Kesler (LK EOS) [31].

In recent years, research aims at overcoming the deficiencies of the EOS presented here, which are mentioned earlier and are a result of the simple structure of the pure-component EOS as well as of the primitive mixing and combining rules. One very successful approach is the SAFT EOS, which has originally been proposed by Huang and Radosz [32, 33] directly in a formulation for the Helmholtz free energy. The SAFT EOS is currently investigated and extended by many authors e.g., to also include very strongly interacting components, polymers, and electrolytes.

3.2 $\tilde{g}^E$- or γ_i-Models

An alternative approach for calculating VLE is to describe the fugacities in the vapor with a possibly simple EOS and in the liquid based on a $\tilde{g}^E$- or γ_i-model:

$$f_i^l = \gamma_i x_i \varphi_i^{s,v} p_i^s \kappa_i, \tag{59}$$

where γ_i is the activity coefficient of component i in the liquid mixture, p_i^s is the pure-component vapor pressure at the specified temperature, $\varphi_i^{s,v}$ is the pure-component fugacity coefficient of the vapor at p_i^s, and κ_i is the so-called Poynting correction which accounts for the compression of the pure component between p_i^s and p^s of the mixture, where the latter is determined by the resulting VLE equilibrium condition which has to be fulfilled for each component:

$$\varphi_i y_i p^s = \gamma_i x_i \varphi_i^{s,v} p_i^s \kappa_i. \tag{60}$$

The Poynting correction can be approximated as

$$\kappa_i \approx \exp\left(\frac{\tilde{v}_i^l (p^s - p_i^s)}{\tilde{R}T}\right) \tag{61}$$

when the liquid is reasonably incompressible, which generally is the case, and where $\tilde{v}_i^l$ is the molar volume of the pure-component liquid at T and p_i^s.

The nonideality in the liquid is described by the activity coefficients which are strongly dependent on mixture composition and which can be determined from a $\tilde{g}^E$-model with

$$\mu_i^E(T,p,x_k) = \tilde{R}T \ln \gamma_i = \left(\frac{\partial N \tilde{g}^E(T,p,x_k)}{\partial N_i}\right) T, p, N_{j\neq i}, \tag{62}$$

where the superscript "E" refers to an excess property defined as the value of a mixture from which the value of an ideal mixture at the same T, p, and x_i has been subtracted. Since all relevant $\tilde{g}^E$-models assume incompressible liquids, the activity coefficients result to be pressure independent.

The fugacity coefficients of the vapor are generally described either with the virial equation or for intermediate and low pressures and temperatures above ambient, and it turns out that $\varphi_i^{s,v} \approx \varphi_i$ and their individual effect can be neglected. Under these conditions also the Poynting correction can usually be neglected ($\kappa_i = 1$), and the molar volume of the pure liquids would need to be known otherwise. With these simplifying assumptions the equilibrium condition simplifies to

$$y_i p^s = \gamma_i x_i p_i^s. \tag{63}$$

If the nonideality of the liquid mixture can also be neglected, which is only the case for components of similar molecular size and chemical structure such as isomers or close neighbors of a homologous series,

$$\gamma_i = 1, \tag{64}$$

which corresponds to Raoult's law, that has been discussed earlier.

For the pure-component vapor pressure any expression for the saturation-pressure curve can be used, often the Antoine equation is applied

$$\log \frac{p_s^s}{1\ \text{bar}} = A - \frac{B}{C+T} \tag{65}$$

for which the temperature coefficients for a variety of components can be found e.g., in Boublík et al. [7, 8, 24]. When the coefficients for the Antoine equation are adopted from the literature, care should be taken that the units of temperature and pressure as well as the base of the logarithm are identical to those for which the coefficients have been determined. If only the critical point and the acentric factor are known, generalized correlation functions can be used like that proposed by Lee and Kesler [31].

With the notation used here, which corresponds to the symmetrical normalization, the activity coefficients approach unity for any pure component. For a composition approaching infinite dilution, the activity coefficients generally deviate strongly from unity and are termed infinite-dilution activity coefficients γ_i^∞. The γ_i^∞ can thus be used to determine the adjustable model parameters of a $\tilde{g}^E$-model in the common case where there are only two adjustable parameters per binary mixture.

Some $\tilde{g}^E$-models are presented in the following. The model parameters of these models have to be fitted to experimental data, preferably VLE data. If the models have only two binary parameters, these can be backed out from both infinite-dilution activity coefficients for which many experimental data have been published [16, 17]. The parameters have been determined and are reported for a wide variety of systems in the DECHEMA Data Series [7]. A simple algorithm for calculating VLE with $\tilde{g}^E$-models is presented in Fig. 7.

3.2.1 Redlich–Kister Model

A simple approach taken by Redlich and Kister [34] is to expand $\tilde{g}^E$ in an appropriate series:

$$\tilde{g}^E = x_1 x_2 \left(\sum_{l=1}^{L} A_l (x_1 - x_2)^{l-1}\right), \tag{66}$$

where the A_i are substance-specific parameters to be fitted to experimental data. Without significant extension the Redlich–Kister model (RK) can only be applied to binary systems. It is mostly used in the cases where very accurate description of $\tilde{g}^E$ is required and a sufficient number of accurate experimental data are available. With Eq. (62) the following results for the activity coefficients are obtained:

$$\tilde{R}T \ln \gamma_1 = x_2^2 \sum_{i=1}^{L-1} (A_i + 2x_1 i A_{i+1})(x_1 - x_2)^{i-1} \tag{67}$$

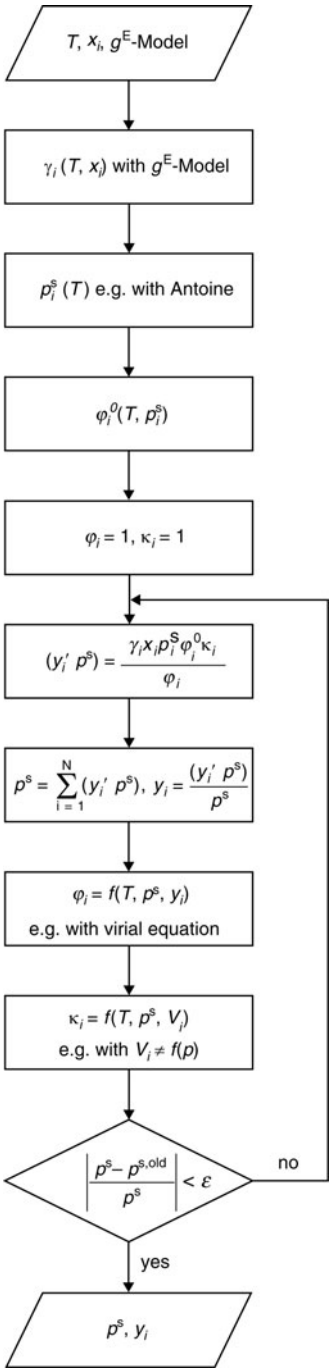
and

$$\tilde{R}T \ln \gamma_2 = x_2^2 \sum_{i=1}^{L-1} (A_i - 2x_2 i A_{i+1})(x_1 - x_2)^{i-1}. \tag{68}$$

3.2.2 Wilson Model

The model proposed by Wilson [35] for the first time introduced the concept of local composition, i.e., the fact that the composition "seen" by one type of molecules in their close vicinity should generally not be identical to the overall composition due to energetic interactions, which leads to some neighborhoods being preferred over others. The Wilson model describes multicomponent mixtures:

$$\tilde{g}^E = -RT \sum_{i=1}^{K} x_i \ln\left(\sum_{j=1}^{K} x_i \Lambda_{i,j}\right), \tag{69}$$



D5.1. Fig. 7. A simple algorithm for the calculation of bubble pressure with $\tilde{g}^E$-models.

where

$$\Lambda_{i,j} = \frac{\tilde{v}_j^L}{\tilde{v}_i^L} \exp\left(-\frac{\lambda_{i,j} - \lambda_{i,i}}{\tilde{R}T}\right) \tag{70}$$

and especially

$$\Lambda_{i,i} = 1. \tag{71}$$

The $\lambda_{i,j}$ are interaction energies between the molecules and $\tilde{v}_i^L$ is the pure-component liquid molar volume. In the beginning it had been discussed whether this molar volume should be treated as a variable, e.g., depending on T. Today, it is agreed that it can be used at any specified T; generally 293°C is used. With the Wilson model multicomponent mixtures can be described based only on the two binary parameters $(\lambda_{i,j} - \lambda_{i,i})$ for each binary subsystem. The feature that calculation of muticomponent mixtures can be described solely based on binary parameters holds for all models described in the following.

For the activity coefficient results

$$\ln \gamma_i = 1 - \ln\left(\sum_{j=1}^{K} x_j \Lambda_{i,j}\right) - \sum_{k=1}^{K} \frac{x_k \Lambda_{k,i}}{\sum_{j=1}^{K} x_j \Lambda_{k,j}}. \tag{72}$$

The Wilson model is able to describe strongly interacting components including polar and hydrogen-bonding substances. The Wilson model cannot describe liquid–liquid equilibria, due to its mathematical structure. This has to be taken into account and can sometimes even be an advantage, since it has to be kept in mind that all $\tilde{g}^E$-models only approximate system behavior. For systems that are strongly nonideal and close to demixing but do not show a miscibility gap, the Wilson model cannot erroneously predict liquid–liquid demixing, which may save computer time otherwise required for testing, if demixing is predicted for the conditions of interest.

3.2.3 NRTL Model

Also based on the local-composition concept, the NRTL model (nonrandom two liquids) has been derived by Renon and Prausnitz [36]:

$$\tilde{g}^E = \tilde{R}T \sum_{i=1}^{K} x_i \frac{\sum_{j=1}^{K} \tau_{j,i} G_{j,i} x_j}{\sum_{j=1}^{K} G_{j,i} x_j} \tag{73}$$

with

$$\tau_{j,i} = \frac{g_{j,i} - g_{j,i}}{\tilde{R}T} \tag{74}$$

and

$$G_{j,i} = \exp(-\alpha_{j,i} \tau_{j,i}). \tag{75}$$

Here, $g_{i,j}$ describes the interaction energy between molecules of type i and j which implies

$$g_{j,i} = g_{i,j} \tag{76}$$

$\alpha_{i,j}$ is the nonrandomness parameter which should lie between 0 and 1. Additionally, it is usually assumed that

$$\alpha_{j,i} = \alpha_{i,j} \tag{77}$$

resulting in

$$\tau_{i,i} = 0 \tag{78}$$

and

$$G_{i,i} = 1. \tag{79}$$

The activity coefficient is described by the following expression:

$$\ln \gamma_i = \frac{\sum_{j=1}^{K} \tau_{j,i} G_{j,i} x_j}{\sum_{j=1}^{K} G_{j,i} x_j} + \sum_{j=1}^{K} \frac{x_j G_{i,j}}{\sum_{k=1}^{K} G_{k,j} x_k} \left(\tau_{i,j} - \frac{\sum_{l=1}^{K} \tau_{l,j} G_{l,j} x_l}{\sum_{l=1}^{K} G_{l,j} x_l}\right). \tag{80}$$

For a binary system the parameters are two values of $(g_{j,i} - g_{i,i})$ as well as $\alpha_{i,j}$. Thus, the NRTL model has three binary parameters which allow relatively flexible fitting even for highly nonideal systems. For most systems though experimental information is not accurate enough to significantly determine the three independent parameters, thus often $\alpha_{i,j}$ is fixed to values of e.g., 0.2 or 0.3, which correspond to typical values of the nonrandomness parameter.

3.2.4 UNIQUAC Model

The UNIQUAC model was first derived by Abrams and Prausnitz [37] and later validated by Maurer and Prausnitz [38]. The expression for the molar Gibbs energy is divided into two expressions

$$\tilde{g}^{\mathrm{E}} = \tilde{g}^{\mathrm{E}}_{\mathrm{comb}} + \tilde{g}^{\mathrm{E}}_{\mathrm{res}}, \tag{81}$$

where the combinatorial part describes the effects of molecular size and shape and the residual part accounts for the effect of energetic interactions. For the combinatorial part, the Guggenheim–Staverman expression is used:

$$\tilde{g}^{\mathrm{E}}_{\mathrm{comb}} = \tilde{R}T \sum_{i=1}^{K} x_i \ln \frac{\varphi_i}{x_i} + \tilde{R}T \frac{z}{2} \sum_{i=1}^{K} q_i x_i \ln \frac{\psi_i}{\varphi_i}, \tag{82}$$

where z is the coordination number, $z = 10$ is assumed. φ_i is the volume fraction of component i in the system

$$\varphi_i = \frac{x_i r_i}{\sum_{j=1}^{K} x_j r_j} \tag{83}$$

and ψ_i its surface fraction:

$$\psi_i = \frac{x_i q_i}{\sum_{j=1}^{K} x_j q_j}, \tag{84}$$

with r_i the volume parameter and q_i the surface parameter determined from van der Waals volumes and surfaces obtained with the Bondi method [39], normalized with appropriate reference values given by Abrams and Prausnitz:

$$r_i = \frac{\tilde{v}_{\mathrm{vdW,Bondi},i}}{\tilde{v}_{\mathrm{ref}}} \quad \text{with } \tilde{v}_{\mathrm{ref}} = 15.17 \ \frac{\mathrm{cm}^2}{\mathrm{mol}}, \tag{85}$$

$$q_i = \frac{\tilde{a}_{\mathrm{vdW,Bondi},i}}{\tilde{a}_{\mathrm{ref}}} \quad \text{with } \tilde{a}_{\mathrm{ref}} = 2.5 \times 10^9 \ \frac{\mathrm{cm}^2}{\mathrm{mol}}. \tag{86}$$

The van der Waals volumes and surfaces can in principle be determined from the increment method given by Bondi [39], but the r_i and q_i can also be found directly in data collections such as [7].

The residual term of the UNIQUAC model accounts for interaction energies $u_{i,j}$:

$$\tilde{g}^{\mathrm{E}}_{\mathrm{res}} = -\tilde{R}T \sum_{i=1}^{K} x_i q_i \ln \sum_{j=1}^{K} \psi_j \tau_{j,i} \tag{87}$$

with

$$\tau_{j,i} = \frac{u_{j,i} - u_{i,i}}{\tilde{R}T}. \tag{88}$$

The expression for the activity coefficient is equally split into two contributions:

$$\ln \gamma_i = \ln \gamma_{i,\mathrm{comb}} + \ln \gamma_{i,\mathrm{res}} \tag{89}$$

with

$$\ln \gamma_{i,\mathrm{comb}} = 1 - \frac{\varphi_i}{x_i} + \ln \frac{\varphi_i}{x_i} - \frac{z}{2} q_i \left(1 - \frac{\varphi_i}{\psi_i} + \ln \frac{\varphi_i}{\psi_i}\right), \tag{90}$$

$$\ln \gamma_{i,\mathrm{res}} = q_i \left(1 - \ln \left[\sum_{j=1}^{K} \psi_j \tau_{j,i}\right] - \sum_{j=1}^{K} \frac{\psi_j \tau_{i,j}}{\sum_{k=1}^{K} \psi_k \tau_{k,j}}\right). \tag{91}$$

Also with the UNIQUAC model strongly nonideal and associating mixtures can be dealt with. Again, from the two parameters $(u_{j,i} - u_{i,i})$ for each binary subsystem the thermodynamic behavior of a multicomponent system can be described.

3.2.5 Group-Contribution Method UNIFAC

The model parameters of the $\tilde{g}^{\mathrm{E}}$-models presented so far have to be determined by fitting to experimental VLE information. It has been shown by Fredenslund et al. [40] that it is possible to consistently represent the thermodynamic behavior not by activity coefficients for the molecular species present in the system but rather for the chemical groups constituting them. This has the advantage that the resulting interaction-energy parameters, which correspondingly refer to the interactions between groups, can first be determined from data for characteristic substances, where the parameters are fitted simultaneously to data of many mixtures of components with the respective groups. The parameters can then be used for any system the components of which consist of these groups. This is obviously a tedious fitting task.

The UNIFAC model can be efficiently evaluated with the notation of Sørensen et al. [41]:

$$\ln(\gamma_i) = 1 - \bar{R}_i + \ln \bar{R}_i + q_i \left[1 - \ln \bar{Q}_i - \frac{z}{2}\left(1 - \frac{\bar{R}_i}{\bar{Q}_i} + \ln \frac{\bar{R}_i}{\bar{Q}_i}\right)\right] - \sum_{j=1}^{N} \left(\Theta_j \frac{S_{j,i}}{\eta_j} - G_{j,i} \ln \frac{S_{j,i}}{\eta_j}\right), \tag{92}$$

where j runs over all N structural groups. The individual variables in this equation follow from

$$r_i = \sum_{j=1}^{N} v_j^{(i)} R_j, \quad q_i = \sum_{j=1}^{N} v_j^{(i)} Q_j, \tag{93}$$

$$\bar{R}_i = \frac{r_i}{\sum_{k=1}^{K} x_k r_k}, \quad \bar{Q}_i = \frac{q_i}{\sum_{k=1}^{K} x_k q_k}, \tag{94}$$

$$G_{j,i} = Q_j v_j^{(i)}, \quad \Theta_j = \sum_{k=1}^{K} G_{j,k} x_k, \tag{95}$$

$$\tau_{m,j} = \exp\left(-\frac{a_{m,j}}{T}\right), \quad z = 10, \tag{96}$$

$$S_{j,i} = \sum_{m=1}^{N} G_{m,i} \tau_{m,j}, \quad \eta_j = \sum_{k=1}^{K} S_{j,k} x_k, \tag{97}$$

where index k counts the components, and indices j and m count the structural groups. $v_j^{(i)}$ is the number of groups of type j within molecule i. The meaning of the other variables closely corresponds to those of the UNIQUAC model. $a_{m,j}$ are the energy parameters corresponding to the interactions between the groups that have been fitted to an entire set of data for many systems of components with various structural groups. A small selection of the parameters is presented in Tables 2 and 3.

The original UNIFAC model has been modified by two groups leading to mod. UNIFAC (Lyngby) [42] and mod. UNIFAC (Dortmund) [43], where the latter appears to be relatively frequently applied. Both modifications take temperature-dependent parameters into account. The parameter base for mod. UNIFAC (Dortmund) is continually extended by Gmehling and coworkers funded by the so-called UNIFAC consortium. These parameters are regularly published with a certain time delay and are then available to the public (see [44] for the most recent set of parameters that can also be downloaded there. Published parameters can be found also in [45–47]).

3.2.6 Quantum-Chemical Predictions

In recent years, the COMSO-RS or COSMO-Therm method has been proposed and developed by Klamt [48, 49]. This model is based on quantum-chemical calculations for the charge distribution on the surface of the molecules. Then suitable thermodynamic expressions are applied to describe the molecules interacting via these surfaces. Thus, a method is available that allows purely predictive description of thermodynamic behavior of mixtures solely based on calculations without any experiments.

It is generally accepted that the COSMO approach gives reasonable values for many systems, where of course a lesser accuracy has to be expected as compared with the aforementioned methods, which are fitted to the experiment. Especially, when comparing different systems COSMO often gives the correct order for the thermodynamic behavior, making the method suitable for screening purposes. Currently, many investigations are under way to test the COSMO method for extreme systems such as e.g., ionic liquids.

Example 1

(a) Calculate the fugacity coefficient at the vapor pressure at $T = 232.15$ K for the pure components 1,4-dioxane (1) and water (2) according to the scheme of Tsonopoulos. The following properties are given:

$p_1^s = 0.159$ bar, $T_{c,1} = 588.15$ K, $p_{c,1} = 54.72$ bar, $\omega_1 = 0.288$, $\mu_1 = 0.45$ D and

$p_2^s = 0.123$ bar, $T_{c,2} = 647.3$ K, $p_{c,2} = 220.64$ bar, $\omega_2 = 0.344$.

(b) Calculate the fugacities in a corresponding gas mixture of dioxane and water at $y_1 = 0.4729$ and $p_1^s = 0.2079$ bar with the same assumptions using the Lorentz combining rule [Eq. (43)].

Solution

(a) With the correlation of Tsonopoulos, Eq. (34), the following values are obtained for the pure-component

D5.1. Table 2. Volume and surface parameters of UNIQUAC and UNIFAC for selected groups (A refers to aromatic, F to furan)

Main group	Subgroup	No.	R_j	Q_j	Examples for group assignment	
1 CH_2	CH_3	1	0.9011	0.848	Hexane	$2CH_3$, $4CH_2$

virial coefficients: $\tilde{B}_{1,1} = -1575\ \mathrm{cm^2/mol}$ and $\tilde{B}_{2,2} = -1674\ \mathrm{cm^2/mol}$. From this, the fugacities result as $\varphi_1 = 0.99067$ and $\varphi_2 = 0.99211$ with Eq. (33). Note that the equation of state has to be solved for molar volume or density at given temperature and pressure, leading to a quadratic equation resulting directly from Eq. (30).

(b) With the Lorentz combining rule $\tilde{B}_{1,2} = \tilde{B}_{2,1} = -1624\ \mathrm{cm^2/mol}$ is obtained, leading to $\tilde{B} = -1638\ \mathrm{cm^3/mol}$, $\varphi_1 = 0.98790$, and $\varphi_2 = 0.98714$.

Example 2

(a) Calculate the VLE for a mixture of 1,4-dioxane (1) and water (2), assuming ideal vapor phase and neglecting the Poynting correction. The nonideality of the liquid can be described with the UNIQUAC model. The following data are given, which can be obtained from the DECHEMA Data Series [7]:
$r_1 = 3.1854$, $q_1 = 2.64$, $r_2 = 0.92$, $q_2 = 1.4$, $z = 10$, $u_{2,1} - u_{1,1} = -1762.7\ \mathrm{J/mol}$, $u_{1,2} - u_{2,2} = 5516.2\ \mathrm{J/mol}$, $x_1 = 0.25$, and $T = 323.15\ \mathrm{K}$. The vapor pressures are specified in example 1.

It should be noted in passing that the DECHEMA values for the geometry parameters obviously do not take decrements for dioxane rings specified by Bondi [39] into account. Since the published parameters for the UNIQUAC model have been fitted assuming these geometry values, the slightly erroneous values have to be used consequently.

(b) Show that the vapor mixture of Example 1b corresponds to the saturated state in equilibrium with the liquid of (a) of this example, if the vapor nonidealities are accounted for with the virial equation and only the Poynting correction is neglected.

Solution

(a) From the UNIQUAC modelresults (Eqs. (89–91)) $\ln(\gamma_1) = 0.4135 + 0.4877$, $\ln(\gamma_2) = 0.1513 + 0.0152$, $\gamma_1 = 2.4626$, and $\gamma_2 = 1.1811$. From Eq. (63) results $p^s = x_1\gamma_1 p_1^s + x_2\gamma_2 p_2^s = 0.207\ \mathrm{bar}$ and $y_1 = 0.4733$.

(b) According to Eq. (60) it has to be shown that

$$x_i y_i p_i^s \varphi_i^{s,v} - y_i \varphi_i p^s \approx 0$$

for both components. With the values determined in Example 1 for the fugacity coefficients, it can be shown that this difference is close to 10^{-6} which can be regarded to be essentially zero compared to the individual terms.

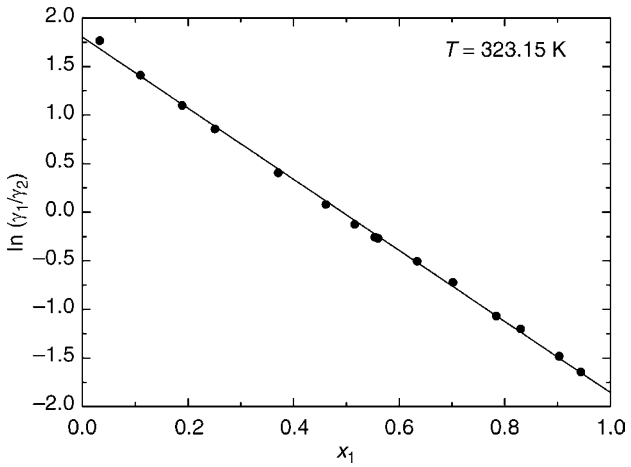
Example 3

According to the DECHEMA Data Series [7], a typical set of VLE data is chosen for the system 1,4-dioxane (1) and water (2) at $T = 323.15\ \mathrm{K}$:

x_1	y_1	p^s
–	–	mbar
0.0000	0.0000	123.34
0.0330	0.2050	153.00
0.1100	0.3960	190.17
0.1890	0.4750	206.84
0.2510	0.5050	214.41
0.3710	0.5340	220.62
0.4610	0.5450	222.43
0.5160	0.5490	223.91
0.5540	0.5540	223.03
0.5600	0.5570	223.63
0.6340	0.5750	223.83
0.7020	0.5970	220.85
0.7840	0.6170	219.41
0.8300	0.6550	212.21
0.9030	0.7320	201.53
0.9440	0.8080	187.78
1.0000	1.0000	160.64

Assuming ideal vapor phase and neglecting Poynting correction, the parameters of the Wilson equation are to be determined from

(a) regression of all data points,
(b) only from the coordinates of the azeotrope, and
(c) from the activity coefficients at infinite dilution.



D5.1. Fig. 8. Graphical determination of infinite-dilution activity coefficients for the system 1,4-dioxane (1) and water (2).

Solution

The activity coefficients can be backed out with the assumptions from Eq. (63), where the pure-component vapor pressures are taken from Example 1.

The coordinates of the azeotrope are $x_{1,az} = y_{1,az} = 0.5540$ and $p^s_{az} = 223.03$ mbar. The activity coefficients at infinite dilution can be determined readily from a plot of $\ln(\gamma_1/\gamma_2)$ versus mol fraction in the liquid as shown in Fig. 8, where a linear dependence has been fitted. It has to be kept in mind that the activity coefficient of the component in excess tends toward unity in this limit. From the regression follows $\ln(\gamma_1^\infty) = 1.8023$ and $\ln(\gamma_2^\infty) = 1.8560$.

The resulting Wilson parameters are

Method of determination	$\Lambda_{1,2}$	$\Lambda_{2,1}$	γ_1^∞	γ_2^∞	Mean deviation Δp mbar	Mean deviation Δy_1 –
(a) All data	0.26048	0.29066	7.8035	7.2075	1.494	0.0082
(b) Azeotropic data	0.17655	0.35077	10.8415	6.4953	2.181	0.0089
(c) Values of γ_i^∞	0.33036	0.30532	6.0633	6.3983	7.429	0.0174

Besides the parameters the predicted infinite-dilution activity coefficients are shown [the exact values are those of solution (c)] as well as mean absolute deviations in the last two columns. It is obvious that quite accurate fitting is possible when all data are taken into account. The simplifying assumptions in (b) and (c) lead to reasonable results as well.

Example 4

Calculate the activity coefficients of the system 1,4-dioxane (1) and water (2) at $x_1 = 0.25$ and $T = 323.15$ K with the UNIFAC method. The following values for the intermediate variables are obtained.

Group j	R_j	Q_j	$v_j^{(1)}$	$v_j^{(2)}$
1 H_2O	0.9200	1.4000	0	1
2 CH_2	0.6744	0.5400	2	0
3 CH_2O	0.9183	0.7800	2	0

Group j	$G_{j,1}$	$G_{j,2}$	Θ_j
1 H_2O	0.0000	1.4000	1.0500
2 CH_2	1.0800	0.0000	0.2700
3 CH_2O	1.5600	0.0000	0.3900

Component i	r_i	q_i	$\bar{R}_i$	$\bar{Q}_i$
1	3.1854	2.6400	2.1431	1.5439
2	0.9200	1.4000	0.6190	0.8187

Group j	$a_{j,1}$(K)	$a_{j,2}$(K)	$a_{j,3}$(K)
1	0.0	300.0	540.5
2	1318.0	0.0	251.5
3	−314.7	83.4	0.0

Group j	$\tau_{j,1}$(K)	$\tau_{j,2}$(K)	$\frac{\tau_{j,3}}{K}$
1	1.0000	0.3952	0.1878
2	0.0169	1.0000	0.4592
3	2.6481	0.7726	1.0000

$S_{1,1}$	4.1494
$S_{2,1}$	2.2853
$S_{3,1}$	2.0559
$S_{1,2}$	1.4000
$S_{2,2}$	0.5533
$S_{3,2}$	0.2629

η_1	2.0873
η_2	0.9863
η_3	0.7111

It follows for $\gamma_1 = 1.8832$ and $\gamma_1 = 1.3145$. Comparing these values to Example 2, it is obvious that they capture the trend but for this strongly nonideal system certain deviations have to be expected.

D5.2 Polymer Solutions: Vapor–Liquid Equilibrium and Diffusion Coefficients

Wilhelm Schabel
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Vapor–Liquid Equilibrium of Polymer Solutions

The phase equilibrium between a polymer solution and the solvent vapor is usually treated like a vapor–liquid equilibrium (VLE) even if the Many thermodynamic models for polymer solutions are available in the literature and in principle the models can be categorized in two groups: equations of state models for the description of both phases e.g., [1, 2] or lattice models for calculating the activity coefficients in the liquid phase. Activity coefficient models are usually easier to use for practical applications and calculations than equations of state. The well-known activity coefficients model for thermodynamics of polymers is the model of Flory [3] and Huggins of 1942 [4]. This (correlative) model is mathematically pretty simple to use and hence suited for practical calculations, but it generally requires tabulated fitting (correlative) parameters of interaction parameters to measured data. An overview of various methods of measuring the VLE of polymer solutions is given e.g., by Schabel et al [5].

On the other hand there are predictive group contribution methods which offer the advantage for the user that the activity coefficients can be calculated solely from known and tabulated group contributions of the molecular structure of the substances. The UNIFAC (Universal Functional Activity Coefficient), and UNIQUAC (Functional Group Activity Coefficients), (see Subchap. D5.1) represents a commonly used group contribution method that has proven its reliability for the determination of activity coefficients in liquid mixtures of low molecular weight. In mixtures of high molecular weight, e.g., polymer solutions, however, the predicted values for the activities are too low because of free-volume effects. Oishi and Prausnitz [6] therefore suggested extending the activity coefficients calculated with the UNIFAC method by an appropriate free-volume contribution named UNIFAC-free volume (UNIFAC-FV). In this chapter both methods (correlative and predictive) will be introduced and equations and examples are given to use them.

1.1 Flory–Huggins Model

The model of Flory [3] and Huggins [4] considers the polymer solution as a three-dimensional lattice of spheres. The solvent molecules are considered as single spheres, whereas the polymer is regarded as a chain of these.

Flory and Huggins calculated the combinatorial entropy of mixing based on statistical deliberations and they set the enthalpy of mixing to zero assuming an ideal athermal mixture.

For the activity a_i, i.e., the ratio of the partial pressure p_i of the solvent over the polymer solution and the saturation vapor pressure of the pure solvent p_{0i} (see also Subchap. D5.1 or, e.g., [7]), it can be written:

$$\ln a_i^{\text{entropy of mixing}} = \ln \frac{p_i}{p_{0i}} = \ln\ \phi_i + \left(1 - \frac{\tilde{\nu}_i}{\tilde{\nu}_\mathrm{P}}\right) \phi_\mathrm{P} \qquad (1)$$

ϕ is the volume fraction of the solvent (i) and the polymer (P), respectively, and $\tilde{\nu}\left(= \tilde{M}_i / \rho_i\right)$ is the molar volume of the component i (m^3/mol). The volume fraction for binary systems is calculated (neglecting excess volumes) from the mass fractions x_i and the densities of the pure substances ρ_i and ρ_P

$$1 - \phi_i = \phi_\mathrm{P} = \frac{x_\mathrm{P}}{x_i \rho_\mathrm{P} / \rho_i + x_\mathrm{P}} \qquad (2)$$

Usually volume fractions or mass fractions are used to determine the composition of polymer solutions. Molar fractions will yield values being close to 1, even at low solvent contents, due to the usually significantly different molar masses of the polymer and the solvent. Since attractive and repulsive forces are interacting between molecules, the exchange of one molecule in a mixture of component 1 against one molecule or parts of a chain of molecules of substance 2 requires work. This work is considered as enthalpy of mixing and contributes to the activity. According to Huggins [4] this contribution can be written as:

$$\ln a_i^{\text{enthalpy of mixing}} = \chi_{i\mathrm{P}}\, \phi_\mathrm{P}^2 \qquad (3)$$

with a Flory–Huggins interaction parameter χ_{iP}. This parameter was considered by this theory to be independent of the composition (entropic influence) but shows a dependence on temperature. Adding the two parts of the activity from Eqs. (1) and (3), the result is the well-known Flory–Huggins equation for the activity of the solvent (i) in a polymer (P).

$$\ln a_i = \ln \phi_i + (1 - \frac{\tilde{v}_i}{\tilde{v}_P}) \phi_P + \chi_{iP} \phi_P^2 \qquad (4)$$

For polymer solutions, the molar volume $\tilde{v}_i \left(= \tilde{M}_i/\rho_i\right)$ of the solvent and the polymer are significantly different $(\tilde{v}_i << \tilde{v}_P)$ and the form of the Flory–Huggins equation for polymer solutions that is usually found in literature is reduced to:

$$\begin{aligned} \ln a_i &= \ln \phi_i + \phi_P + \chi_{iP}\phi_P^2 \\ \text{or} \quad a_i &= \phi_i \exp\left(\phi_P + \chi_{iP}\phi_P^2\right) \end{aligned} \qquad (5)$$

According to Hildebrand and Scott [8], the Flory–Huggins interaction parameter χ_{iP} can be predicted for a polymer-solvent system (independently of the composition) using solubility parameters. Various experimental results of the past, however, show that the interaction parameter χ_{iP} is often dependent on the composition of the system [9–12] which has to be taken into account. This discrepancy can be explained by the assumption that the macromolecules are like a chain of spheres occupying certain lattice positions and, according to theory, the other lattice positions are readily accessible for the solvent molecules. But most polymer systems will create knots and entanglements making the free lattice positions on the inside inaccessible for the solvent molecules. Therefore an important assumption of the F–H Theory is not fulfilled and χ_{iP} has to include entropic influences that are dependent on the configuration and the composition within the lattice. Tapavicza and Prausnitz [13] and Flory [14] show that this entropic contribution has to be taken into account and can be significantly large. Therefore, it is usually not possible to predict the interaction parameters and they must be determined and fitted to measured data. Flory [14] proposes to fit the interaction parameter as a function of the volume fraction with the following empirical polynomial expression:

$$\chi_{iP}(\phi_P) = \chi_1 + \chi_2 \cdot \phi_P + \chi_3 \cdot \phi_P^2 \qquad (6)$$

In Table 1 the coefficients [The given parameters cannot be used for the calculation of the excess Gibbs energy (G^E).] for describing the concentration dependence of $\chi_{iP}(\phi_P)$ according to Eq. (6) are listed for some polymer-solvent systems. Further values and measured data can be found, e.g., in [9, 10, 15–17]. The temperature dependence of the interaction parameter can be described by the following equation according to Koningsveld and Kleintjens [18]:

$$\chi_{iP}(\phi_P, T) = \chi_{iP}(\phi_P) \cdot (1 + \beta/T + \gamma \cdot T + \delta \cdot \ln T) \qquad (7)$$

This equation can as well be used to describe phase separation of polymer solutions. Danner and High [10] has successfully described critical upper and lower separation temperatures (UCST and LCST) by fitting this equation to measured data. An extension of the Flory–Huggins equation for cross-linked polymers can be found, e.g., in [19]. The swelling of the polymer is accounted for by an additional summand in the exponent of Eq. (5). The values given here in this chapter and Table 1 are fitted to predict VLE and are not suited to predict phase separation by means of G^E models.

D5.2. Table 1. Coefficients[1] for describing the concentration dependence of the Flory–Huggins interaction parameter $\chi_{iP}(\phi_P)$ according to Eq. (6). For a few polymer–solvent systems the equilibrium data from [9, 11, 12], has been used to fit Eq. (6) for a defined temperature or a temperature interval

1.2 UNIFAC-FV Model

With the extension of the UNIFAC (Subchap. D5.1) method for polymers, UNIFAC-FV, vapor–liquid equilibrium of polymer-solvent systems can be predicted from group contributions of the molecules without having any experimental data. The model provides good results for organic solvents and (normal) polymers. It fails, however, for water as a solvent and for block copolymers and cross-linked polymers.

The UNIFAC model by Fredenslund and Gmehling is based on the assumption that the molecules of a mixture can be divided into functional groups. The interactions between the molecules are thought to be caused by the interactions of these groups. Some surface and volume interaction parameters are listed in Subchap. D5.1. In the UNIFAC-FV model the activity is the sum of a combinatorial, a residual and a free-volume contribution:

$$\ln a_i = \ln a_i^C + \ln a_i^R + \ln a_i^{FV} \qquad (8)$$

The third term $\left(\ln a_i^{FV}\right)$ takes the influence of the free-volume into account. This is the volume that is not occupied by molecules on a microscopic scale whereas it is part of the macroscopic volume of a substance. The free-volume is for instance also responsible for the thermal expansion behavior of liquids. The free-volume contribution can be neglected for the calculation of the activity of monomers and is therefore absent in the original UNIFAC model. However, it has to be considered when calculating an equilibrium involving a polymer component because polymer chains tend to form clusters making certain positions inaccessible for solvent molecules as it was explained above. Oishi and Prausnitz [6] used an equation of state

simplified by Flory to derive the contribution of the free-volume to the activity.

The combinatorial contribution (see Subchap. D5.1, vapor–liquid equilibium) can be written as follows:

$$\ln a_i^{\mathrm{C}} = \ln \varphi_i' + 1 - \frac{\varphi_i'}{\tilde{x}_i} + \frac{z}{2} \cdot \tilde{M}_i \cdot q_i \cdot \ln \frac{\theta_i}{\varphi_i'} - \frac{z}{2} \cdot \tilde{M}_i \cdot q_i \cdot \left(1 - \frac{\varphi_i'}{\theta_i}\right) \tag{9}$$

In a binary mixture of polymer and solvent it follows:

$$1 - \frac{\varphi_i'}{\tilde{x}_i} = \varphi_P' \left(1 - \frac{\tilde{v}_i}{\tilde{v}_P}\right) \approx \varphi_P' \tag{10}$$

With Eq. (10) the first two summands in Eq. (9) have the same form as the Flory–Huggins Eq. (4). The index ′, however, shows that the volume fractions are calculated differently. The reduced group volume r and the reduced group surface q are calculated as follows:

$$r_i = \frac{1}{\tilde{M}_i} \cdot \sum_k \nu_k^{(i)} R_k \tag{11}$$

$$q_i = \frac{1}{\tilde{M}_i} \cdot \sum_k \nu_k^{(i)} Q_k \tag{12}$$

with the number ν_k of functional groups of the type k in component i. Q and R are group parameters (See Subchap. D5.1). The volume fraction φ_i' and the surface fraction θ_i are defined by

$$\varphi_i' = \frac{x_i r_i}{\sum_j^n x_j r_j} \tag{13}$$

$$\theta_i = \frac{x_i q_i}{\sum_j^n x_j q_j} \tag{14}$$

with x_i being the mass fraction of component i in a mixture of n components. In Eq. (9), z is the coordination number. According to Oishi and Prausnitz [6] z can be set to 10.

The residual contribution of component i which is composed of groups with the index k is:

$$\ln a_i^{\mathrm{R}} = \sum \nu_k \left(\ln \Gamma_k - \ln \Gamma_k^{\text{pure } i}\right) \tag{15}$$

Here Γ_k is the residual group activity.

$$\ln \Gamma_k = Q_k \left(1 - \ln\left(\sum_m \Theta_m \Psi_{mk}\right) - \sum_m \frac{\Theta_m \Psi_{km}}{\sum_n \Theta_n \Psi_{nm}}\right) \tag{16}$$

with

$$\Theta_m = \frac{Q_m W_m / \tilde{M}_m}{\sum_n Q_n W_n / \tilde{M}_n} \tag{17}$$

and

$$W_m = x_i \frac{\nu_m^{(i)} \tilde{M}_m}{\tilde{M}_i} \tag{18}$$

$\tilde{M}_m$ is the molar mass of group m and W_m the mass fraction of this group. Ψ_{mn} is a group interaction parameter (see Subchap. D5.1) that is given by:

$$\Psi_{mn} = \exp\left(-\frac{a_{mn}}{T}\right) \tag{19}$$

a_{mn} is a group interaction parameter that can be found in Subchap. D5.1. It is not to be confused with the activity a.

The term $\Gamma_k^{\text{pure } i}$ in Eq. (15) is calculated using Eqs. (16) through (18) with a mass fraction x_i of 1. Its purpose is to ensure that the activity of the pure substance is 1.

The free-volume contribution to the activity can be calculated according to Oishi and Prausnitz [6] using the following formula:

$$\ln a_i^{\mathrm{FV}} = 3c_i \cdot \ln\left(\frac{\hat{v}_i^{1/3} - 1}{\hat{v}_{\mathrm{M}}^{1/3} - 1}\right) - c_i \cdot \frac{\hat{v}_i / \hat{v}_{\mathrm{M}} - 1}{1 - 1 \Big/ \hat{v}_i^{1/3}} \tag{20}$$

Here, $\hat{v}$ is the reduced volume of component i and the mixture M, respectively. It is a measure of the ratio of the free volume and the total volume. $\hat{v}_i$ can be calculated with the density and the molar group volume using the following empirical correlation [6]:

$$\hat{v}_i = \frac{1}{15.17 \cdot 1.28 \cdot r_i \cdot \rho_i / (\mathrm{g/cm^3})} \tag{21}$$

However, this correlation fails for aqueous solutions due to the anomalous expansion behavior of water.

The reduced volume of the mixture is given by [6]:

$$\hat{v}_{\mathrm{M}} = \frac{\sum_i x_i / \rho_i / (\mathrm{g/cm^3}) - 1}{15.17 \cdot 1.28 \cdot \sum_i r_i \cdot x_i} \tag{22}$$

c_i is a parameter derived from the perturbed hard-chain theory [1, 6] specifying the total number of external degrees of freedom. For solvents like methanol or ethanol c_i equals 1.1, for larger molecules a "somewhat larger value should be used" (quote [6]). For benzene $c_{\text{benzene}} = 1.54$ is found in [1], for toluene $c_{\text{toluene}} = 1.649$ in [20].

2 Diffusion Coefficients in Polymer Solutions

Values for diffusion coefficients in polymer-solvent systems can span several orders of magnitude. Depending on solvent concentration and temperature, they range from the values for diffusion in liquids ($\sim 10^{-9}$ m^2/s) to those for solids from (10^{-13} to $\sim 10^{-19}$ m^2/s) (see Fig. 3).

Common approaches for the calculation of diffusion coefficients in liquids such as those by Einstein [21], Wilke and Chang [22] and Reid et al [23] are therefore only applicable for very dilute polymer solutions. Their predictive power fails for high polymer concentrations because of the specific properties of the macromolecules.

Over the past decades the free-volume theory has established itself as an apt model for the description of the concentration and temperature dependence of diffusion coefficients in polymer solutions. This model has been based on the extension of the free-volume theory to liquids by Cohen and Turnbull [24]. They assumed that the volume of a liquid described by a

hard-sphere model can be divided into the volume that is occupied by molecules and a volume of vacancies which are distributed throughout the material (free volume). This free volume is continuously redistributed by thermal fluctuations. A diffusion step (jump) can occur if a sufficiently large free-volume element is adjacent to a molecule. These assumptions lead to the following expression for the self-diffusion coefficient in a pure liquid.

$$D_i = A \cdot \exp\left(-\gamma \frac{V^*}{V^f}\right) \tag{23}$$

Equation (23) resembles the Arrhenius equation and describes the probability that there is a free volume V^f next to a molecule which is larger than its size V^*. The volume of the liquid at 0 K is used for estimating the size of a molecule. The overlap factor γ is introduced because two molecules may share the same free volume. γ should lie between 0.5 and 1.

Fujita [25] has adapted the free-volume theory for the description of diffusion in polymer solutions. Vrentas and Duda [26] have refined and complemented this concept. They assume that not only an entire molecule can act as a jumping unit but also parts of a polymer chain. For the self-diffusion (Based on the original model for *pure* liquids [24], this expression is called self-diffusion coefficient even if used for solvents in polymers. Strictly speaking this nomenclature is only valid for diffusion processes of one component in itself and in absence of concentration gradients.) coefficient of solvents in polymers they present the following equation:

$$D_i = D_{0i} \cdot \exp\left(-\frac{x_i \hat{V}_i^* + \xi_{iP} \cdot x_P \hat{V}_P^*}{\hat{V}^{FH}/\gamma_{iP}}\right) \tag{24}$$

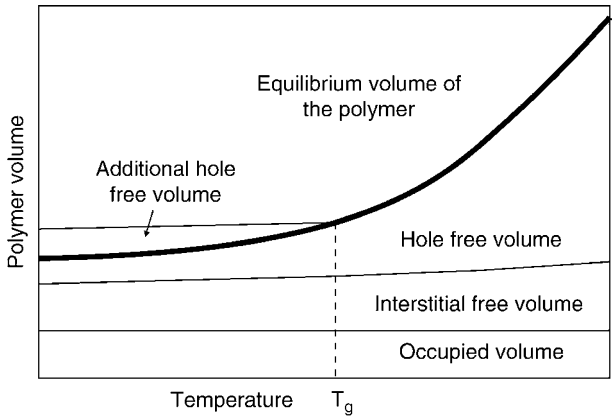
D_{0i} is a pre-exponential factor, $\hat{V}_i^*$ is the specific critical hole free volume of component i, ξ_{iP} is the ratio of the critical molar volume of solvent jumping units and the critical molar volume of polymer jumping units, and γ_{iP} is the overlap factor. $\hat{V}^{FH}$ is the specific average hole free volume of the polymer solution. It is additively composed of the hole free volume of the different components.

In polymers not the entire free volume is redistributed by thermal fluctuations. Therefore, Vrentas and Duda [26] classify the free volume in two parts: the interstitial free volume whose redistribution requires a large amount of energy and which is thus distributed evenly among the molecules of one species and the hole free volume which is continuously redistributed by thermal fluctuations and is therefore the critical variable in diffusion (see Fig. 1).

Below the glass transition temperature T_g a part of the hole free volume is "frozen" so that it is larger than the equilibrium value. Above the glass transition temperature of the polymer solution Vrentas and Duda [26] suggest the following equation for the specific average hole free volume $\hat{V}^{FH}$ in Eq. (24):

$$\begin{aligned}\hat{V}^{FH} &= x_i \hat{V}_{FH,i} + x_P \hat{V}_{FH,P} \\ &= x_i K_{I,i}\left(K_{II,i} - T_{gi} + T\right) + x_P K_{I,P}\left(K_{II,P} - T_{gP} + T\right)\end{aligned} \tag{25}$$

T_{gi} is the glass transition temperature of the component i, and T the temperature of the polymer solution in Kelvin. $K_{I,i}$ and $K_{II,i}$ are free volume parameters derived from other physical parameters describing the expansion behavior of component i.



D5.2. Fig. 1. Schematic diagram of the free-volume as a function of temperature.

According to Zielinski and Duda [27] free-volume parameters can be predicted using data of pure substances and group contribution methods. For the pre-exponential factor D_{0i} and the ratio of the critical molar volumes of the jumping units ξ_{iP} varying values are found in the literature. As they have a significant influence on the precision of the diffusion coefficients, these two parameters are usually fitted to measured data [28].

In the literature often a thermodynamic factor θ is introduced into Eq. (23) leading to the following form:

$$D = D_i \cdot \theta = D_i \cdot (1-\varphi_i)^2 \cdot (1 - 2\chi_{iP}\varphi_i) \tag{26}$$

The factor θ is calculated with the Flory–Huggins interaction parameter χ_{iP}. This derivation, however, is only valid for a constant, concentration independent value for χ_{iP}. Table 1 shows that this is not the case for the majority of polymer-solvent systems. It must be noted that if using an average constant value for χ_{iP} the thermodynamic factor θ can also assume negative values. It is recommended to calculate diffusion coefficients exclusively using Eqs. (23) and (24). This has to be considered when fitting D_{0i} and ξ_{iP} in Eq. (23) to measured data. Free-volume parameters for some common solvents and polymers can be found in the literature [27, 29].

3 Examples

3.1 Example 1: Phase Equilibrium of Polymer Solutions

The activity of methanol in polyvinyl acetate (PVAc) is to be determined at 20°C and for a solvent ratio (kg solvent/kg polymer) of $X = 0.1$.

Calculation of the activity according to Flory–Huggins:

From Chap. D3: $\rho_1 = 0.792$ g/cm^3 and from [12] $\rho_P = 1.189$ g/cm^3. Equation (2) yields:

$$\phi_p = \frac{1}{0.1\left(1.186/0.792\text{g/cm}^3\right) + 1} = 0.869$$

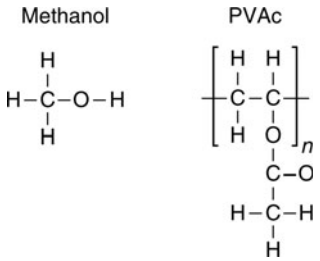
The interaction parameters in Eq. (6) for the material system methanol–PVAc are taken from Table 1.

$$\chi_{lP} = 0.41 - 0.25\phi_P + 1.21\phi_P^2 = 1.106$$

The activity is calculated using Eq. (5):

$$a_1 = 0.131 \exp\left(0.869 + 1.106 \cdot 0.869^2\right) = 0.720$$

Calculation of the activity according to UNIFAC-FV:
Step 1: Breaking down the components into different functional groups and preparing the group parameters



Component 1 is methanol:
$1 \times CH_3OH$ main group no. 6, sub-group no. 16 (not $1 \times CH_3$ and $1 \times$ OH!)
Component 2 is PVAc:
$1 \times CH_2$ – main group no. 1, sub-group no. 2
$1 \times CH$ – main group no. 1, sub-group no. 3
$1 \times COOCH_3$ – main group no. 11, sub-group no. 22
From Subchap. D5.1:

$R_2 = 0.6744 \quad Q_2 = 0.540 \quad \tilde{M}_2 = 14\,\text{g/mol}$
$R_3 = 0.4469 \quad Q_3 = 0.228 \quad \tilde{M}_3 = 13\,\text{g/mol}$
$R_{16} = 1.4311 \quad Q_{16} = 1.432 \quad \tilde{M}_{16} = 32\,\text{g/mol}$
$R_{22} = 1.9031 \quad Q_{22} = 1.728 \quad \tilde{M}_{22} = 59\,\text{g/mol}$
$a_{16} = 697.2\,\text{K} \quad a_{61} = 16.51\,\text{K}$
$a_{111} = 232.1\text{K} \quad a_{111} = 114.8\,\text{K}$
$a_{611} = -10.72\,\text{K} \quad a_{116} = 249.63\,\text{K}$

$(a_{1\,1} = a_{6\,6} = a_{11\,11} = 0)$
from [14]: $c_1 = 1.1$.

Step 2: Mass fractions

$$x_1 = \frac{0.1}{1+0.1} = 0.0909;\; x_2 = \frac{1}{1+0.1} = 0.9091$$

Step 3: Volume and surface fractions (p = degree of polymerization): Eqs. (11–14)

$$r_1 = \frac{1}{32} \cdot (1 \cdot 1.4311) = 0.04472$$

$$r_2 = \frac{1}{p \cdot 86} \cdot p \cdot (1 \cdot 0.6744 + 1 \cdot 0.4496 + 1 \cdot 1.9031) = 0.03517$$

$$q_1 = \frac{1}{32} \cdot (1 \cdot 1.432) = 0.04475$$

$$q_2 = \frac{1}{p \cdot 86} \cdot p \cdot (1 \cdot 0.540 + 1 \cdot 0.228 + 1 \cdot 1.1728) = 0.02902$$

$$\varphi_1' = \frac{0.0909 \cdot 0.04472}{0.0909 \cdot 0.04472 + 0.9091 \cdot 0.03517} = 0.1128$$

$$\varphi_2' = \frac{0.9091 \cdot 0.03517}{0.0909 \cdot 0.04472 + 0.9091 \cdot 0.03517} = 0.8872$$

$$\theta_1 = \frac{0.0909 \cdot 0.04475}{0.0909 \cdot 0.04475 + 0.9091 \cdot 0.02902} = 0.1336$$

Step 4: Combinatorial contribution to the activity Eq. (9):

$$\ln a_1^C = \ln 0.1128 + 0.8827 + \frac{10}{2} \cdot 32 \cdot 0.04475 \cdot \ln\frac{0.1336}{0.1128} - \frac{10}{2} \cdot 32 \cdot 0.04475 \cdot \left(1 - \frac{0.1128}{0.1336}\right) = -1.198$$

Step 5: Interaction parameters Eq. (19):

$$\Psi_{16} = \exp\left(-\frac{679.20\text{k}}{293.15\text{k}}\right) = 0.0927$$

$\Psi_{61} = 0.9452 \quad \Psi_{111} = 0.4531$
$\Psi_{111} = 0.6760 \quad \Psi_{611} = 1.0372$
$\Psi_{116} = 0.4268 \quad \Psi_{11} = \Psi_{66} = \Psi_{1111} = 1$

Step 6: Group mass fractions Eq. (18):

$$W_2 = 0.9091 \cdot \frac{p \cdot 14}{p \cdot 86} = 0.1480$$

$$W_3 = 0.9091 \cdot \frac{p \cdot 13}{p \cdot 86} = 0.1374$$

$$W_{16} = 0.0909 \cdot \frac{1 \cdot 32}{32} = 0.0909$$

$$W_{22} = 0.9091 \cdot \frac{p \cdot 59}{p \cdot 86} = 0.6237$$

Step 7: Group surface fractions Eq. (17):

$$\Theta_2 = \frac{0.540 \cdot (0.1480/14)}{0.540 \cdot (0.1480/14) + 0.228 \cdot (0.1374/13) + 1.432 \cdot (0.0909/32) + 1.728 \cdot (0.6237/59)} = 0.1875$$

$$\Theta_3 = \frac{0.228 \cdot (0.1374/13)}{0.540 \cdot (0.1480/14) + 0.228 \cdot (0.1374/13) + 1.432 \cdot (0.0909/32) + 1.728 \cdot (0.6237/59)} = 0.0791$$

$$\Theta_{16} = \frac{1.432 \cdot (0.0909/32)}{0.540 \cdot (0.1480/14) + 0.228 \cdot (0.1374/13) + 1.432 \cdot (0.0909/32) + 1.728 \cdot (0.6237/59)} = 0.1336$$

$$\Theta_{22} = \frac{1.728 \cdot (0.6237/59)}{0.540 \cdot (0.1480/14) + 0.228 \cdot (0.1374/13) + 1.432 \cdot (0.0909/32) + 1.728 \cdot (0.6237/59)} = 0.5998$$

Step 8: Residual group activity Eq. (16):

$$\ln \Gamma_{16} = 1.432 \cdot \left[1 - \ln(0.1875 \cdot 0.0927 + 0.0791 \cdot 0.0927 + 0.1336 \cdot 1 + 0.5998 \cdot 0.4268) - \frac{0.1875 \cdot 0.9452}{0.1875 \cdot 1 + 0.0791 \cdot 1 + 0.1336 \cdot 0.9452 + 0.5998 \cdot 0.6760} - \frac{0.0791 \cdot 0.9452}{0.1875 \cdot 1 + 0.0791 \cdot 1 + 0.1336 \cdot 0.9452 + 0.5998 \cdot 0.6760} - \frac{0.1336 \cdot 1}{0.1875 \cdot 0.0927 + 0.0791 \cdot 0.0927 + 0.1336 \cdot 1 + 0.5998 \cdot 0.4268} - \frac{0.5998 \cdot 1.0372}{0.1875 \cdot 0.4531 + 0.0791 \cdot 0.4531 + 0.1336 \cdot 1.0372 + 0.5998 \cdot 1}\right] = 0.7433$$

Pure comp. 1: $W_2 = W_3 = W_{22} = 0 \quad W_{16} = 1$;

$$\Theta_2 = \Theta_3 = \Theta_{22} = 0 \quad \Theta_{16} = 1.$$

$$\ln \Gamma_{16}^{\text{pure 1}} = 1.432 \cdot \left[1 - \ln(0 + 0 + 1 \cdot 1 + 0) - 0 - 0 - \frac{1 \cdot 1}{0 + 0 + 1 \cdot 1 + 0} - 0\right] = 0$$

Step 9: Residual contribution to the activity Eq. (15):

$$\ln a_1^R = 1 \cdot (0.7433 - 0) = 0.7433$$

Step 10: Reduced molar volumes Eqs. (21) and (22):

$$\hat{v}_1 = \frac{1}{15.17 \cdot 1.28 \cdot 0.04472 \cdot 0.792} = 1.4540$$

$$\hat{v}_M = \frac{(0.0909/0.792) + (0.9091/1.189)}{15.17 \cdot 1.28 \cdot (0.04472 \cdot 0.0909 + 0.03517 \cdot 0.9091)} = 1.2566$$

Step 11: Free volume contribution Eq. (20):

$$\ln a_1^{FV} = 3 \cdot 1.1 \cdot \ln\left(\frac{1.4540^{1/3} - 1}{1.2566^{1/3} - 1}\right) - 1.1 \cdot \frac{(1.4540/1.2566) - 1}{1 - (1/1.4540^{1/3})} = 0.2386$$

Step 12: Predicting the activity Eq. (8):

$$a_1 = \exp(-1.1980 + 0.7433 + 0.2386) = 0.806$$

(The result is approximately 10% higher than the measured values according to [11, 12]) (Fig. 2)

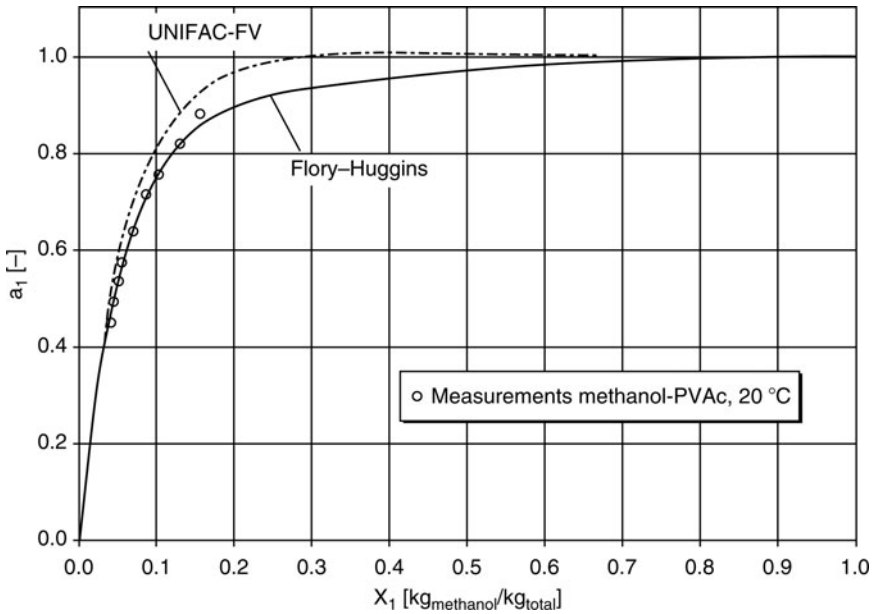
3.2 Example 2: Diffusion Coefficients in Polymer Solutions

The diffusion coefficient of methanol and toluene in PVAc at 40°C and at a solvent ratio of $X_i = 0.10$ are to be determined.

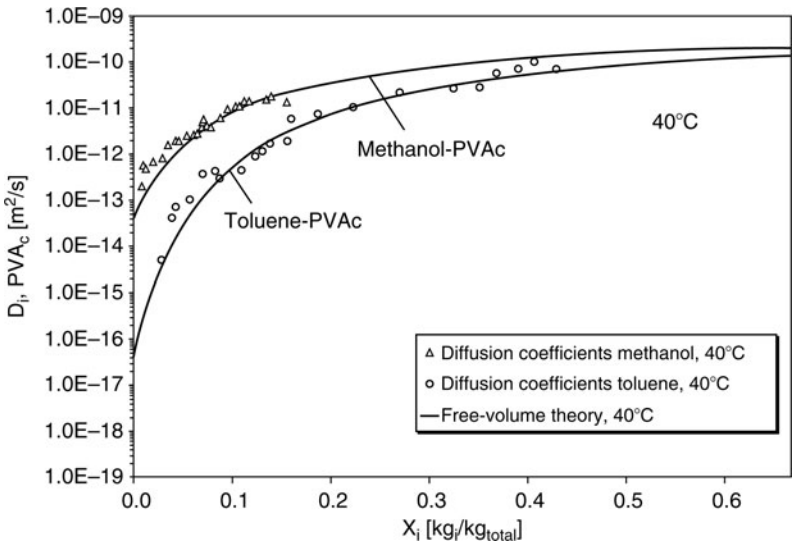
Calculating the diffusion coefficients with the free-volume theory [26]:

$$x_i = \frac{X_i}{(1 + X_i)} = \frac{0.1}{1 + 0.1} = 0.0909$$

The free-volume parameters of the systems methanol/toluene–PVAc from the literature are listed in Table 2.



D5.2. Fig. 2. Activity a_1 of methanol in PVAc as a function of the mass fraction x_1. Measured values from [11] at 20°C are compared to the calculations with the Flory–Huggins and the Universal Functional Activity Coefficient (UNIFAC-FV) models of the example.



D5.2. Fig. 3. Diffusion coefficients of methanol and toluene in PVAc at 40°C as a function of the solvent ratio. The diagram shows measured values from [28] and the calculations using the free-volume theory of the example. The diffusion coefficient of the larger molecule toluene exhibits a stronger dependence on the composition than that of the smaller molecule methanol.

D5.2. Table 2. Free-volume parameters for methanol, toluene and polyvinyl acetate (PVAc) from [11, 27, 29]

FV-parameter(source)	PVAc	
	Methanol	Toluol
$\hat{V}_1^*$ (cm^3/g)	0.961 [29]	0.917 [27]
$\hat{V}_p^*$(cm^3/g)	0.728 [27]	
$K_{1,i}/\gamma_{iP}$ (cm^3/g K)	$1.17{\cdot}10^{-3}$ [29]	$1.45{\cdot}10^{-3}$ [29]
$K_{1,P}/\gamma_{iP}$ (cm^3/g K)	$0.433{\cdot}10^{-3}$ [27]	
$K_{II,i}$-T_{gi} (K)	−48.4 [29]	−86.32 [27]
$K_{II,P}$-T_{gP} (K)	−258.2 [27]	
D_{0i} (m^2/s)	$6.53{\cdot}10^{-9}$ [11]	$3.9{\cdot}10^{-9}$ [11]
ξ_{iP} (–)	0.39 [11]	0.60 [11]

With Eqs. (24) and (25) it can be calculated:
Methanol–PVAc:

$$\left(\frac{\hat{V}^{FH}}{\gamma_{iP}}\right) = 0.0909 \cdot 1.17 \cdot 10^{-3}(-48.4 + 313.15) + 0.9091 \cdot 0.433 \cdot 10^{-3}(-258.2 + 313.15)\,(cm^3/g) = 0.0498\ (cm^3/g)$$

$$D := 6.53 \cdot 10^{-9} \cdot \exp\left(-\frac{0.0909 \cdot 0.961 + 0.39 \cdot 0.9091 \cdot 0.728}{0.0498}\right)$$

$$(m^2/s) = 6.33 \cdot 10^{-12}\,(m^2/s)$$

Toluol–PVAc:

$$\left(\frac{\hat{V}^{FH}}{\gamma_{iP}}\right) = 0.0909 \cdot 1.45 \cdot 10^{-3}(-86.32 + 313.15) + 0.9091 \cdot 0.433 \cdot 10^{-3}(-258.2 + 313.15)(cm^3/g) = 0.0515\ (cm^3/g)$$

$$D = 3.9 \cdot 10^{-9} \exp\left(-\frac{0.0909 \cdot 0.917 + 0.6 \cdot 0.9091 \cdot 0.728}{0.0515}\right)$$

$$(m^2/s) = 3.48 \cdot 10^{-13}\,(m^2/s)$$

D5.3 Vapor Pressures of Aqueous Salt Solutions

Hartwig Wolf
Alstom Switzerland Ltd., Baden, Switzerland

1 Introduction

Solving a nonvolatile salt (2) in water (1) results in a reduction of the vapor pressure p_1 of the solution compared to the saturation vapor pressure p_1^* of pure water. The lowering of the vapor pressure is considered as colligative property such as boiling point elevation, freezing point depression, and osmotic pressure, i.e., a property that depends only on the number of solved molecules. These phenomena are caused by the presence of the solved salt, which lowers the chemical potential of the solution compared to the solvent. If the interactions between the molecules of solute and solvent are the same as those between the molecules of each substance by itself, the solution is called an ideal solution and the lowering of the vapor pressure Δp_1 represents a pure entropy effect and is proportional to the mole fraction $\tilde{x}_2$ of the solute:

$$\Delta p_1 = \tilde{x}_2 p_1^*. \tag{1}$$

In case of salts, the calculation of $\tilde{x}_2$ has to take into account the amount of substance n_2 of the ions that are dissolved:

$$n_2 = n_{2,0}(1 + \alpha(i - 1)), \tag{2}$$

which is depended on the amount of substance of the salt $n_{2,0}$ in the solution, the degree of dissociation α, and the number of ions i of the salt molecule.

When interactions between like and unlike molecules are different, the solution shows a nonideal behavior. The lowering of the vapor pressure can be calculated using the extended Raoult's law:

$$\Delta p_1 = [1 - (1 - \tilde{x}_2)\gamma_1]p_1^*, \tag{3}$$

in which the activity coefficient γ_1 takes into account the deviation from ideal behavior. Both the degree of dissociation α and the activity coefficient γ_1 depend strongly on the mole fraction $\tilde{x}_2$ of the solute; thus, a prediction of the lowering of the vapor pressure relies strongly on experimental data.

2 Data and Approximations for Vapor Pressure Estimation

Boiling temperatures of different saturated salt solutions are shown in Tables 1a and 1b as a function of vapor pressure and salt precipitation. A further column lists the relative vapor pressure $\varphi = p_1/p_1^*\{T.\}$ above the salt solutions at a temperature of $T = 25°C$. In addition, parameters A and B for a basic approximation

$$p_1/[Pa] = \mathrm{A}\, 10^{10} \mathrm{e}^{-\frac{10^3\ \mathrm{B}}{273.15\ +\ T/[°\mathrm{C}]}}, \tag{4}$$

are given. The relative error of the approximation is less than 5% for all data used. The applicable temperature range for the exponential function is listed in the column aside.

Tables 2a–2d comprise the dependency of the temperatures of different unsaturated solutions on the vapor pressure and the salt concentration. Otherwise, the tables correspond to Tables 1a and 1b with respect to their structure.

The vapor pressures above different salt solutions at temperatures 25 and 100°C are indicated in Tables 3a–3c as a function of the salt concentration m. Likewise, the parameters of an elementary function, i.e., of a polynomial of third order, fit:

$$p_1 = p_1^* + A\, m + B\, m^2 + C\, m^3, \tag{5}$$

The underlying data are reflected with a relative error less than 5%, mostly less than 2%.

Finally, Table 4 covers values of vapor pressures for saturated salt solutions at high temperatures as a function of temperature. Table 5 contains data for temperatures of saturated solutions of salt mixtures under variation of the vapor pressure.

All the tables are based on the data from the literature listed in the chapter bibliography. The parameters of the approximations have been set using the least-squares method. Substances for which an insufficient number of data have been found and measured data, which have been recognized as not reliable were not considered within this article.

3 Enclosure A: Saturated Salt Solutions

D5.3. Table 1a. Vapor pressure above saturated salt solutions; given are the temperatures of the salt solution in °C as function of the vapor pressure p_1

Solute	Formula of precipitation	Vapor Pressure p1 (Pa)										ϕ (25°C)	$p_1/[Pa] = A\,10^{10} e^{-\frac{10^3 B}{273.15+T/[°C]}}$		Temperature range (°C)

D6.1 Thermodynamic Properties of Pure Metals and Metal Alloys

Matthias Neubronner[1] · *Thomas Bodmer*[2]
[1]EON Energie, Munich, Germany
[2]Marl, Germany

Tables 1–7 indicate numeric values for various physical properties of materials often used in process equipment and plant engineering. The dependence on the temperature of these numeric values is indicated. Table 1 shows these properties for pure metals. Table 2 provides an overview of alloys, which can be categorized into different groups by their properties and their alloying constituents. Here, the group of steels is the most significant, which have, therefore, been subdivided according to their respective material properties. As well as two representative gray cast iron materials, some nonferrous materials have been listed. Out of these, the nickel alloys due to their acid resistance and the aluminum alloys are frequently employed in process equipment and plant engineering.

All materials are to be identified by their material numbers and – standard designations (DIN or EN) according to [1] for steels and according to [2] for nonferrous materials. Table 2 illustrates the chemical composition for all materials listed. Where no range is stated, the values shown are the respective maximum values of a constituent. The density at 20°C is also shown. The figures for steels have been taken from the sources [1, 3]. The chemical compositions of the nonferrous materials have been taken from the provided standards for each material, as stated in source [4]. The material numbers, designations, and chemical compositions for most of the materials shown here correspond to the standards as valid today. A small number of additional materials without currently valid standards have been listed, because they can still be found in plant operation. These materials have been labeled clearly in Table 2. The material properties shown in Tables 3–7 have, in some cases, been determined for older materials based on currently valid standards. The current materials listed in Table 2 generally only differ from their predecessors by terminology and a very minor variation in their chemical composition. Therefore, the thermodynamic properties in Tables 3–7 are also valid for these materials.

For these materials, Tables 3–7 contain the thermal conductivity, the specific heat capacity, the average thermal expansion coefficient between 20°C and the temperature, the dynamic modulus of elasticity and the Poisson's ratio for various temperatures.

The thermal conductivity significantly depends on the percentage by mass of the various alloying constituents. Furthermore, constituents, which only occur in trace quantities, can substantially influence the thermal conductivity. In general, the thermal conductivity is different for all materials. It has, therefore, been tabulated separately for each material.

The thermodynamic properties for heat capacity, thermal expansion, the modulus of elasticity, and the Poisson's ratio, show a lower dependence on the alloying constituents. In particular, for many steels for which the chemical composition does not differ greatly, these are very similar. Therefore, the figures for various steels have been combined in Tables 4–7. The dynamic Poisson's ratio, subject to temperature, can, by acceptable approximation, be described with the same numerical values for all steels. The indicated serial numbers in Tables 3–7 refer to Table 2.

The measuring errors for steels are ±7% for the thermal conductivity, ±3% for the specific heat and the Poisson's ratio, ±2% for the thermal expansion and approximately ±1% for the modulus of elasticity. Those thermodynamic properties put in brackets are uncertain values. They have either been extrapolated from measured values at other temperatures, or been determined for a similar material. The thermodynamic properties for steels have been taken from the literature [3–6]. The thermodynamic properties for the other materials can be found in [7–9]. Data for the dynamic Poisson's ratio are not available for all the materials listed here.

Further, thermodynamic properties can easily be estimated based on the values stated in the tables:

For any temperature in centigrade, the density can be determined by approximation from the density (20°C) according to Table 2 and the average thermal expansion coefficient between 20°C and, as in Table 5, according to the following correlation:

$$\rho(\vartheta) = \frac{\rho(20°\mathrm{C})}{[1+\tilde{\beta}(20°\mathrm{C},\vartheta)(\vartheta - 20°\mathrm{C})]^2}.$$

For the thermal diffusivity, the following correlation applies at any temperature:

$$a(\vartheta) = \frac{\lambda(\vartheta)}{\rho(\vartheta)c(\vartheta)}.$$

The density deviates only slightly from the density at 20°C. The thermal diffusivity can, therefore, be determined directly from the figures in the table by acceptable approximation:

$$a(\vartheta) \approx \frac{\lambda(\vartheta)}{\rho(20°\mathrm{C})c(\vartheta)}.$$

The heat penetration capacity has been defined as follows:

$$b(\vartheta) = \sqrt{\lambda(\vartheta)\rho(\vartheta)c(\vartheta)}.$$

Also, the heat penetration capacity can be approximated based on the density at 20°C.

D6.2 Polymers

Christof Hübner · Paul Bernd Kempa
Fraunhofer-Institut für Chemische Technologie (ICT), Pfinztal, Germany

The tables in this section contain a selection of physical properties for different commonly used polymers and composites, some of them as a function of temperature.

Table 1 gives a survey over some polymers and their basic characteristics. The nomenclature follows DIN ISO 1629 [1] and DIN 7728 [2]. The polymers are divided into three groups: elastomers, thermoplastics, and thermosets depending on their chemical structure and mechanical properties (cf. DIN 7724 [3]).

Elastomers consist of slightly cross-linked macromolecules. They exhibit a rubber elastic behavior in their temperature range of use.

Thermoplastics and thermosets behave mainly elastic in the range of low deformations. Once thermoplastics, which consist of non-interlinked macromolecules, are heated above their application temperature, they exhibit viscoelastic flow behavior. At higher temperatures, they are decomposed. Cooling down again reverts this process and brings the thermoplastic material back into the state of elastic behavior.

Thermosets, which are heated over their temperature of application, show no flow behavior, because they consist of closely cross-linked macromolecules. At higher temperatures they are decomposed as well. Table 1 shows further characteristics such as morphology and the production process.

1 Properties

Table 2 shows the properties of the pure base polymers and of the reinforced polymers. In most applications, the base polymers are combined with fillers and reinforcements in order to tailor their mechanical, thermal, electrical, or magnetic properties. The fillers or further components can be softeners, talcum, soot, graphite or as reinforcements glass and carbon fibers or even natural fibers. The physical properties of the composites can be roughly estimated from the properties of their constituents and the percentage of the single constituents of the material with the help of mixing rules, which hold best in the range of small filler contents. For the exact determination of electrical, thermal, or mechanical properties, more detailed considerations of the structure of the fillers or reinforcements are necessary. In the case of reinforcing fibers their length and diameter as well as their spatial distribution (random distribution, fabrics, alignments...) must be considered. Especially for fiber reinforced materials, the processing plays an important role, because it strongly influences the orientation of the fibers in the matrix and therefore it normally produces highly anisotropic material properties.

In Table 1 some of the listed polymer types (e.g., polyamide, polyester, polycarbonate, polyurethane, epoxy resin) represent a complete group of polymers. For polyamides, the values are explicitly listed for PA6 and PA66 where data is available. The properties of the other polyamide types can be expected to be in a similar range. For polyesters, polycarbonates, polyurethanes, and epoxies, the grade is given as far as known from literature. In all the cases, the listed values are just recommended values, because the values within the groups can vary.

In Table 2 the maximum application temperatures for short-term use and for long-term use are listed [4, 13, 14]. Further, the density ρ, the modulus of elasticity E (Young's modulus) and Poisson's ratio ν, and the quotient of the lateral contraction and the elongation of a sample in a tensile test both expressed in terms of engineering strains, are given for a temperature of 20°C, where available. These values were taken from the literature [5–9].

Tables 3–5 show values for the thermal conductivity λ, the specific heat capacity c, and the linear differential coefficient of thermal expansion β for different temperatures θ. The values were taken from several works [6–8, 10–14]. For some polymers, no data for the differential coefficient of thermal expansion β is available, but only for the average linear coefficient of expansion $\overline{\beta}$ between the considered temperature and 20°C. Between these values the following relation holds

$$\overline{\beta}\,(\theta, 20^\circ\mathrm{C}) = \frac{1}{\theta - 20^\circ\mathrm{C}} \int_{20^\circ\mathrm{C}}^{\theta} \beta(\theta)\,\mathrm{d}\theta,$$

where $\beta(\theta) = \mathrm{d}L/L\,\mathrm{d}\theta$.

For many of the cited values in Tables 2–5, data sheets of different manufacturers and distributors of polymeric materials as well as different databases were used, which are not listed in the bibliography, because they were arbitrarily picked in order to achieve a representative survey but cannot be regarded as a complete research of all available sources. Many of the values from Tables 2–5 originate from the last volume 10 of the VDI Wärmeatlas [15]. They were verified and adopted where possible.

D6.2. Table 1. Survey of the basic characteristics of some polymers

Name of the polymer	DIN	Type	Structure	Synthesis

D6.3 Thermal Conductivity of Packed Beds

Evangelos Tsotsas
Otto-von-Guericke-Universität Magdeburg, Magdeburg, Germany

1 Introduction

The effective thermal conductivity of stagnant multiphase media depends on the thermal conductivities and volume fractions of the constituent phases. Consequently, the thermal conductivity of packed beds is a function of the thermal conductivity λ_p of the particles, the thermal conductivity λ_f of the fluid that fills the voids between particles, and the porosity ψ of the bed:

$$\lambda_{bed} = \lambda_{bed}(\lambda_p, \lambda_f, \psi) \tag{1a}$$

The quantities λ_p, λ_f, and ψ are called primary parameters. Apart from these, several secondary parameters may also have an influence, due to processes such as:

- Heat transfer by radiation: The intensity of heat transfer by radiation depends on temperature T, the optical properties of the fluid and the surface of particles, and the size of voids, which correlates with the particle diameter d.
- Pressure dependence: According to kinetic gas theory, the thermal conductivity of unconfined, dilute gas is independent of pressure. However, the thermal conductivity of gas surrounded by solid surfaces – as in a packed bed – decreases with decreasing pressure. The same happens with the thermal conductivity of the entire bed (Smoluchowski effect). Particle diameter d and the mean free path of the gas molecules – which depends on pressure, temperature, and thermodynamic properties – are important for the extent of this decrease.
- Heat transfer through flattened interparticle contacts: Particles can flatten around contact points due to external forces or due to their own weight of the packed bed. Deformation and heat transfer over the solid bridge depend, among others, on the mechanical properties of the solid and the morphology of particle surface.

Adding particle shape and particle size distribution to this list of secondary influence parameters, the functional dependence

$$\lambda_{bed} = \lambda_{bed}(\lambda_p, \lambda_f, \psi;\ p,\ T,\ d,\ \text{particle shape},\ \text{particle size distribution},\ \text{mechanical and optical properties of particles},\ \text{thermodynamic and optical properties of fluid},\ \text{and flattening of contacts}) \tag{1b}$$

is obtained.

2 Requirements to Models

It is the task of models to specify the functional relationships described in a general way by Eq. (1a) or (1b). A successful model should take all primary and as many secondary influence parameters as possible into account, possess some flexibility by appropriate fitting parameters, enable easy calculations, and reliably predict measured thermal conductivities. Furthermore, it should fulfill physically reasonable limiting cases. Such limiting cases can be expressed without the consideration of secondary influence parameters, that means on Eq. (1a), as follows:

$$\begin{aligned}
&1:\ \psi = 0 &&\curvearrowright\ \lambda_{bed} = \lambda_p,\\
&2:\ \psi = 1 &&\curvearrowright\ \lambda_{bed} = \lambda_f,\\
&3:\ \lambda_p = \lambda_f &&\curvearrowright\ \lambda_{bed} = \lambda_p = \lambda_f,\\
&4:\ \lambda_f \to \infty &&\curvearrowright\ \lambda_{bed} \to \infty,\\
&5:\ \lambda_p \to \infty &&\curvearrowright\ \lambda_{bed} \to \infty,\\
&6:\ \lambda_f \to 0 &&\curvearrowright\ \lambda_{bed} \to 0,\\
&7:\ \lambda_p \to 0 &&\curvearrowright\ \lambda_{bed}/\lambda_f = \delta_{bed}/\delta.
\end{aligned}$$

Most of these relationships are evident and do not require further explanation. The limiting case 5 presupposes point or area contacts between particles. Limiting case 6 is valid for particles that do not touch each other, or have point contacts. Finally, limiting case 7 means that the reduced thermal conductivity of a bed of nonconducting particles should be equal to the effective diffusion coefficient δ_{bed} of this bed divided by the molecular diffusivity δ. The ratio δ_{bed}/δ is relatively easy to measure, so that a basis for comparison and an assessment of model behavior are provided by the limiting case $\lambda_p \to 0$ (see Sect. 4.2).

3 Types of Models

Prediction of the thermal conductivity of packed beds is a topic of intensive research in physics and engineering since more than one century. The numerous models that have emerged can be classified into three categories according to a proposal by Tsotsas and Martin [1], as illustrated in Fig. 1.

Type I. In type I models, the Laplace equation for heat conduction is solved analytically or numerically to compute the temperature field in and around the particles. The oldest and simplest analytical solution of this kind has been provided by Maxwell in 1873. It can be expressed in the form

$$k_{bed} = (1 + 2\phi)/(1 - \phi), \tag{2a}$$

with

$$\phi = (1 - \psi)(k_p - 1)/(k_p + 2) \tag{2b}$$

and

$$k_{bed} = \lambda_{bed}/\lambda_f, k_p = \lambda_p/\lambda_f. \tag{3a, b}$$

Maxwell's solution is based on the assumption that individual particles do not exert any thermal influence on each other. Therefore, it is well suited for application to dilute suspensions und emulsions. In the case of packed beds, Eqs. (2a) and (2b) give reliable results only in the region of small values of the ratio λ_p/λ_f ($\lambda_p/\lambda_f < 20$).

Subsequent authors have tried to relax the assumption of infinite dilution. Analytical solutions can be derived only for regular packing structures and are mathematically demanding. Therefore, numerical computations have also been conducted as soon as digital computers became available. Wakao and Kato [2] calculated in a pioneering work the thermal conductivity of simple cubical and orthorhombic arrangements of spheres of equal size. Such regular packed beds have porosities of $\psi = 0.476$ and $\psi = 0.395$, respectively. Nowadays, fields of temperature can be calculated numerically even for relatively large, random assemblies of particles [3]. However, such calculations are not free of limitations (see Sect. 5) and hardly appropriate for everyday use.

Type II. Models of the second type (Ohmic analogs) introduce thermal resistances for conduction in the solid and the fluid phases; such resistances are combined in order to specify the functional relationship of Eq. (1a). The simplest possible combinations are the series arrangement of Fig. 2a with

$$k_I = \frac{\lambda_I}{\lambda_f} = \left(\psi + \frac{1 - \psi}{k_p}\right)^{-1} \tag{4a}$$

and the parallel arrangement of Fig. 2b with

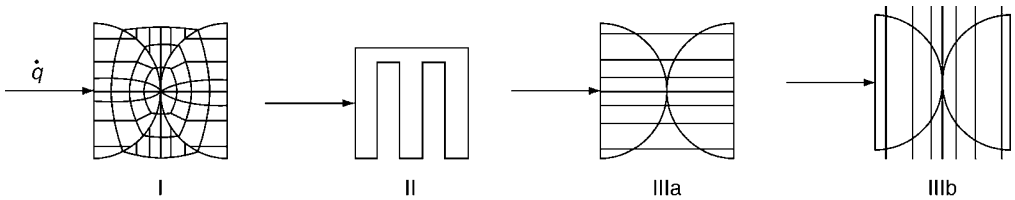
$$k_{II} = \lambda_{II}/\lambda_f = \psi + (1 - \psi)k_p. \tag{4b}$$

For a given set of primary parameters λ_p, λ_f, and ψ the series combination has the lowest and the parallel combination has the highest possible conductivity (lower-bound and upper-bound solutions according to Wiener, 1904).

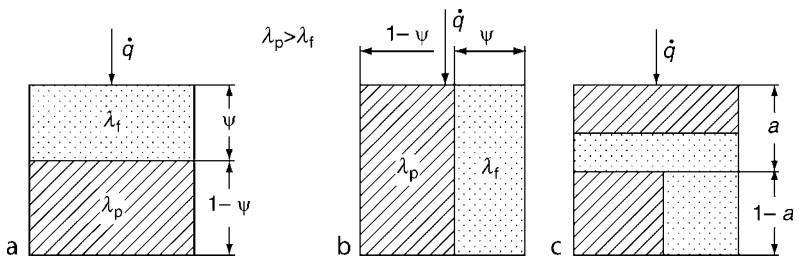
The usually broad region between upper bound and lower bound contains thermal conductivities of, among others, consolidated porous media and loose particle beds. To distinguish between them, at least one additional structural parameter is necessary. The relative proportion a of series arrangement plays this role in the Ohmic combination according to Fig. 2c, which has been proposed by Krischer [4]. The thermal conductivity of this combination is obtained to

$$k_{bed} = \left(\frac{a}{k_I} + \frac{1 - a}{k_{II}}\right)^{-1}. \tag{4c}$$

For packed beds, a value of $a = 0.20$ can be recommended [4]. The resistance scheme of Fig. 2c enables simple and quick estimations of packed-bed thermal conductivity. However, it is



D6.3. Fig. 1. Types of models to predict the thermal conductivity of packed beds: Type I. Exact analytical or numerical computation of the temperature field. Type II. Combination of resistances. Type IIIa. Unit cell, parallel heat flux lines; Type IIIb. Unit cell, parallel isotherms.



D6.3. Fig. 2. Plate model according to Krischer [4] for the thermal conductivity of dispersed fluid–solid systems: (**a**) Arrangement with maximal resistance (series combination); (**b**) Arrangement with minimal resistance (parallel combination); (**c**) Combination of (**a**) and (**b**).

not adequate for precise calculations, especially when secondary parameters have a relatively large influence. The same is true for most models of type II.

Type III. Models of this type calculate the thermal conductivity of a unit cell, which is then set equal to the thermal conductivity of the packed bed. For the sake of easy calculation, either parallel lines of heat flux (type IIIa) or parallel isotherms (type IIIb) are assumed (Fig. 1). Both assumptions are fulfilled exactly only at the trivial limit of $\lambda_p = \lambda_f$. Models of the third type are popular compromises between the realistic, but computationally expensive models of the first and the simple, but coarse models of the second type.

Tsotsas and Martin [1] evaluated many different models for the thermal conductivity of packed beds in terms of the requirements and criteria from Sect. 2, coming to the conclusion that type III models can be recommended for practical use. This is especially true for one model from this family that has been developed by Zehner, Bauer, and Schlünder. This model will be presented in some detail in Sect. 4.

4 The Model of Zehner/Bauer/Schlünder

4.1 General

The unit cell of the Zehner/Bauer/Schlünder model is depicted in Fig. 3. It consists of a cylindrical core, where two half particles are placed opposite to each other, and of an annular fluid-filled section around the core. The main idea of the model is to repair the incorrect assumption of parallel heat flux lines by using fictitious, nonspherical particles to simulate the thermal behavior of spherical ones. The contor of such "model particles" is defined by means of the deformation parameter B. In Sect. 4.2, a model version that considers only the primary parameters λ_p, λ_f, and ψ will be presented. This basis version will be extended in Sect. 4.3 in order to capture the influence of secondary parameters.

4.2 Influence of Primary Parameters

According to Fig. 3, the reduced thermal conductivity of the bed can be calculated to

$$k_{bed} = 1 - \sqrt{1-\psi} + \sqrt{1-\psi}\ \ k_c, \tag{5a}$$

with

$$k_c = \frac{2}{N}\left(\frac{B}{N^2}\frac{k_p - 1}{k_p}\ln\frac{k_p}{B} - \frac{B+1}{2} - \frac{B-1}{N}\right), \tag{5b}$$

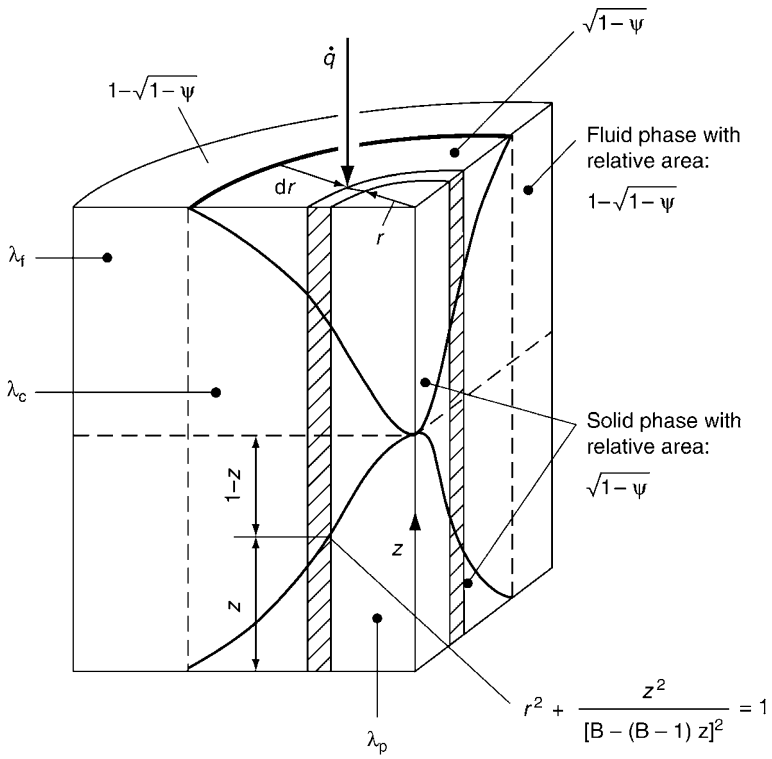
and

$$N = 1 - \left(B/k_p\right), k_c = \lambda_c/\lambda_f. \tag{5c, d}$$

Here, λ_c is the thermal conductivity of the core of the unit cell [5]. The deformation parameter B is derived for spherical particles by putting the porosity of the unit cell equal to the porosity of the packed bed. This leads approximately to

$$B = 1.25\left(\frac{1-\psi}{\psi}\right)^{10/9}. \tag{5e}$$

Equations (5a)–(5e) fulfill the limiting cases 1–6 from Sect. 2. Due to the mentioned separation of the unit cell in a core and a margin zone (Fig. 3; Eq. (5a))



D6.3. Fig. 3. Unit cell of the model of Zehner/Bauer/Schlünder.

$$\lambda_p = 0, \text{ then } \lambda_{bed}/\lambda_f = \delta_{bed}/\delta = 1 - \sqrt{1-\psi} \qquad (6)$$

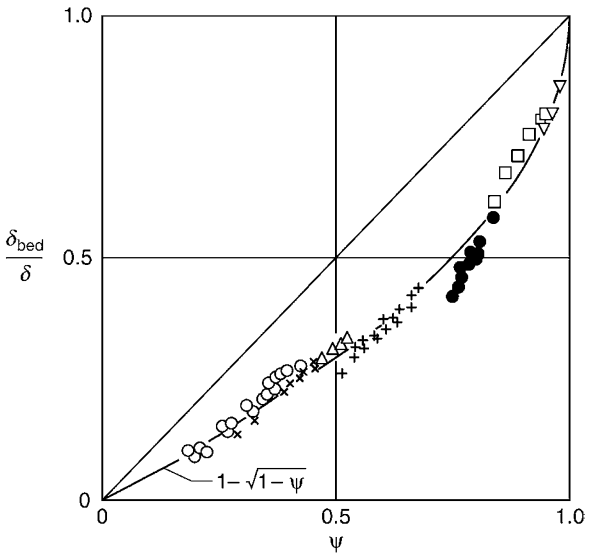
is obtained in limiting case 7.

Equation (6) can well describe diffusion coefficients measured by Currie [6], as in Fig. 4. To cover a broad range of porosities, Currie investigated not only monodispersed packed beds of spheres, but also polydispersed beds of spherical particles, beds of irregular particles, loose beds, and highly porous materials.

Taking into consideration only spheres of equal size reveals a slight underprediction of measured data by Eq. (6). This is illustrated in Fig. 5, which is based on a collection of effective diffusion coefficients for random, regular, and sintered beds from [1]. A still larger deviation between Eq. (6) and experimental results is observed for dilute solid–liquid suspensions and liquid–liquid emulsions. Respective data points are plotted in Fig. 6 [7, 8]. They stem from measurements of electrical conductivity, which does not make a difference, because diffusion and electrical conduction are described mathematically by the same equation. Excellent agreement is obtained with Maxwell in Fig. 6 (broken line according to Eq. (2) with $k_p = 0$).

The foregoing discussion shows that the ratio δ_{bed}/δ does not depend uniquely on porosity ψ (volume fraction of the continuous phase), but also on the structure of binary systems. The respective structural parameter, which has been denoted by a in the treatment of the model by Krischer, cannot, unfortunately, be predicted in an easy way. However, Eq. (6) does provide a good approximation for practical use if only packed beds or binary systems with a similar structure are considered.

The dependence of reduced packed bed thermal conductivity k_{bed} from the ratio $k_p = \lambda_p/\lambda_f$ at $\psi = 0.40$ is depicted in Fig. 7.

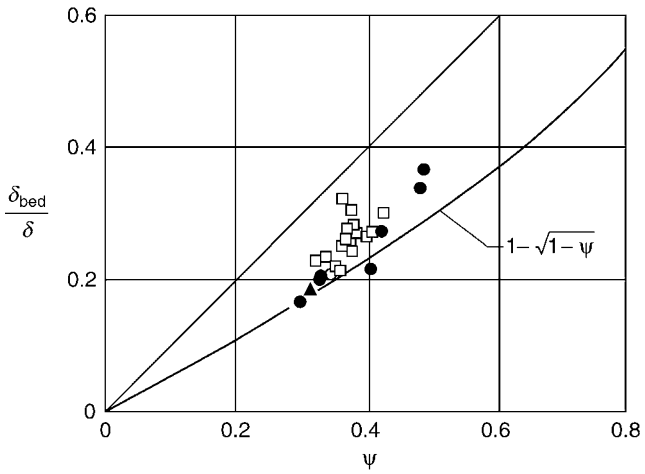


D6.3. Fig. 4. Reduced effective diffusion coefficients δ_{bed}/δ in dependence of porosity ψ according to measurements by Currie [6] for:
○ Glas spheres and sand (monodispersed beds and mixtures);
× Carborundum (monodispersed beds and mixtures);
Δ Salt (particles of irregular shape); + Soil crumbs; ● Kaolin; □ Celite;
▽ Steel wool. The solid curve corresponds to Eq. (6).

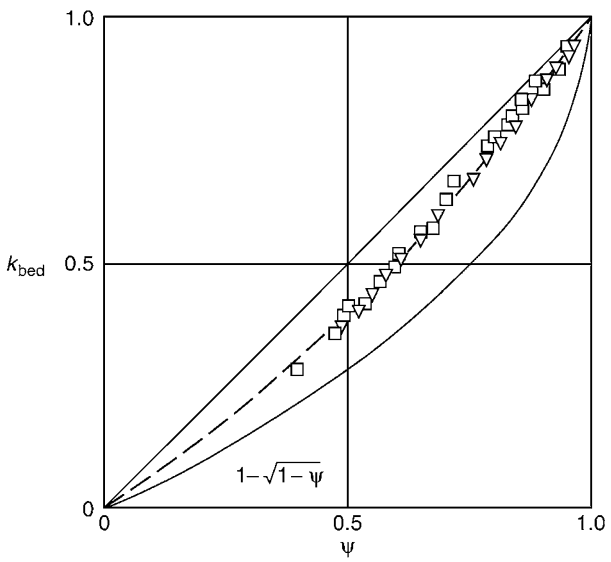
There is an excellent agreement between Eq. (5) and the previously mentioned numerical results for a regular, orthorhombic packing of spheres from Wakao and Kato [2]. On contrary, the models of Krischer and Maxwell agree with the numerical calculations only within certain ranges of k_p.

4.3 Influence of Secondary Parameters

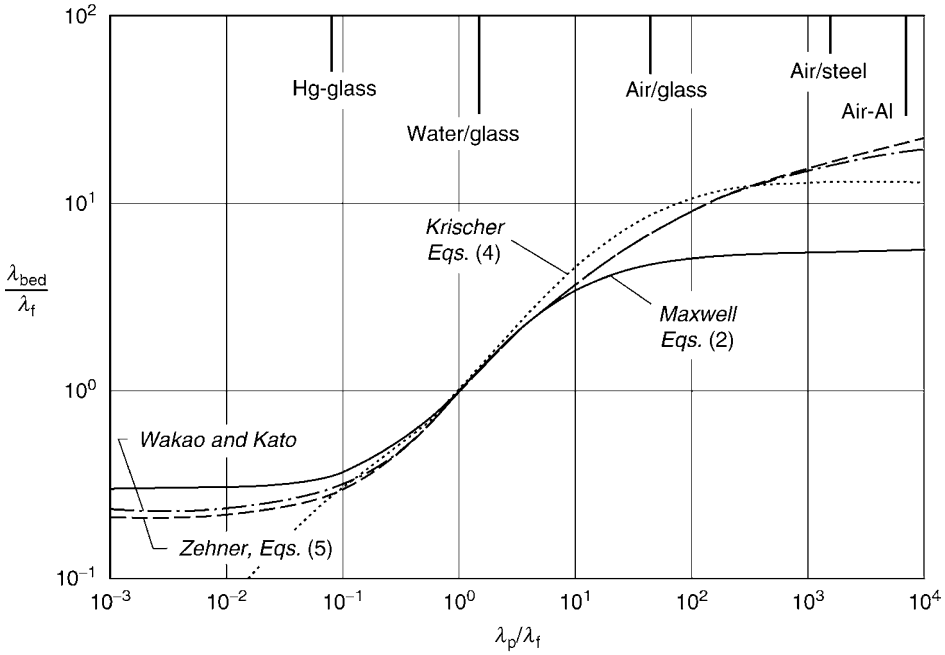
Zehner/Schlünder [9] and Bauer/Schlünder [10] have extended the model by taking into consideration the secondary parameters listed in Sect. 1. The resulting equations are:



D6.3. Fig. 5. Reduced diffusion coefficients δ_{bed}/δ for assemblies of equally sized spheres against porosity ψ. Measured data of various authors [1] for: □ random beds; ● regular beds; ▲ sintered beds. The solid curve corresponds to Eq. (6).



D6.3. Fig. 6. Reduced electrical conductivity k_{bed} of binary systems with nonconducting dispersed phase as a function of porosity ψ: □ solid–liquid suspensions (Turner [7]); ▽ liquid–liquid emulsions (Meredith and Tobias [8]). The solid curve corresponds to Eq. (6), the broken curve corresponds to the model of Maxwell (Eq. (2) with $k_p = 0$).



D6.3. Fig. 7. Influence of particle-to-fluid conductivity ratio $k_p = \lambda_p/\lambda_f$ on the reduced thermal conductivity of packed beds. Solid line: Maxwell, Eq. (2) with $\psi = 0.40$; Dashed line: Krischer, Eq. (4) with $a = 0.20$ and $\psi = 0.40$; Broken line: Zehner and Schlünder, Eq. (5) with $\psi = 0.40$; Broken-dashed line: numerical calculation by Wakao and Kato for orthorhombic packings of spheres ($\psi = 0.395$).

$$k_{bed} = \left(1 - \sqrt{1-\psi}\right)\psi\left[\left(\psi - 1 + k_G^{-1}\right)^{-1} + k_{rad}\right] + \sqrt{1-\psi}\left[\varphi k_p + (1-\varphi)k_c\right] \tag{7a}$$

with

$$k_c = \frac{2}{N}\left\{\frac{B(k_p + k_{rad} - 1)}{N^2 k_G k_p}\ln\frac{k_p + k_{rad}}{B\left[k_G + (1-k_G)(k_p + k_{rad})\right]} + \frac{B+1}{2B}\left[\frac{k_{rad}}{k_G} - B\left(1 + \frac{1-k_G}{k_G}k_{rad}\right)\right] - \frac{B-1}{Nk_G}\right\} \tag{7b}$$

$$N = \frac{1}{k_G}\left(1 + \frac{k_{rad} - Bk_G}{k_p}\right) - B\left(\frac{1}{k_G} - 1\right)\left(1 + \frac{k_{rad}}{k_p}\right) \tag{7c}$$

$$B = C_f[(1-\psi)/\psi]^{10/9} f(\zeta), \tag{7d}$$

$$k_{rad} = \frac{\lambda_{rad}}{\lambda_f} = \frac{4\sigma}{(2/\varepsilon) - 1}T^3\frac{d}{\lambda_f}, \tag{7e}$$

and

$$k_G = \lambda_G/\lambda_f = [1 + (l/d)]^{-1}. \tag{7f}$$

The influence of thermal radiation is taken into account by means of the quantity k_{rad}, Eq. (7e), where ε is the emissivity of particle surfaces, σ is the radiation coefficient of the black body ($\sigma = 5.67 \times 10^{-8}\,W/m^{-2}\,K^{-4}$), and T is the temperature in Kelvin. Pressure dependence (Smoluchowski effect) is expressed by the quotient k_G in Eq. (7f). The modified mean free path l of gas molecules can be calculated from Eq. (46) in ❯ Chap. M6. If the continuous phase is not a gas, one may set $k_G = 1$. Possible flattening around particle contacts is considered by the flattening coefficient φ in Eq. (7a). Although some proposals of modeling and computation exist in the literature (see Sect. 5), the coefficient φ in most cases will be determined empirically. Another model parameter that has to be gained by fitting to experimental data is C_f. The shape factor C_f describes in Eq. (7d) the influence of particle shape on packed-bed thermal conductivity. For random or regular orthorhombic beds made of equally large spheres the shape factor has a value of $C_f = 1.25$ (compare with Eq. (5e)). For the particle diameter d one should always use the diameter of a sphere of equal volume. Herein, intraparticle voids should be neglected.

Apart from the shape factor C_f, a distribution function $f(\zeta)$ is also foreseen in the calculation of the deformation parameter B by Eq. (7d). The idea of this function is to capture the influence of different particle sizes in the bed by correlating f with a parameter expressing the broadness of particle size distribution. The distribution parameter

$$\zeta = \left[\frac{\sum Q_i/d_i^2}{(\sum Q_i/d_i)^2} - 1\right]^{0.5} \tag{8}$$

can be used for this purpose. Here, Q_i is the volume fraction of particles with diameter d_i (sphere of equal volume) in the mixture. However, numerous experimental results with binary and polydispersed packed beds show [11–16] that thermal conductivities can be calculated quite accurately by setting the distribution function simply equal to unity:

$$f(\zeta) = 1. \tag{9}$$

In other words, polydispersed beds can be treated as monodispersed when calculating thermal conductivity – provided that the right value of bed porosity is used [11]. Bed porosity is

always smaller for a polydispersed bed than for a monodispersed one, and can be measured quite easily. Additionally, particle diameters calculated from

$$d = \left(\sum Q_i/d_i\right)^{-1} \tag{10}$$

should be used in the equations for k_{rad} and k_G when dealing with polydispersed packings.

Table 1 summarizes values for the shape factor C_f and the flattening coefficient φ according to Bauer [17].

Inserting into Eq. (7) $k_{rad} = 0$, $k_G = 1$, $\varphi = 0$, $C_f = 1.25$, and $f(\zeta) = 1$, again the simpler set of Eq. (5) is obtained, which does not account for the influence of secondary parameters on bed thermal conductivity.

The model is also applicable to particles covered with a thin solid layer. To this purpose, the ratio k_p should be replaced in model equations by

$$k_p^* = \frac{k_p}{1 + Bi} \tag{11a}$$

The *Biot* number is defined as

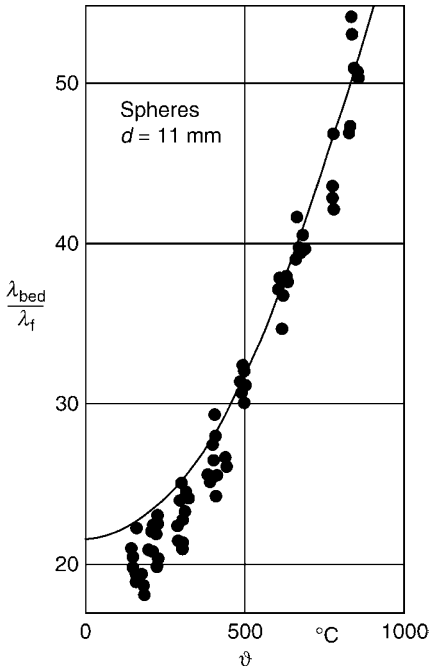
$$Bi = \frac{s}{\lambda_s}\frac{\lambda_p}{d} \tag{11b}$$

where s is the thickness and λ_s is the thermal conductivity of the coating. The coating may be applied on purpose, or it may be undesired. Thin oxide layers created spontaneously on metallic particles during contact with air are typical undesired coatings. In this case, Bauer [17] recommends the use of $s/\lambda_s = 0.15 \times 10^{-3}$ W^{-1} m^2 K in Eq. (11b).

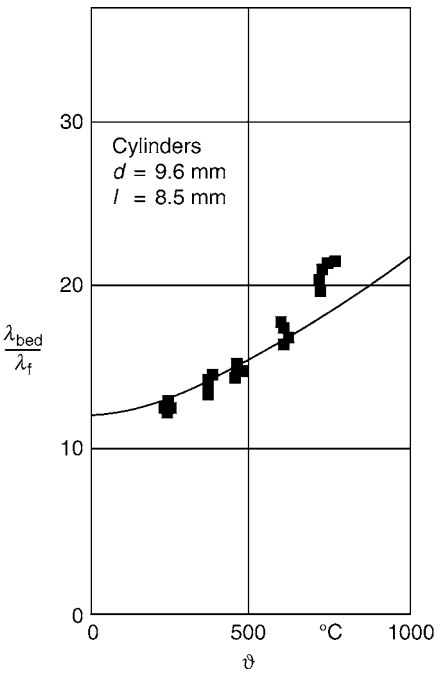
Some examples for the influence of radiation and particle shape on the thermal conductivity of packed beds are given in Figs. 8–11. Experimental data have been taken from Yagi and Kunii [18] for spheres, cylinders, Raschig rings, and broken, irregular materials. The solid lines correspond to calculations with Eq. (7). As the figures show, thermal radiation is important for high temperatures and/or large particles (see Eq. (7e)). Pressure dependence is illustrated in Figs. 12 and 13 on the basis of data from [19]. Both the measured points and the solid curves from Eq. (7) have a characteristic sigmoid shape. Residual thermal conductivities at very low pressures are due to radiation and flattened particle contacts. Values of $k_{bed} = \lambda_{bed}/\lambda_f < 1$ can easily be reached in this region. This means that evacuated packed beds transport less heat than stagnant gas layers of the same thickness. Therefore, they can be used for the purpose of

D6.3. Table 1. Shape factors and flattening coefficients for Eq. (7); (d_i, d_o: inner and outer diameter, respectively).

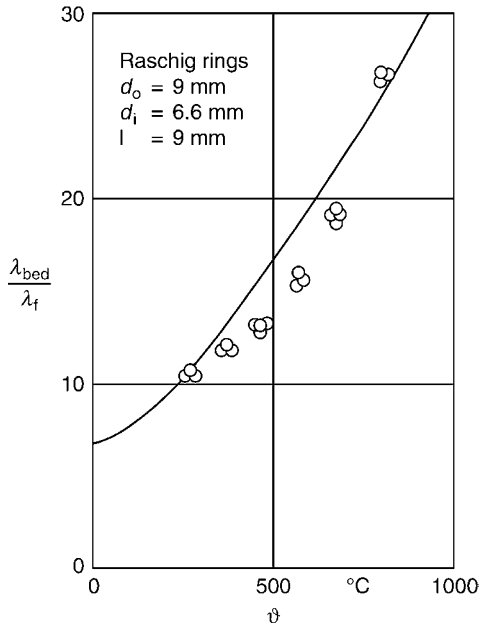
Particle shape	C_f	φ	Material
Spherical	1.25	0.0013	Steel
		0.0077	Ceramic
		0.0253	Copper
Irregular (broken)	1.40	0.0010	Sand
Cylindrical	2.50	?	
Raschig rings	2.5 [1 + $(d_i/d_o)^2$]	?	



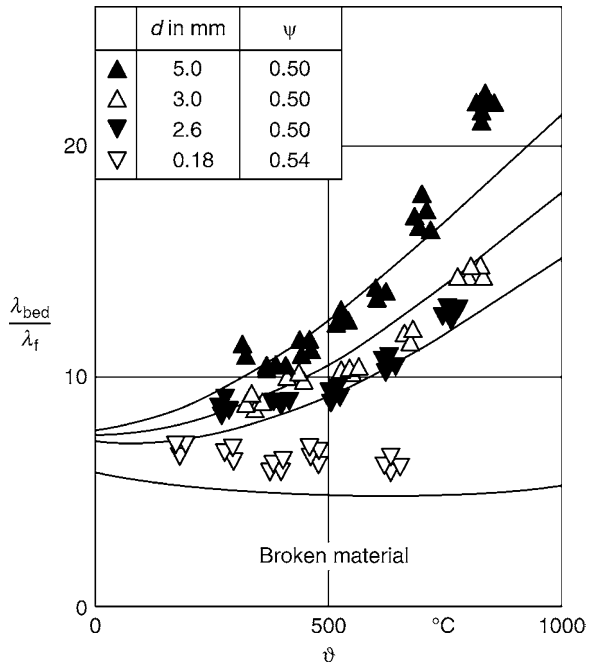
D6.3. Fig. 8. Temperature dependence of the reduced effective thermal conductivity $k_{bed} = \lambda_{bed}/\lambda_f$ for spherical steel particles (d = 11 mm, λ_p = 52 W m^{-1} K^{-1}, ε = 0.80, φ = 0.0013, ψ = 0.40) in air ($p = 10^5$ Pa). Experimental data: Yagi and Kunii [18]; calculation: Eq. (7).



D6.3. Fig. 9. Temperature dependence of the reduced effective thermal conductivity $k_{bed} = \lambda_{bed}/\lambda_f$ for cylindrical ceramic particles (d = 9.6 mm, l = 8.5 mm, λ_p = 1.63 W m^{-1} K^{-1}, ε = 0.93, φ = 0.0077, ψ = 0.43) in air ($p = 10^5$ Pa). Experimental data: Yagi and Kunii [18]; calculation: Eq. (7).



D6.3. Fig. 10. Temperature dependence of the reduced effective thermal conductivity $k_{bed} = \lambda_{bed}/\lambda_f$ for ceramic Raschig rings (d_o = 9 mm, d_i = 6.6 mm, l = 9 mm, λ_p = 1.63 W m^{-1} K^{-1}, ε = 0.93, φ = 0.0077, ψ = 0.72) in air ($p = 10^5$ Pa). Experimental data: Yagi and Kunii [18]; calculation: Eq. (7).



D6.3. Fig. 11. Temperature dependence of the reduced effective thermal conductivity $k_{bed} = \lambda_{bed}/\lambda_f$ for different size fractions of broken, irregularly shaped material (cement clinker, λ_p = 1.98 W m^{-1} K^{-1}, ε = 0.93, φ = 0.0077) in air ($p = 10^5$ Pa). Experimental data: Yagi and Kunii [18]; calculation: Eq. (7).

insulation (compare with Chap. K6). The high impact of flattened contacts on the residual thermal conductivity of packed beds is illustrated in Fig. 14 with calculated curves (φ = 0: point contacts, φ large: large flat areas). On the contrary, heat transfer over solid bridges is usually not very important at normal or elevated pressure.

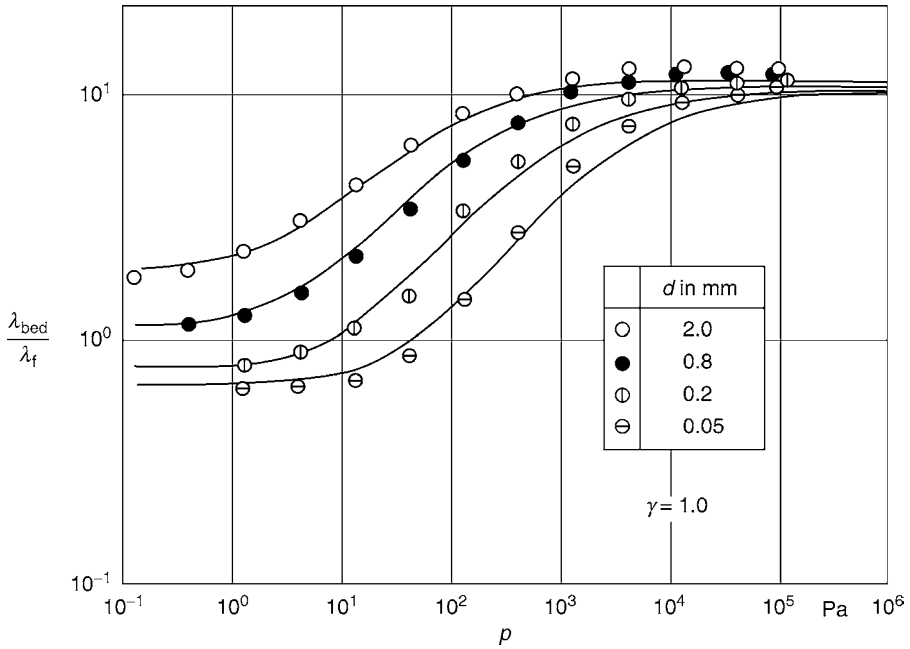
4.4 Comparison with Experimental Data

The basis version of the model (Eq. (5)) has been compared to a large amount of experimental results measured by various authors by Zehner/Schlünder [5] and Tsotsas/Martin [1]. Tsotsas and Martin conducted their systematic comparison not only for packed beds, but also for emulsions (two liquid phases), suspensions (solid particles in a liquid), and dispersions (two solid phases). In almost all cases the model was found to predict the data with an accuracy of better than ±30%. A comprehensive control of the influence of secondary parameters (extended model version according to Eq. (7)) has been carried out by Bauer [17]. Again, good agreement was found between model predictions and the data.

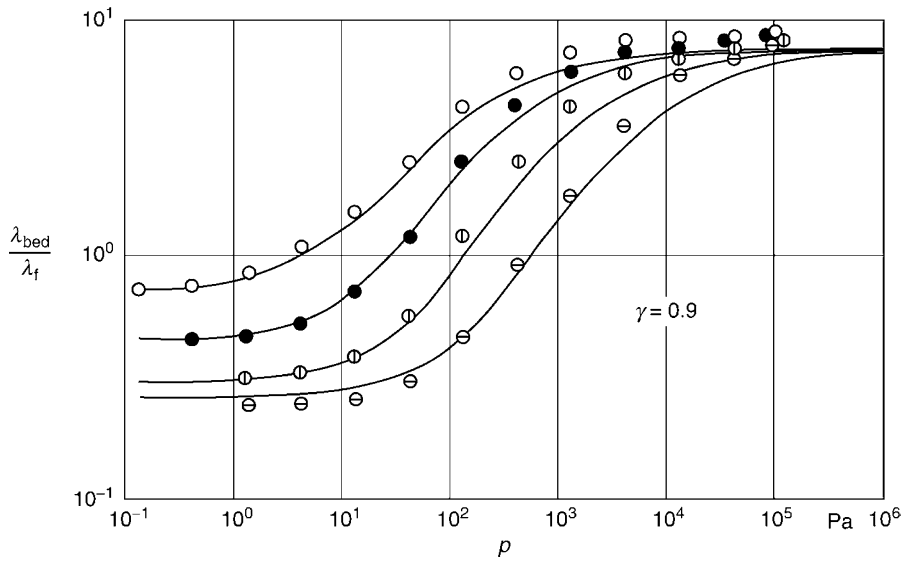
5 Complementary Remarks

The entire previous discussion is based on the assumption that heat conduction in packed beds can be described with an effective thermal conductivity – similarly as in the case of a homogeneous body. This approach has been successful in practice. It is reasonable for all steady state and the majority of transient heat transfer problems. However, significant temperature differences may occur between the solid and the fluid phase in the course of very fast transient processes. If this happens, the packed bed cannot be considered any more as a continuum with the effective thermal conductivity λ_{bed}. Unfortunately, no general quantitative criteria are available for the validity of the continuum assumption. A specific situation, where the continuum approach fails, is the stepwise change of thermal boundary condition at the outer surface of a gas-filled packed bed. Defining the time of the change as $t = 0$ and considering the bed as a homogeneous body, leads to heat transfer coefficients between the boundary and the body that go to infinity as time goes to zero ($\alpha \to \infty$ for $t \to 0$, see Eq. (5) in Chap. M6). This is a wrong result. In reality, the heat transfer coefficient is limited to a certain maximal value by conduction through the gas gap between outer boundary of the bed and the adjoining, first particle layer. The respective thermal resistance is called a contact resistance and denoted by $1/\alpha_{ws}$. Its prediction and practical use are treated in Chap. M6. There, a criterion applicable to this specific case (a critical time) is also discussed.

Another assumption implicit to the previous discussion is that the effective thermal conductivity has the same value in every spatial direction. This is true for packed beds, but it is not true for anisotropic bodies with a preferential orientation of their structural elements. If the medium is periodic, a special



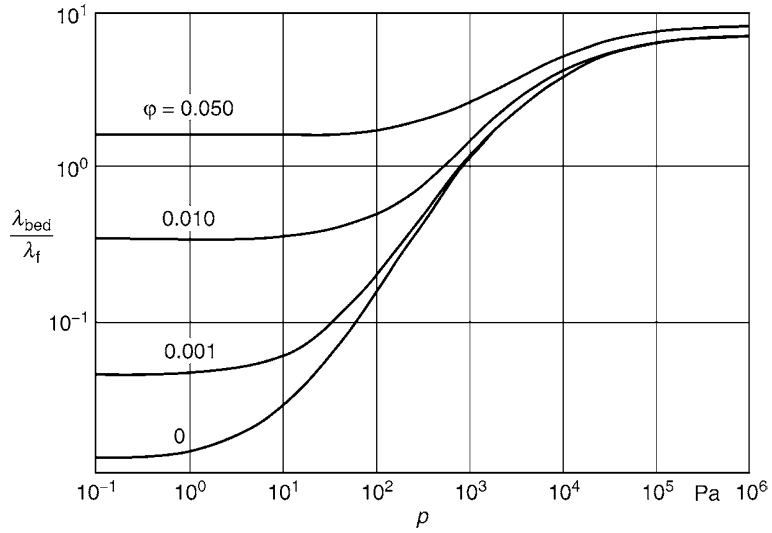
D6.3. Fig. 12. Pressure dependence of the reduced effective thermal conductivity $k_{bed} = \lambda_{bed}/\lambda_f$ of packed beds of spherical ceramic particles ($k_p = \lambda_p/\lambda_f = 104$, $\varepsilon = 0.90$, $\varphi = 0.0077$, $\psi = 0.39$) in Freon 12 (CF_2Cl, $\vartheta = 30°C$, $\gamma = 1.0$). Experimental data: Imura and Takegoshi [19]; calculation: Eq. (7).



D6.3. Fig. 13. Continuation of Fig. 12 with nitrogen as the fluid ($k_p = \lambda_p/\lambda_f = 41$, $\gamma = 0.90$). All other conditions are the same.

mathematical technique called homogenization can be used to derive direction-dependent thermal conductivities [20]. The simplest possible example of anisotropy is that of the two parallel plates of Fig. 2. Applying homogenization to a respective unit cell leads to the upper-bound solution (Eq. (4b); Fig. 2b) in one direction and to the lower-bound solution (Eq. (4a); Fig. 2a) in the other.

As already discussed (Fig. 7), predictions of Eq. (5) are almost identical to the numerical results by Wakao and Kato [2] for the orthorhombic packing of spheres with $\psi = 0.395$. Such an excellent agreement is not obtained for the simple cubical packing ($\psi = 0.476$). Respective numerical calculations [2, 21] show a slight dependence of the factor in Eq. (5e) – that means of C_f – from the conductivity ratio k_p. This result is not really surprising, if it is remembered that the task of the deformation parameter B is to correct the inaccurate assumption about parallel lines of heat flux. Since the deviation of heat flux lines from linearity depends on $k_p = \lambda_p/\lambda_f$, it is reasonable to expect the same kind of dependence in B and, consequently, also in C_f. Numerical results for the simple cubical packing are predicted very well by replacing the factor $C_f = 1.25$ in Eq. (5e) with a value of $C_f \approx 1.8$ [21].



D6.3. Fig. 14. Influence of pressure on the reduced effective thermal conductivity $k_{bed} = \lambda_{bed}/\lambda_f$ at different flattening coefficients φ. Calculations after Eq. (7) for spherical particles in nitrogen with $d = 0.05$ mm, $k_p = \lambda_p/\lambda_f = 41$, $\varepsilon = 0.90$, $\psi = 0.39$, $\vartheta = 30°C$, $\gamma = 0.90$.

Field distortions due to different conductivities in the fluid and the particle phase depend on the arrangement of particles in space and are often called non-Maxwell or higher-order effects. The recommended model of Zehner, Bauer, and Schlünder accommodates such interactions by geometric distortion of the unit-cell particle. The same principle has been applied by other authors on the Maxwell formula [22] or on Ohmic cells [23]. Raghavan and Martin [23] show that Ohmic analogs can be equivalent to Maxwell's solution (Eq. (2)) under certain circumstances.

Concerning radiation, it should be noted that its remote influence has been neglected in Eq. (7). This is well justified for packed beds of opaque particles, but inaccurate in case of transparent particles or highly porous materials. Furthermore, heat transfer by radiation has been incorporated in Fourier's law, which is not exactly correct. A more fundamental treatment of such aspects can be found in publications that concentrate on thermal radiation in porous media [24–26].

The treatment of flattened contacts by the coefficient φ in the recommended model is also approximate. In case of dominance of this path of heat transfer, more detailed approaches that take particle roughness into account [27] may be used. Additionally, particle deformation may be considered as a function of local stress. This cannot be accomplished on a unit cell, but requires solution of the thermal and the coupled mechanical problem for the entire packed bed. Such solutions can be achieved by the thermal version of the discrete element method (thermal DEM) [28, 29]. Their benefit is that they make the influence of external loads and weight on thermal conductivity accessible – including inhomogeneous distributions of stress ("stress chains") that correlate with bed structure. The price to be paid is that conduction through flattened contacts is treated only approximately (by a deformation-dependent resistance or conductance), while other paths of heat transfer are neglected completely. A similar dilemma is connected with numerical computations of the temperature field in entire packed beds. Assessing the influence of an additional liquid phase (liquid bridges) is the benefit of such calculations in [3]. The price is a relatively low spatial resolution, which means less accuracy in the determination of non-Maxwell effects than in unit-cell computations.

Finally, it should be noticed that ψ can be replaced with $(1 - \psi)$, k_p with $1/k_p$, and k_{bed} with k_{bed}/k_p in either Eq. (2) or Eq. (5). This is called phase inversion, and gives estimates for the thermal conductivity of bodies that consist of a continuous solid and a dispersed fluid phase. A modification of the Zehner/Bauer/Schlünder model for such sponge-like materials or foams has been presented by Hsu et al. [30]. Carson et al. [31] discuss respective conductivity bounds. Models specific to ceramic or metallic foams can also be found in the literature (e.g., [32]).

6 Examples

Examples 1

Calculate the thermal conductivity of a monodispersed packed bed of ceramic spheres ($d = 2$ mm, $\lambda_p = 2$ W m^{-1} K^{-1}, $\varepsilon = 0.90$, $\psi = 0.40$) in air at a pressure of $p = 10^5$ Pa and a temperature of $\vartheta = 20°C$.

Subchap. D2.2 ↷ $\lambda_f = 25.69 \times 10^{-3}$ W m^{-1} K^{-1}, $c_{p,f} = 1{,}007$ J kg^{-1} K^{-1}, $\tilde{M} = 28.96$ kg kmol^{-1}

Chap. A1 ↷ $\tilde{R} = 8314.41$ J kmol^{-1} K^{-1}

Chap. M6, Eq. (47) ↷ $\gamma = 0.904$

Chap. M6, Eq. (46) ↷ $l = 2.62 \times 10^{-7}$ m

Eq. (7f) ↷ $k_G = 0.99987$, Eq. (7e) ↷ $k_{rad} = 0.364$

Furthermore, it is: $k_p = \lambda_p/\lambda_f = 77.85$.

Table 1 ↷ $C_f = 1.25$, $\varphi = 0.0077$.

Eq. (9), Eq. (7d) ↷ $B = 1.961$, Eq. (7c) ↷ $N = 0.9794$, Eq. (7b) ↷ $k_c = 10.76$, Eq. (7a) ↷ $k_{bed} = 8.99$, $\lambda_{bed} = 0.231$ W m^{-1} K^{-1}.

Neglecting the secondary influence parameters ($k_G = 1$, $k_{rad} = 0$, $\varphi = 0$) one can obtain

Eq. (5c) ↷ $N = 0.9748$, Eq. (5b) ↷ $k_c = 10.33$

Eq. (5a) ↷ $k_{bed} = 8.23$, $\lambda_{bed} = 0.211$ W m^{-1} K^{-1}

For comparison:
According to Maxwell:
Eq. (2) ↷ $\phi = 0.577$, $k_{bed} = 5.10$, $\lambda_{bed} = 0.131$ W m^{-1} K^{-1}
According to Krischer:
Eq. (4) ↷ $k_I = 2.45$, $k_{II} = 47.11$, $k_{bed} = 10.15$
$\lambda_{bed} = 0.261$ W m^{-1} K^{-1}

Example 2

Calculate the thermal conductivity of the same packed bed as in Example 1 at a pressure of $p = 10^2$ Pa and a temperature of $\vartheta = 700$°C. All other input data remain the same.
Subchap. D2.2 ↷ $\lambda_f = 66.46 \times 10^{-3}$ W m^{-1} K^{-1}
$c_{p,f} = 1137$ J kg^{-1} K^{-1}
Chap. M6, Eq. (47) ↷ $\gamma = 0.571$
Chap. M6, Eq. (46) ↷ $l = 2.22 \times 10^{-3}$ m
Eq. (7f) ↷ $k_G = 0.474$, Eq. (7e) ↷ $k_{rad} = 5.146$
Furthermore, it is: $k_p = \lambda_p/\lambda_f = 30.09$.
Eq. (7c) ↷ $N = -0.143$, Eq. (7b) ↷ $k_c = 7.18$
Eq. (7a) ↷ $k_{bed} = 6.22$, $\lambda_{bed} = 0.414$ W m^{-1} K^{-1}
Under consideration of just one secondary parameter at a time one would obtain
$k_G = 1$, $k_{rad} = 5.146$, $\varphi = 0.0077$ ↷ $k_{bed} = 10.33$
$k_G = 0.474$, $k_{rad} = 0$, $\varphi = 0.0077$ ↷ $k_{bed} = 0.812$
$k_G = 0.474$, $k_{rad} = 5.146$, $\varphi = 0$ ↷ $k_{bed} = 6.09$
Comparison with the right value of $k_{bed} = 6.22$ shows that thermal radiation and the Smoluchowski effect are now very important.

Example 3

Repeat the calculation of Example 2 for a binary mixture of irregular particles with $d_1 = 1$ mm, $d_2 = 5$ mm, $Q_1 = Q_2 = 0.50$, $\psi = 0.32$, and $\varphi = 0$. All other data remain the same.
Eq. (10) ↷ $d = 1.67$ mm
Eq. (7f) ↷ $k_G = 0.429$, Eq. (7e) ↷ $k_{rad} = 4.289$
Table 1 ↷ $C_f = 1.40$
With f(ζ) = 1 (Eq. (9)) it follows
$B = 3.235$, $N = -2.364$, $k_c = 5.42$, $k_{bed} = 4.75$ and
$\lambda_{bed} = 0.315$ W m^{-1} K^{-1}

D6.4 Industrial Refractories

Axel Eschner
Osterode (Harz), Germany

1 Introduction

Refractories generally consist of crystalline phases, a glassy phase, and pores. Each of the phases and their chemical and mineralogical composition influence their thermal and physical properties. The chemical and mineralogical composition determines the specific heat and the thermal expansion. The quantity of crystalline phases and the quantity of the pores as well as their distribution within the material influence the thermal conductivity. The density (bulk density) of refractories is a result of their chemical–mineralogical composition and the porosity.

Refractory materials can be divided into two groups – shaped and burnt or thermally treated products (bricks), and unshaped products (castables, mortars, and mastics).

In the following typical values with rising temperature of the thermal conductivity, the specific heat capacity and the thermal linear expansion as well as the density are shown for diverse shaped products. Based on these values, the thermal diffusivity *a* for instationary calculations can be generated. The general references below the tables and figures should be taken into consideration.

2 Thermal Conductivity of Shaped Refractories

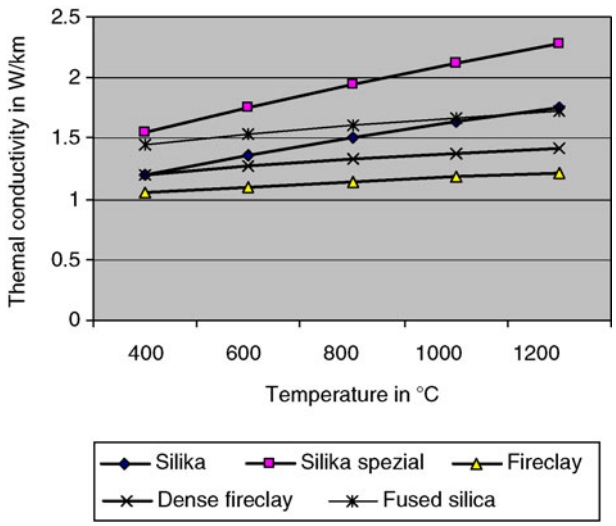
With rising temperature the thermal conductivity of crystalline dielectric material decreases ($\lambda \sim 1/T$), and in amorphous (glassy) material the thermal conductivity increases with temperature ($\lambda \sim T$). In the pores, thermal conductivity is determined by heat conduction (λg) and by a heat radiation ($a \sim T^3$). Depending on which component supersedes, thermal conductivity decreases with rising temperature, for example for products with a high content of crystalline phases such as magnesia, silicon carbide, corundum or zircon, or increases with rising temperature, for example for products with high X-ray amorphous phase – fireclay bricks or amorphous carbon containing bricks. Also the gas in the pores has an influence on the thermal conductivity. Normal air or combustion gases show a very low thermal conductivity, hydrogen increases thermal conductivity of refractory products especially with great open pores, as is the case of insulating bricks.

Because of the predominantly heterogeneous structure of refractories, thermal conductivity can be affected by the grain sizing, the contact conditions in the matrix, reformation or new formation during the burning process or in the application, and the conditions of the emission. There is a diversity of methods to investigate the thermal conductivity, which give results that partly differ from each other, depending on measuring of the thermal conductivity by the stationary method (panel steady-state method – according to American Society for Testing and Materials (ASTM) or method of plate comparison KLASSE) or by the instationary method (transient method – hot wire method). The lowest values for thermal conductivity are measured by the ASTM calorimeter method, the highest values by the hot wire method. The values for the KLASSE method are in between. In the following, properties are presented which have been investigated by the KLASSE method and the hot wire method. Because of the predominantly heterogeneous, coarse-grained structure of refractory materials, the Laser Flash method for determining the thermal diffusivity is only limited. The deviation between the results measured by each method can be up to 15%, especially for insulating refractory bricks.

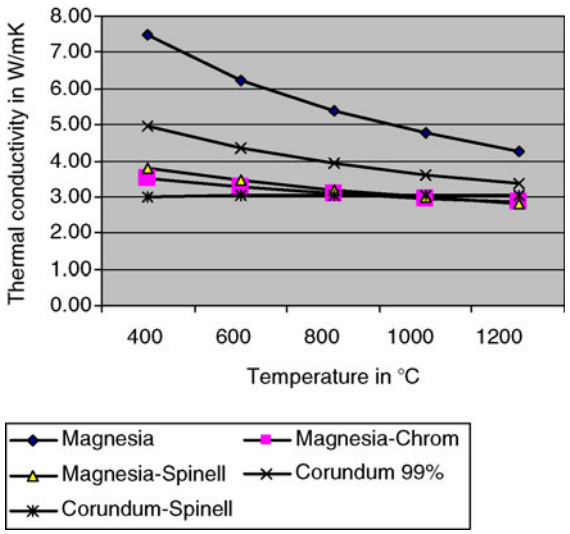
In the following, the typical properties of the most eminent shaped and burnt, thermally treated refractory products are shown in the Figs. 1–8 and in Table 1. The properties correlate with the data given in the tables.

3 Thermal Conductivity of Unshaped Refractories (Monolithics)

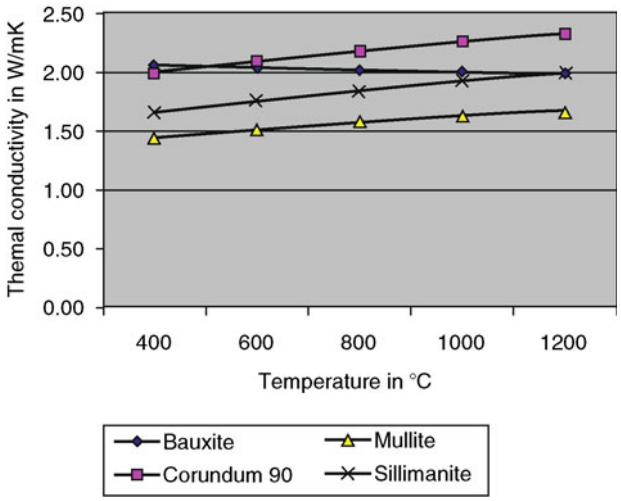
Unshaped refractories (material for monolithic installations, castables, mortars, and mastics) have a thermal conductivity which is 20–50% lower than that of burnt or carbon-bond materials (see Table 1). The reduction of thermal conductivity varies according to the bond type, hydraulic, chemical, and pitch- or resin- bond. A hydraulic bond by alumina cement



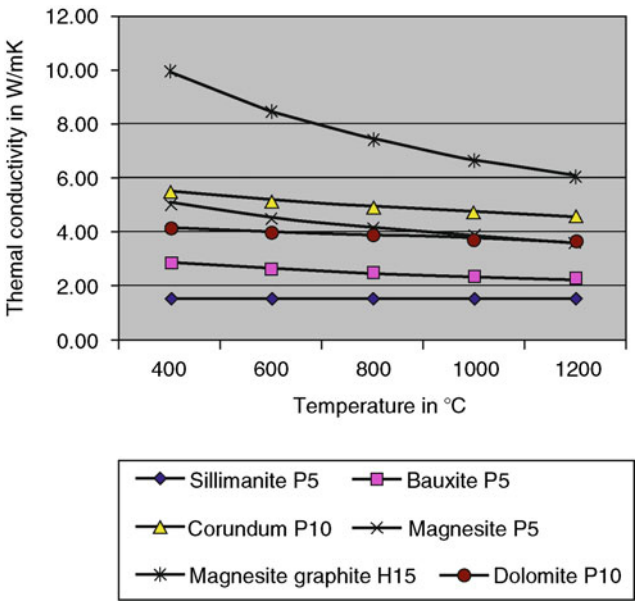
D6.4. Fig. 1. Typical values for thermal conductivity of silica bricks, fused silica bricks, and fireclay bricks. Silica bricks and fireclay bricks show an increase in thermal conductivity caused by elevated amount of X-ray amorphous phase.



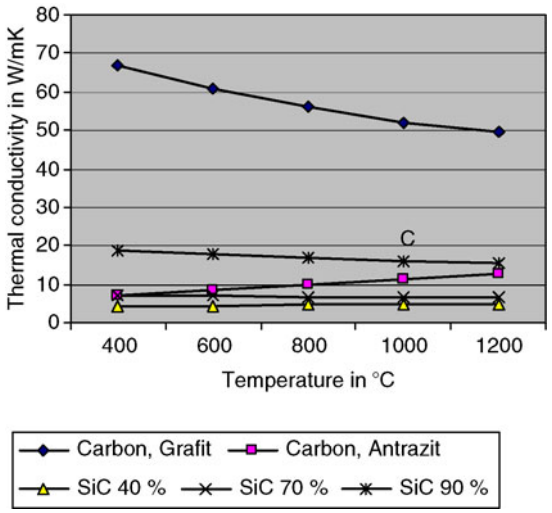
D6.4. Fig. 2. Typical values for thermal conductivity of magnesia bricks and corundum bricks. Pure magnesia and corundum bricks reveal a strong temperature dependence of thermal conductivity. With decreasing amount of the mineral phase Periklas (magnesia) and corundum in the products, the thermal conductivity and temperature dependence decrease.



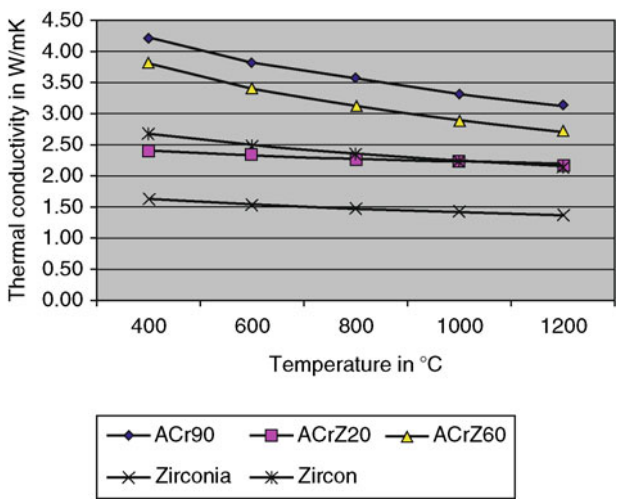
D6.4. Fig. 3. Typical values for thermal conductivity of sillimanite-, mullite-, bauxite- and corundum bricks. If the content of Al_2O_3 in bricks is lower than 90%, the thermal conductivity decreases and shows an increase or constant values at rising temperature compared to pure corundum bricks.



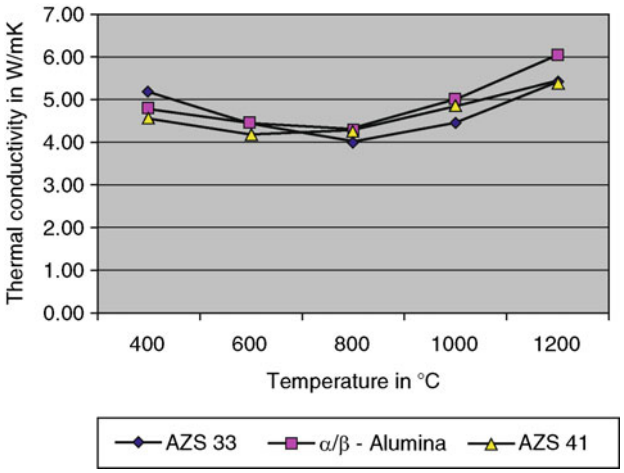
D6.4. Fig. 4. Typical values for thermal conductivity of bricks based on magnesia, dolomite, and alumina with carbon bond. P means pitch bond, H means resin bond; the following number indicates the contents of carbon after carbonization. If products on the basis of magnesia are bound with pitch or resin or impregnated later with tar and are finally coked, so that carbonization with carbon crystalline lattice emerges in the structure, thermal conductivity increases. If the product contains additional graphite, thermal conductivity significantly increases.



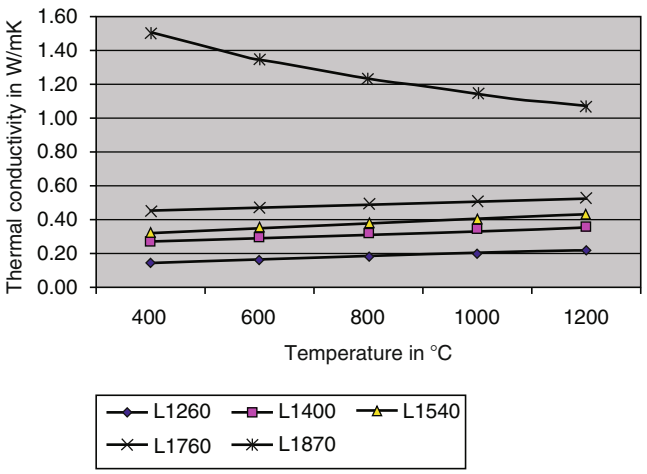
D6.4. Fig. 5. Typical values for thermal conductivity of carbon bricks and silicon carbide bricks. Products based on graphite and SiC have a high thermal conductivity. Graphite is characterized by anisotropy of thermal conductivity, which is dependent on the orientation of the graphite flakes to the direction of the heat flow. Parallel to the graphite flakes, thermal conductivity is extreme, and perpendicular to it, there are lower values. With regard to the example carbon/graphite, the thermal conductivity of a technical product with a predominant thermal alignment of the flakes is shown. The product based on anthracite has a sognificant content of amounts of amorphous carbon, which therefore shows an increase in thermal conductivity with temperature. Ceramic-bond silicon carbide shows an increase of thermal conductivity with rising SiC content. Also the correlation with temperature changes.



D6.4. Fig. 6. Typical values for thermal conductivity of alumina chrome bricks, alumina chrome zircon, zirconia, and zircon bricks. The number indicates the percentage of alumina. Materials based on alumina with chromium oxide or with chromium oxide and zirconia, zirconia, and zircon show the typical behaviour of refractory products with crystalline phases.



D6.4. Fig. 7. Typical values for thermal conductivity of fused bricks (A=Al_2O_3, S=SiO_2, and Z=ZrO_2). In fused products, there is a significant increase in the heat radiation starting from about 800°C, due to their high amount of glass phase and their lack of porosity.



D6.4. Fig. 8. Typical values for thermal conductivity of lightweight fire bricks. The number indicates the classification temperature in °C. Due to the use of raw materials with higher alumina content, the classification temperature increases and the lightweight firebricks become more resistant to temperature. By this they become more dense with decreasing porosity. Consequently, thermal conductivity increases. The firelight brick L1870 consists of bubble alumina, thus showing the typical decrease of thermal conductivity of crystalline materials in relation to temperature. With rising classification temperature the porosity declines, which is the reason for an increase of thermal conductivity.

reduces thermal conductivity more significantly than a chemical bond (phosphate, water glass, etc.). As for the pitch- or resin-bond, the reduction of thermal conductivity is a minor one in comparison with burnt or soaked materials. The characteristics of thermal conductivity and its dependence on

D6.4. Table 1. Typical values of the thermal conductivity (W/mK) for different refractory product groups

Product group	Temperature (°C)

temperature generally are the same within the material groups, whether they are bricks or monolithics. Due to the diversity of the binding possibilities in case of the unshaped refractory products, the presentation of typical properties of unshaped products is refrained.

Furthermore, it has to be considered that – in case of the design of a wall using unshaped products – a temperature gradient in the direction of the thermal flow performs that can lead to a distinctive sintered body, where the thermal conductivity on the side affected by temperature can be higher, due to sintering, than on the "cold" side.

4 Specific Heat Capacity

The mean specific heat capacity is indicated as a heat capacity in a temperature range, starting with 20°C. It can be calculated from the specific heat of the singular oxides. Tables 2 and 3 indicate the specific heat capacities of each of the oxides as well as of carbon.

D6.4. Table 2. Mean specific heat capacity of some refractory oxides (KJ/Kg K)

Oxide	SiO_2	Al_2O_3	Fe_2O_3	CaO
Temperature (°C)				
20–100	0.746	0.866	0.676	0.79

The mean heat capacity results from

$$c_{p_m} = \sum x_i * c_{p_i} \quad (1)$$

with

c_{p_m} = mean specific heat capacity in a temperature sector,
x_i = mass fraction of component i, and
c_{p_i} specific heat capacity of the component i

The specific heat capacity can be calculated regardless of the nature of the material type, it can be equally made for shaped and unshaped products.

Typical specific heat capacities for different product groups are shown in Fig. 9 and Table 4.

5 Density, Porosity, and Thermal Expansion

In Table 5, typical bulk densities of shaped refractory products as well as the thermal expansions for a defined temperature sector are assembled. Figure 10 shows the effects for silica bricks and unstabilized zirconia bricks.

The density comprises the porosities caused by their production process, which can vary from 0% for fused material and 80% for lightweight refractory bricks. Together with the thermal expansion, the densities of the products change. Thermal expansion is nearly independent from porosity.

The thermal conductivities shown in Table 1 refer to the porosities indicated in Table 4. If the porosity and consequently the density change, the alteration of the thermal conductivity for porosity deviations up to 5% can be approximately calculated by use of the following formula:

$$\lambda(\mathrm{P1}) = \lambda(\mathrm{P2})\frac{1-\mathrm{P1}[1+0.35(1-\mathrm{P1})]}{1-\mathrm{P2}[1+0.35(1-\mathrm{P2})]} \quad (2)$$

with λ(P1) the thermal conductivity concerning the new porosity P1

λ(P2) of the thermal conductivity concerning the well-known porosity P2

and

P1 and P2 are the porosities divided by 100.

Example: In case of porosity P2 = 12%, corundum (99%) has a thermal conductivity of 3.6 W/mK.

For a porosity of 15%, this will give accordingly Eq. (2):

$$\lambda(\mathrm{P1}) = 3.6\frac{1-0.15[1+0.35(1-0.15)]}{1-0.12[1+0.35(1-0.12)]} = 3.44\,\mathrm{W/mK}.$$

6 Thermal Diffusivity *a*

Typical values of the thermal diffusivity a are shown in Table 6

The thermal diffusivity a in m^2/h results from

$$a = \frac{\lambda}{p \times c_p} \quad (3)$$

with λ = thermal conductivity (W/mK)

p = density (Kg/m^3)

c_p = specific heat capacity (3.6 KJ/Kg K)

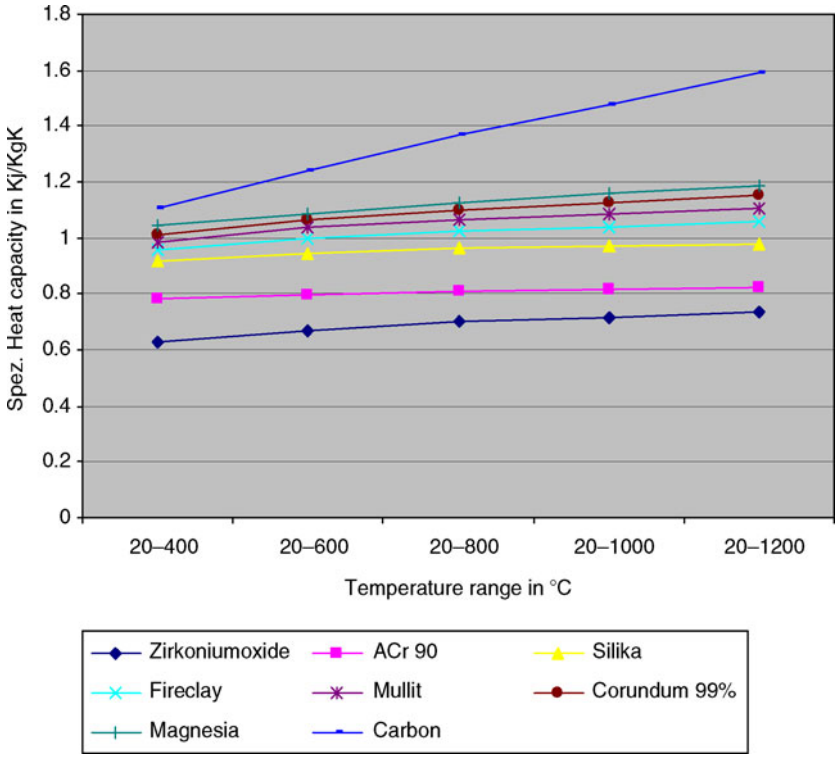
The rate of conversion 3.6 results from the conversion of the specific heat capacity of KJ/Kg K to Wh/Kg K.

The thermal diffusivity is needed for instationary temperature calculations and for the formation of the Fourier number Fo.

7 General Remarks Concerning the Application and Heat Engineering with Refractories

The properties indicated in the above chapters refer to the state of delivery of the refractories.

During use, especially in case of contact with liquid metals, slags, inorganic melts, or condensed vapours, the thermal properties may change. Infiltration of liquid metals may raise the thermal conductivity and the thermal diffusivity significantly. Slag has only a slight influence on the thermal properties; by diminishing the porosity, the thermal conductivity of the infiltrated zone increases by 10–20%. Gases, with the exception



D6.4. Fig. 9. Typical values for specific heat capacity of some product groups.

of hydrogen, have only a slight changing effect on thermal conductivity.

In general, products according to ISO/R836 are "Refractories" if their melting or softening point is higher than 1500°C. But the refractories can also be affected and modified chemically and mineralogically far below their melting point. Normally, refractory lining is built up in several layers, for thermal and economic reasons. The inner layer, which borders the "reaction zone," must be resistible to the process reactions. The following layers in the wall serve to reduce the temperature and diminish thermal losses.

The diverse refractories used in wall designs have to be chosen with regard to their chemical and physical characteristics. Exemplary here is referred again to the example of the thermal expansion of the refractories. If the expansion of the refractories has not been considered in design e.g., by using expansion joints etc., the forces emerging may exceed the compressive strength of the refractories caused by preventing expansion in the heating process, which leads to self-destruction. Especially, refractories on the basis of silica and zirconia with irregular thermal expansion require specific heating programs.

8 Briefly Characterization of the Most Used Refractories

8.1 Silica Products

For silica products, their expansion anomaly caused by modifications and density alterations in connection with rising temperature has to be considered. Up to about 700°C, the products are highly sensitive to temperature cycling; they have to be heated up very slowly. Above 1000°C, they have a very good thermal shock resistance. Silica products have a high hot crushing strength up to 1700°C and have a good chemical consistency, except against alkali containing melts.

8.2 Fireclay- and Alumina-Rich Products

The properties of the products in the binary system SiO_2–Al_2O_3 are substantially characterized by the quantity of Al_2O_3. With increasing Al_2O_3 content, the density and thermal conductivity increase as well as their specific heat capacity.

The thermal shock resistance in this product group is good.

Fireclay products can be used up to 1500°C in accordance with their composition.

Products with a high amount of alumina, e.g., on the basis of bauxite, sintered mullite or fused mullite, and sintered or fused corundum show a high strength and good chemical resistance, except against basic reacting substances and slag or melts containing iron oxide FeO. Products with a high amount of alumina, too, are consequently manufactured by using graphite additives, pitch- or resin-bond, for the application in steel industry. Thermal conductivity and thermal diffusivities of products with a high amount of alumina, pitch- or resin-bond, are a little bit higher than for burnt products. They increase with the amount of graphite.

Alumina spinel products, with or without carbon (AMC products with pitch- or resin-bond) with supplements of magnesia, are used in metallurgy. The percentage of MgO can increase up to 30%. With increasing MgO content, the thermal conductivity rises.

Alumina products with quantities of chromium oxide and/or zirconia are used for specific requirements of thermal combustion of industrial waste and for special applications in the glass industry. Due to the additives, their densities increase whereas the thermal conductivities decrease by 10–30% compared to pure corundum bricks.

The resistance toward oxidation of the carbon products has to be taken in account.

8.3 Magnesia and Dolomite Products

Magnesia and dolomite products have a very high thermal expansion and are therefore extremely sensitive to thermal shock. Pure magnesia bricks show high thermal conductivity with a strong dependence upon rising temperature. According to their composition, they can be used up to 2000°C. They are resistible against basic slag and basic reacting products, for

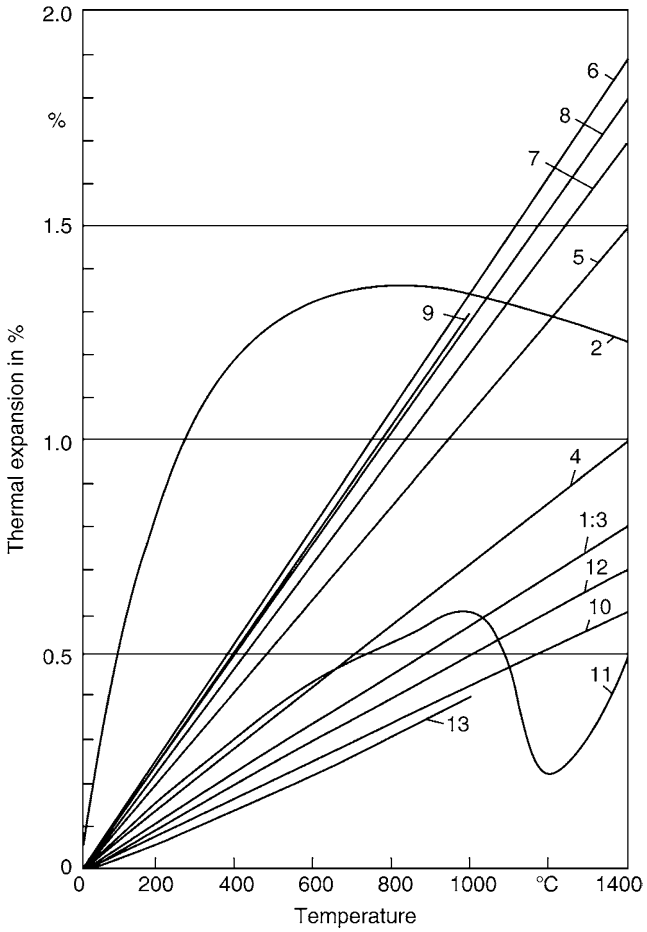
*Means that the development of the thermal expansion at rising temperature is not a steady one, but can prove significant deviations and steps, which is due to changes in modifications with temperature



D6.4. Fig. 10. Thermal expansion in % of shaped refractory products: 1 high-duty firebrick, 2 silica brick, 3 sillimanite brick, 4 corundum brick, 5 forsterite brick, 6 magnesia brick, 7 magnesia spinel brick, 8 magnesia chrome brick, 9 doloma brick, 10 zircon brick, 11 zirconia brick (unstabilized), 12 silicon carbide brick, and 13 carbon brick.

instance in the production of cement and lime. They are irresistible against acid slags and acid reaction products. In order to improve their resistance against thermal shock and chemical attack, in magnesia products, chromium oxide, alumina (for the spinel formation), spinel, hercynite, gallaxit, or zirconia can be added. Burnt or carbon-bond products are in use. Quantities of carbon, especially graphite additives, increase the thermal conductivity; all the other additives reduce the thermal conductivity by 10–40%.

Dolomite products have a very poor hydration resistance and are normally impregnated by tar or pitch- or resin-bond. Like magnesia products, they have a high thermal conductivity. By the use of zirconia or carbon, their resistance against thermal shock can be improved.

Fortsterite products belong to basic products (Magnesia–Silicates). They have a high resistance against slag enriched by iron oxide. It is minor in use.

8.4 Carbon Products and Products with Higher Carbon Additives

Products based on carbon have a high thermal conductivity, especially products based on graphite, and low thermal expansion. Therefore, they provide an enormous thermal shock

Carbon, graphite	140.445	113.313	95.306	81.686	72.354

resistance. They will be only slightly or not infiltrated by slag. In oxidizing atmosphere they can be used up to 400°C because of their inconsistency against oxygen, steam, and carbon dioxide. In reducing atmosphere, the temperature limit of their appliance may rise up to 3000°C.

In the steel making processes, products on the basis of magnesia, alumina, and/or zirconia are used with a percentage of graphite and pitch- or resin-bond that amounts up to 30% carbon. Due to the amount of graphite, these products have a significantly improved structural flexibility and an excellent thermal shock resistance.

In extreme situations, they can be contacted cold with liquid steel.

8.5 Zirconia-Containing Products

During heating up, zirconia (Baddeleyite) performs three different modifications with different mole volumes that have a great influence on thermal expansion.

By adding certain metal oxides, normally magnesia oxide, calcium oxide, or yttrium oxide, the cubic high temperature modification remains nearly stable within the whole temperature range. The materials then show a nearly linear dependence of thermal expansion. A low thermal conductivity and a relatively high thermal expansion result in a low thermal shock resistance. Due to their high strength and resistance toward metal melts, zirconia products possess a high abrasion resistance when steel is cast or glass is melted.

Compared to zirconia products, zircon products have a lower thermal expansion and a higher thermal conductivity. That is why they have a slightly better thermal shock resistance. Zircon products are like zirconia products primarily used in steelmaking and in the glass industry because of their strong resistance to acid slag/melts.

8.6 Silicon Carbide Products

Silicon carbide products have a strong mechanical strength and hardness, a very high thermal conductivity and – due to their high thermal diffusivity – an enormous thermal shock resistance. They can be produced with ceramic bond (clay or alumina bonding) or nitrogen bond (silicon oxinitride, silicon nitride, or siliconaluminia-oxinitride). They have an excellent stability against fused lead, zinc, cadmium, and copper. Products containing silicon carbide are inconsistent against fused alkalies, basic slags, steam, hydrogen, carbon monoxide as well as chlorine gas. In an oxidizing atmosphere, silicon carbide disintegrates above 900°C and forms SiO_2 and CO or CO_2. Above 1250°C, a protective layer of SiO_2 is built up at the surface, which prevents further oxidation. Because of their high thermal conductivity, silicon carbide products are used in cooled furnace walls and as kiln furniture in the ceramic industry.

8.7 Fused Refractories

Fused refractories are fused in electric arc furnaces and then cast in shapes. They can be based on alumina, zirconia, alumina zirconia silica with or without chromium oxide, alumina chromium oxide, alumina magnesia chrome oxide, magnesia chromium oxide, alumina mullite, and alumina zirconia. Due to their dense structure, they have a low thermal shock resistance. The heating up process of fused castables has to proceed

slowly. Fused products are mainly used in glass melting furnaces. The corrosion resistance against glass melts is excellent.

Fused Silica is quite different from all the other fused refractories; it has an extremely low thermal expansion (nearly zero) and can be heated up extremely quickly without discomposure. But above 1250°C, it devitrifies and produces christobalite, developing the thermal properties of a silica product.

D6.5 Insulations Materials

Günther Kasparek
Munich, Germany

1 Introduction

The insulation performance of insulants is caused by the cell gas, usually air, which is enclosed in open or closed cells and by the reduction of thermal radiation by the solid material.

Heat transfer within the insulation material occurs not only over the solid particles and the gas enclosed in the cavities, but also through radiation between the surfaces of fibers or cell cavities.

The most important property of thermal insulation materials is their thermal conductivity. Due to the temperature dependent conductivity of air and thermal radiation, the thermal conductivity of insulants increases with increasing temperature. An exception are cellular plastics blown with blowing agents such as pentane or HCFCs. The characteristic saddle curves as seen in Fig. 1 result due to the condensation of these gases in the cells.

Because of their small dimensions local convection in the cells does not occur. However, global convection may occur in open cell (fibrous) insulants when great temperature differences exist.

Example, this is the case in the insulation of heat generators.

Reliable methods for precalculation of the thermal conductivity do not exist. Therefore, it must be determined by experiments, which are of international standards.

Moisture in the form of liquid water in the insulants has a significant influence on the conductivity. The conductivity already increases with low moisture contents.

In addition to the conductivity, other properties may be of interest. The most important are

- Apparent density which was named to distinguish from the density of the solid material.
- The service temperature range.
- Compressive strength or compressive stress.
- The dimensionless water vapor diffusion resistance factor to calculate water vapor diffusion processes.
- Fire behavior.
- Behavior with chemicals.
- Sound absorbing properties.

There is to be distinguished between open cell insulants e.g., mineral wool (MW) and closed cell materials e.g., extruded polystyrene or cellular glass (CG). Only open cell insulants have good sound attenuation properties. On the opposite, closed cell insulants have to be used for cold insulations.

Cellular plastics are usually driven with blowing agents whose conductivities are lower than that of air, e.g., pentane, CO_2, or HCFC. However, an exchange of gas due to diffusion takes place so that also in this case air is finally the cell gas. This "aging effect" must be accounted for in the conductivity declared by manufacturers.

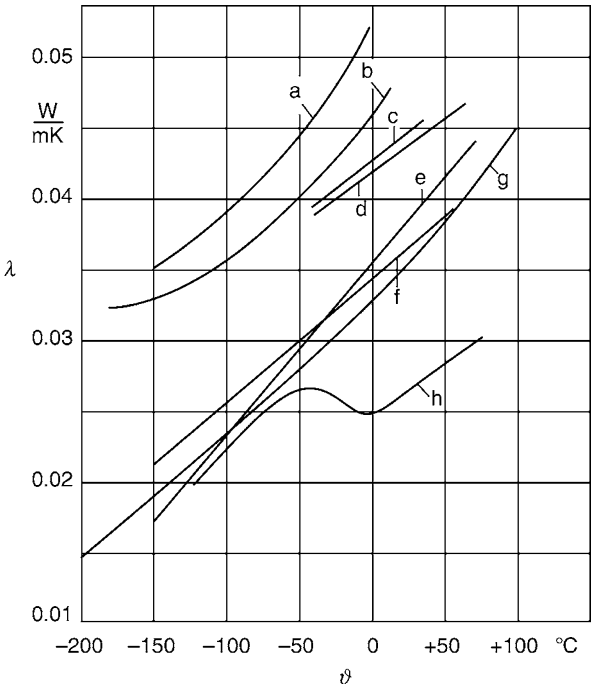
For thermal insulation materials, applications for buildings and for industrial insulation have to be distinguished.

2 European Standardization

Insulants with application in the building sector or for industrial installations are subject to the European Construction Product Directive. For these products, there exist (the so-called harmonized) obligatory standards. For building application, these are the series EN 13162–EN 13171, and for industrial installations the drafts prEN 14303–prEN 14314 which have not been put into force yet. Furthermore, a series for in situ insulants which are made on site exists, which has not been put into force either. Conformity with these standards allows the products to obtain the CE mark, which is necessary for a free trade within Europe. To avoid fatal errors, it should be mentioned, that for all insulants which are delivered acc. to CEN or ISO standards the data for the product characteristics are written with decimal commas.

To designate the different insulation materials, a system of abbreviations has been installed as follows:

- MW mineral wool
- CG cellular glass
- FEF flexible elastomeric foam
- XPS extruded polystyrene foam
- EPS expanded polystyrene foam
- PUR polyurethane foam
- PIR polyisocyanurate foam
- CS calcium silicate
- PEF polyethylene foam
- PF phenolic foam
- EP expanded perlite
- EV vermiculite



D6.5. Fig. 1. Thermal conductivity of cold insulants. Abscissae: temperature in °C, Ordinate: heat conductivity in W/(mK). a, cellular glass (CG) – sections; b, CG – boards; c, polyethylene; d, flexible elastomeric foam; e, polystyrene; f, cork – boards 100 kg/m^3; g, polyurethane (PUR) blown with CO_2; h, PUR blown with R142 b or pentane.

In contrast to the conventional norms as they had been installed in Germany for example, the European Norms do not standardize the insulants and their performances. They especially do not contain any requirements but only standardize how to describe the properties in the form of classes and levels and therefore, they are only a "frame of description," which has to be used by public bodies and comparable institutions when calling for tenders.

3 Building Application

The thermal conductivity of insulants for building application is declared for a reference mean temperature of 10°C. The "declared value" (Germ.: Nennwert) has to be given and guaranteed by the manufacturer. For design purposes, the declared value has to be transformed into a "design value" (Germ.: Bemessungswert). The rules to be applied are subject to national regulations. In Germany, DIN 4108–4 applies. DIN 4108–10 prescribes the minimum values of the properties depending on the field of application. In other countries, comparable prescriptions exist.

Table 1 shows reference values for some characteristics.

4 Industrial Installations

Since industrial application covers a wide temperature range, thermal conductivity is declared as a function of temperature.

D6.5. Table 1. Reference values of insulants for building application

	Declared thermal conductivity in W/(m*K) at 10 °C	Water vapor diffusion resistance factor μ	Apparent density in kg/m^3
Mineral wool	0.035–0.05	1	20–200
Expanded polystyrene	0.035–0.05	20–100	20–30
Extruded polystyrene	0.030–0.036	80–250	30–50
Rigid polyurethane	0.025–0.024	40–200	35–80
Cellular glass	0.045–0.055	Vapor tight	110–130
Flexible elastomeric foam	0.037–0.046	1,000–7,000	40–90
Phenolic foam	0.020–0.045	10–60	40–200
Wood wool products	0.060–0.065	2–5	60–200
Vermiculite	0.060–0.07		
Expanded perlite	0.045–0.07	3–5	65–80

While for flat products conductivity is given in dependence on the temperature, for cylindrical products conductivity is a function of the mean temperature of the hot and cold sides of the insulation. Attention must be paid to this fact when comparing data.

According to the AGI Working documents series Q [1], the manufacturer can give the thermal conductivity in the form of limitation curves.

The conversion of the declared value to the design value is described in VDI 2055 or the international standard EN ISO 23993. There the expression "design value" is replaced by "operational thermal conductivity" (Germ.: Betriebswärmeleitfähigkeit). Supplementary values for thermal bridges as joints, metallic substructure, or reinforcements on plane surfaces have to be taken into account.

4.1 Influences on the Thermal Conductivity

The most important characteristics which influence thermal conductivity are temperature and apparent density. As mentioned above, conductivity generally increases with increasing temperature due to the temperature dependence of gas conductivity and the contribution of thermal radiation.

The influence of the apparent density is different and is dependent upon the temperature. At low temperatures, the effect of the comparably high conductivity of the solid structure is predominant, so that with increasing apparent density the conductivity of the insulant increases as well.

By contrast, at high temperatures conductivity decreases with increasing apparent density. This is due to a higher amount of solid structure reducing thermal radiation.

Furthermore, moisture in the form of condensated water leads to high conductivities. This intensifies when ice formation occurs and may result in a total loss of the insulation property and destruction of the insulation system. The data in Figs. 1 and 2 are valid for dry insulants. For references about the influence of moisture, see [2–5 and Subchap. D6.6]

As mentioned before, it has been frequently discussed whether free convection in the insulants occurs. No convection takes place within the small cells or pores. However, with high temperature differences global convection movement occurs in air-permeable insulants such as MW and causes a significant additional heat loss. Effective countermeasures are the use of insulants with a longitudinal airflow resistance >50 kPa*s/m^2 and non–air-permeable foils at the faces of the insulant. Detailed investigations and calculation advice are given in [6].

4.2 Service Temperature Range

There is to be distinguished between the maximum service temperature and the service temperature, which is of practical interest. The former is determined according to standardized tests (EN 14706 and EN 14707) and given by the manufacturer on its product label, whereas the latter is a matter of experience.

For MW products, the service temperature is approximately 80–90% of the maximum service temperature.

Table 2 shows some relevant properties of insulants for industrial installations.

4.3 Insulation Materials for Cold Insulations

Cold insulations are defined as insulations where the medium temperature is below the ambient temperature. They have to reduce the heat ingress into the system to be insulated as well as to prevent dew formation on the surface of the insulation system and in the insulant itself.

Moisture in the insulation in the form of liquid water or ice increases the thermal conductivity and can damage the insulation.

For this purpose it is necessary that the two transport mechanisms – water vapor diffusion and air movement into the insulation – are prevented or reduced, respectively.

The water-vapor diffusion can be reduced by an insulant with a high water-vapor diffusion resistance factor, e.g., FEF, or by applying a vapor retarder onto the surface of the insulant. To prevent ingress of moisture by air movement into the insulation, a closed cell insulant has to be used.

Therefore, for cold insulations only closed cell materials have to be used. Exceptions exist for technical reasons e.g., insulation of air-treatment installations with MW or tanks for liquid natural gas insulated with perlite. In these cases, special means as double-skin coverings, which are soldered or welded air-tight, are necessary.

There is a contrast in the requirements for protection of sound. For this purpose, open cell insulation materials in combination with closed cell insulants are necessary.

The most important properties of cold insulants including their fire behavior are listed in Table 3.

The fire behavior refers to DIN 4102, which in future will be replaced by the European standard EN 13501.

Cold insulants can also be used as hot insulants in the service temperature range given in Table 3.

There does not exist any minimum service temperature caused by the properties of the insulants. The lower limit depends on the design of an insulation system.

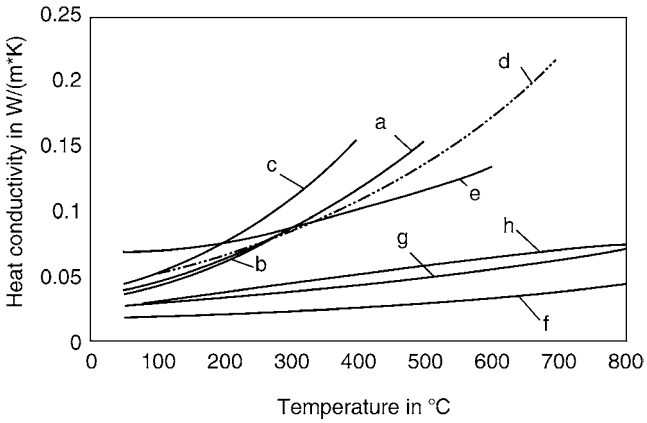
Due to the German Rules and regulations of the accident prevention, the use of organic insulants is restricted to a temperature above −180°C because of explosion risk in the presence of liquid oxygen as far as the presence of air cannot be prevented definitely.

D6.5. Table 2. Properties of insulants for industrial installations

Insulant	Apparent density in kg/m^3	Service temperature in °C
Mineral wool		
Wired mats	70–90	520
	80–120	540
	100–160	580
Sections	50–160	450–680
Lamella mats, pressure resistant	40–60	500
Loose wool	60–170	550–750
Cellular glass	110–130	400
Calcium–magnesium–silicate fibers, mats	96–160	850
Calcium silicate	250–350	850
Microporous insulants	140–400	1,000
Expanded perlite	65–80	750

D6.5. Table 3. Insulants for cold insulations for industrial installations

Insulant	Apparent density in kg/m^3	Upper service temperature in °C	Fire behavior according to DIN 4102
Expanded polystyrene	20–30	80	B1, B2
Extruded polystyrene	30–50	80	B1, B2
Rigid polyurethane (PUR)	40–70	130	B1, B2
In situ PUR	40–60	100	B1, B2
Cellular glass	110–130	400	A1
Flexible elastomeric foam	40–90	105	B2, B1
Expanded cork (ICB)	80–120	100	B2, B1



D6.5. Fig. 2. Thermal conductivity of hot insulants. Abscissae: temperature in °C, ordinate: heat conductivity in W/(m*K). a, mineral wool – mats; b, mineral wool – sections; c, cellular glass; d, calcium–magnesium–silicate fiber; e, calcium silicate; f, microporous insulant; g, microporous insulant (slatted panels); h, static air.

4.4 Insulation Materials for Hot Insulations

For hot insulations, all types of insulation materials can be used.

The apparent density and the service temperature are given in Table 2. Reference values for the thermal conductivity can be found in Fig. 2.

The actual service temperature depends on the operating conditions. The thermal conductivity as well as other properties can be influenced by the manufacturer through the production process. Therefore, values given by the manufacturer should be used.

By far the most common insulating material is MW. MW is the generic term for glass wool and stone wool. Slag wool is no longer used in Europe. Forms of delivery are wired mats, mats, sections, lamella mats, slabs/boards, felts, and loose wool.

CG is predominantly used when high compressive loads occur or a non–combustible insulant is required.

Calcium–magnesium–silicate (CMS) fibers are normally used in high temperature application as a preinsulation to reduce the temperature to values where MW can be installed.

D6.5. Table 4. Specific heat capacities of insulants

Insulant	kJ/(kg*K)
Mineral wool	0.84
Calcium silicate	1.1
Polyurethane	1.4
Polystyrene	1.2
Perlite	0.84
Cellular glass	0.84
Microporous insulants	1.05

CMS fibers replace the before used ceramic fibers which now are prohibited for heat insulation application due to the danger of cancer.

CS is a solid material which has a low thermal conductivity at high temperatures and high compressive strength.

A special case with thermal insulation materials are the microporous insulants, also called super isolation materials. In these materials, the distances between the particles respectively cell walls are smaller than the mean free path length of air. Due to the Smoluchowski effect, the conductivity of these materials is below that of static air.

Table 4 shows the specific heat capacity of insulants.

D6.6 Thermal Conductivity of Insulation Materials Depending on Moisture Content and Temperature

Fabian Ochs · Hans Müller-Steinhagen
Universität Stuttgart, Stuttgart, Germany

1 Introduction

In VDI Heat Atlas Subchap. D6.3 [1], most significant works related to the measurement and modelling of the thermal conductivity of porous media are listed, see also [2, 3]. In general, the availability of measured thermal conductivity data of (bulk) insulation at elevated moisture contents is very limited. Almost no measured data for the thermal conductivity of insulation materials can be found for temperatures above ambient.

2 Definitions

Bulk densities (ρ) of typical insulation materials range from 100 kg/m^3 to almost 400 kg/m^3, with reference thermal conductivities (λ_R) in the range from 0.05 to 0.12 W/(m K) according to DIN 4108 [4] or manufacturer information. The grain (particle) size (d) of the particular bulk insulation materials is 0–1, 2–4, 4–8 or 8–16 mm for expanded glass, expanded clay, and expanded perlite and 0/20, 0/60, 0/90 or 10/50 mm for foam glass gravel.

The fraction of open pores (accessible for water) and closed pores (non-accessible for water) are important parameters for the thermal conductivity. The total (or bulk) pore fraction (Ψ) can be determined using the total (bulk) density (ρ) and the density of the solid (ρ_s) according to the following equation.

$$\Psi = 1 - \frac{\rho}{\rho_s} \tag{1}$$

The macro-porosity, which corresponds to the fraction of the voids between the grains (Ψ_{macro}) and the fraction of closed pores (Ψ_{cl}) can be measured according to the method described in [5]:

$$\Psi_{op} = \Psi - \Psi_{cl} = \Psi_{macro} + \Psi_{micro} \tag{2}$$

The open porosity (Ψ_{op}) consists of the macro-porosity (Ψ_{macro}) and the micro-porosity (Ψ_{micro}). Micro-porosity is the fraction of open porosity and is, thus, used for water-accessible pores of the grain.

For a single grain, the porosity can be calculated using total porosity (Ψ) and macro-porosity (Ψ_{macro}).

$$\Psi_g = \frac{\Psi - \Psi_{macro}}{1 - \Psi_{macro}} \tag{3}$$

with

$$\Psi_{macro} = \frac{V_{macro}}{V} \tag{4}$$

The free saturation water content (u_{fs}) is determined as the drain weight according to DIN EN 13755 [6] see Table 1. It can be significantly lower than the maximum water content (u_{max}) which is obtained if 100% of the voids are filled with water:

$$u_{max} = \Psi_{op} \cdot \rho_w \tag{5}$$

3 Prediction of Thermal Conductivity

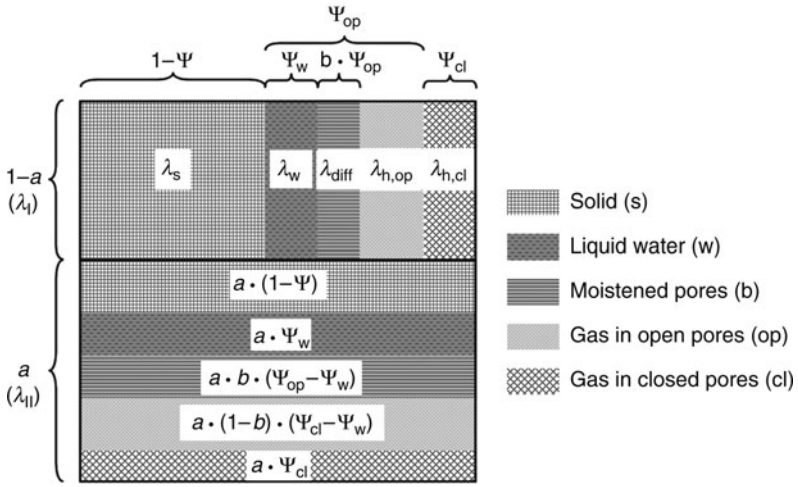
3.1 Thermal Conductivity of Moistened Porous Materials

The VDI Heat Atlas [1] distinguishes between three types of prediction models for the thermal conductivity of porous materials. Type I considers the temperature and heat flux profile of two particles which are in contact (unity cell). It is the most complex model in terms of calculation effort and has to be solved numerically. A simplification is presented by Type III.

D6.6. Table 1. Grain size (d), density (ρ), reference thermal conductivity (λ_R), density (ρ_s) and thermal conductivity (λ_s) of solid matrix, open (Ψ_{op}), and total (Ψ) void fraction and free saturation water content (u_{fs}) of bulk insulation material

Material	Grain size	Bulk density	Solid density	Reference thermal conductivity	Solid thermal conductivity	Total void fraction	Open void fraction	Free saturation
	d	ρ	ρ_s	λ_R	λ_s	Ψ	Ψ_{op}	u_{fs}
	(mm)	(kg/m³)		(W/(m K))		(–)		(kg/m³)
Expanded glass	4–8	185	2,480	0.08	1.16	0.93	0.61	500
Expanded clay	4–8	270	2,650	0.10	3.44	0.90	0.51	300

λ_R: reference thermal conductivity, dry at 10°C according to DIN 4108 [4] or manufacturer data; density (ρ): manufacturer information (ρ_s), and thermal conductivity (λ_s) of solid matrix from [4, 7], free saturation water content [8].



D6.6. Fig. 1. Extended layer model taking into account the fraction of closed and thus, by moisture unaffected pores.

Analog to Type I the unity cell is regarded, but instead of a grid of isotherms and heat flux lines either parallel isotherms or heat flux lines are considered. A frequently used representative is the model developed by Zehner, Bauer and Schlünder (see [2] for details). It describes thermal conductivity very well, if secondary parameters like the thermal contact resistance or flattening effects are considered.

According to a suggestion by Krischer [3], that is, prediction model type II, the thermal conductivity of (moistened) porous materials can be expressed in terms of an aggregation of serial and parallel layers consisting of solid (s), liquid water (w), humid air and dry air (a). Typical bulk insulation materials have a fraction of 23–44% of closed pores (see Sect. 2). It is advantageous to consider the closed pores as an additional layer as will be shown later. This leads to a five-layer model according to Fig. 1.

The summation of the serial layers yields the maximum thermal conductivity.

$$\lambda_I = (1-\Psi)\cdot\lambda_s + \Psi_w\cdot\lambda_w + b\cdot(\Psi_{op}-\Psi_w)\cdot(\lambda_p+\lambda_{diff}) + (1-b)\cdot(\Psi_{op}-\Psi_w)\cdot\lambda_p + \Psi_{cl}\cdot\lambda_{p,cl} \quad (6)$$

The minimum thermal conductivity is obtained by adding the parallel layers, which are weighted with the share of poor conductive layers (a). The maximum thermal conductivity in Eq. (7) is weighted accordingly with (1– a).

$$\lambda_{II} = \left(\frac{1-\Psi}{\lambda_s} + \frac{\Psi_w}{\lambda_w} + \frac{b\cdot(\Psi_{op}-\Psi_w)}{\lambda_p+\lambda_{diff}} + \frac{(1-b)\cdot(\Psi_{op}-\Psi_w)}{\lambda_p} + \frac{\Psi_{cl}}{\lambda_{p,cl}}\right)^{-1} \quad (7)$$

The addition of the weighted maximum (λ_I) and minimum (λ_{II}) thermal conductivity results in the effective thermal conductivity (λ_{eff}) of the porous medium.

$$\lambda_{eff} = \frac{1}{\frac{1-a}{\lambda_I} + \frac{a}{\lambda_{II}}} \quad (8)$$

For dry materials with air as pore gas, the number of layers in the model is reduced to two, that is, solid with the fraction ($1-\Psi$) and air with the fraction (Ψ).

$$\lambda_I = (1-\Psi)\cdot\lambda_s + \Psi\cdot\lambda_p \quad (9)$$

and correspondingly

$$\lambda_{II} = \frac{1}{\frac{1-\Psi}{\lambda_s} + \frac{\Psi}{\lambda_p}} \quad (10)$$

The thermal conductivity of the solid can be measured according to a method proposed in [7] if the literature data are not available. Here, data for glass, clay, perlite or sand/stone are given.

The effective thermal conductivity of the pore (p) consists of a contribution of molecular conduction of the pore gas (pg) and a contribution due to radiation (rad).

$$\lambda_p = \lambda_{pg} + \lambda_{rad} \tag{11}$$

In most cases, the pore gas is air. The thermal conductivity of air can be approximated using a second order polynomial [3].

$$\lambda_a = 0.0243 + 7.8421 \cdot 10^{-5}\vartheta - 2.0755 \cdot 10^{-8}\vartheta^2 \tag{12}$$

The effect of the radiation can be considered using Eq. (13).

$$\lambda_{rad} = \frac{4 \cdot \sigma_s \cdot d_m}{(2/\varepsilon) - 1} T^3 = c_{rad} \cdot T^3 \tag{13}$$

where σ_s is the blackbody radiation constant, ε the coefficient of emission of the particle surface, T the absolute temperature in K and d_m is the mean pore diameter. As the coefficient of emission is not available in most of the cases the parameters in Eq. (13) are lumped to the radiation constant (c_{rad}), which can be determined from experiments.

Using the Nelder-Mead method [9] the unknown parameters a and c_{rad} may be identified.

Convection can be neglected in the present application as, according to Zeitler [10], it only takes place when the Rayleigh number, defined in Eq. (14), exceeds the critical value $Ra_{crit} > 1708$:

$$Ra = Gr \cdot Pr = \frac{g \cdot \beta_{pg} \cdot \Delta T_p \cdot d_{p,m}^3}{\nu_{pg} \cdot a_{pg}} \tag{14}$$

Even for coarse-grained materials with mean grain diameters of 12 mm the Rayleigh number remains smaller than the critical value under the given boundary conditions.

3.2 Influence of Moisture as a Function of Temperature

In order to model the presence of moisture, the thermal conductivity of liquid water (λ_w) and of water saturated air ($\lambda_{a,sat}$) in Eqs. (6) and (7) have to be calculated. The thermal conductivity of water can be represented by a third order polynomial approach according to [3]. The thermal conductivity of water vapour (v) as a function of temperature is given by Quast [11]:

$$\lambda_v = \frac{1.713 \cdot 10^{-4} \cdot (1 + 0.0129 \cdot T) \cdot \sqrt{T}}{1 - 80.95/T} \tag{15}$$

Ackermann [12] provides an equation for the thermal conductivity of water saturated air with the saturation pressure p_{sat} according to Eq. (23) at an absolute pressure of $p_{amb} = 1$ bar.

$$\lambda_{a,sat} = 0.5 \cdot \left[p_{sat} \cdot \lambda_v + (1 - p_{sat}) \cdot \lambda_a + \left(\frac{p_{sat}}{\lambda_v} + \frac{1 - p_{sat}}{\lambda_a} \right)^{-1} \right] \tag{16}$$

The fraction of pores filled with liquid water can be estimated using the absolute moisture content (u).

$$\Psi_w = u/\rho_w \tag{17}$$

3.3 Thermal Conductivity Due to Pore Diffusion

For the moistened pores, the conductive terms of solid λ_s, of water λ_w and of dry air λ_a or saturated air $\lambda_{a,sat}$ are taken into account according to Eqs. (6) and (7). Additionally heat transfer due to evaporation at the warm side of a pore and condensation at the opposite cold side of the pore occurs (heat pipe effect). The effective thermal conductivity due to pore diffusion (λ_{diff}) is modelled introducing an additional term, which is added to the thermal conductivity of the pore λ_p.

$$\lambda_{p,op} = \lambda_p + \lambda_{diff} \tag{18}$$

The term (λ_{diff}) describing the heat transport due to pore diffusion is expressed in different ways in the literature. Krischer [3] who developed the original model proposed:

$$\lambda_{diff} = \frac{D_v}{R_v \cdot T} \cdot \frac{p_{amb}}{p_{amb} - p_{sat}} \cdot \frac{dp_{sat}}{d\vartheta} \Delta h_v \tag{19}$$

In the VDI Heat Atlas [13] a similar correlation can be found.

$$\lambda_{diff} = \frac{D_v}{R_v^2 T^2} \frac{p_{amb}}{p_{amb} - p_{sat}} \Delta h_v^2 \tag{20}$$

De Vries [14] suggests the following correlation for the thermal conductivity due to pore diffusion:

$$\lambda_{diff} = D_v \cdot \frac{dp_{sat}}{d\vartheta} \cdot \Delta h_v \tag{21}$$

Whereas the equations according to Krischer and VDI Heat Atlas provide similar results, the De Vries approach yields significant deviations above 70°C.

For the temperature-dependent parameters, the vapour diffusion coefficient (D_v) and the saturation vapour pressure (p_{sat}), different empirical correlations are suggested in the literature (Krischer [3], De Vries [14], Schirmer [15], Vos [16]): The following empirical function given in VDI Heat Atlas [13] is recommended:

$$D_v = \frac{2.252}{p_{amb}} \cdot \left(\frac{T}{273} \right)^{1.81} \tag{22}$$

Furthermore, different correlations for the vapour saturation pressure can be found in the literature (e.g., VDI Heat Atlas [13], Magnus [17] or the Antoine correlation [18]). The Antoine correlation was originally used by Krischer and is, thus, also used in this work

$$p_{sat} = 610.8 \cdot \exp\left(\frac{17.08085 \cdot \vartheta}{234.175 + \vartheta} \right) \tag{23}$$

It is valid in a temperature range from 0°C to 100°C. The derivation of the saturation pressure in Eq. (23) yields

$$\frac{dp_{sat}}{d\vartheta} = \frac{2.44314.10^6}{(234.175 + \vartheta)^2} \cdot \exp\left(\frac{17.08085 \cdot \vartheta}{234.175 + \vartheta} \right) \tag{24}$$

The gas constant of water vapour is R_v = 461.5 KJ/(kg K) and the specific heat of evaporation is Δh_v = 2260 kJ/kg.

3.4 Approximation of the Fraction of Moistened Pores

The moistened pores, that is, the pores in which diffusion takes place, can be determined by subtracting the share of water-filled pores from the share of open pores. Hence,

$$\Psi_{\mathrm{diff}} = b \cdot (\Psi_{\mathrm{op}} - \Psi_{\mathrm{w}}) \tag{25}$$

The fraction of the moistened pores (b) is, therefore, a function of the water content (u). Between water content zero (dry material) and the free saturation (u_{fs}), the parameter b can take values between 0 and 1. For free water saturation b becomes 1. If the free saturation water content (u_{fs}) is equal to the maximum water content, which applies in the case of open-porous materials such as mineral wool, no air remains in the pores of the material. Consequently, the fraction of moistened pores $\Psi_{\mathrm{op}} - \Psi_{\mathrm{w}}$ and thus Ψ_{diff} is zero: no pore diffusion takes place. The fraction b has to be determined by iterative curve-fitting using, for example, the Nelder-Mead algorithm [9]. For each data set of thermal conductivity as a function of temperature and moisture content (u) the corresponding b value has to be determined.

For the predictions of the fraction of moistened pores (b) as a function of water content (u), the following empirical correlation developed by Krischer [3] is suggested in the VDI Heat Atlas [13]:

$$b = 1 - \left(1 - \frac{u}{u_{\mathrm{fs}}}\right)^9 \tag{26}$$

However, the present measurements indicate that the fraction of pores (b) in which pore diffusion takes place does not depend on the free saturation water content only. Therefore, a more complex correlation may be required.

The correlation between (b) and the water content (u) is similar to the moisture storage function of porous materials (or water retention curve of soils) which describes the moisture content (u) as a function of the relative humidity (Φ). Thus, already known correlations may be applied. A one-parameter approach (model II) with the empirical factor (c) and the free saturation water content (u_{fs}) is given with Eq. (27) from [19]

$$b = \frac{u \cdot c}{u_{\mathrm{fs}} \cdot (1 - c) + u} \tag{27}$$

while better results can be achieved using an approach with two empirical parameters (m_1, m_2) according to Eq. (28) which is suggested in [20]

$$b = \exp\left(m_1 \cdot \left(\frac{u_{\mathrm{fs}}}{u} - 1\right)^{m_2}\right) \tag{28}$$

In Fig. 2, the comparison of the predictions of the three models and the experimental data (iteratively determined data $b(u)$ for expanded glass granules 4–8 mm and expanded clay 4–8 mm) is shown. The best agreement between model prediction and experimental data is obtained using model III, Eq. (28).

3.5 Temperature Dependence of the Closed Pore Fraction

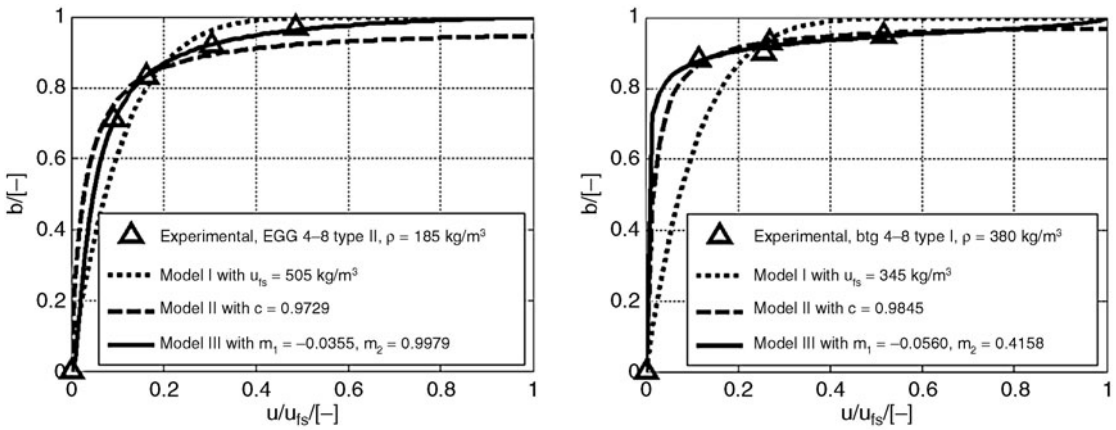
By definition, closed pores are not accessible to water (see Sect. 2). Due to the decreasing dynamic viscosity (η) and surface tension (σ) of water with increasing temperature (ϑ), the fraction of non-accessible pores is assumed to decrease with increasing temperature according to the following equation:

$$\Psi_{\mathrm{cl}}(\vartheta) = \chi \cdot \Psi_{\mathrm{cl,ref}} \cdot \frac{\eta(\vartheta)}{\eta_{\mathrm{ref}}} \cdot \frac{\sigma(\vartheta)}{\sigma_{\mathrm{ref}}} \tag{29}$$

The dynamic viscosity and the surface tension can be approximated by polynomial functions according to [21]. Good agreement between calculated and experimental results can be achieved by setting the correction factor (χ) in Eq. (29) equal to 0.5.

4 Model Validation

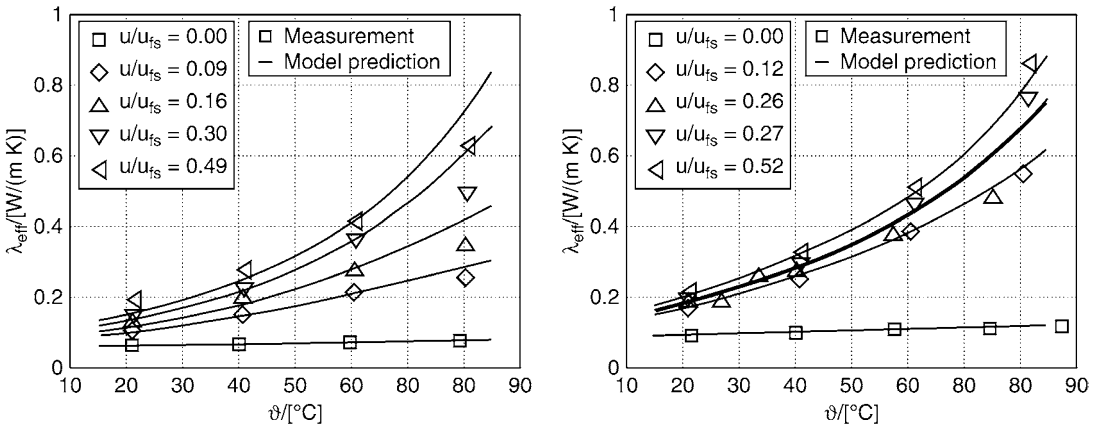
The effective thermal conductivity of several different (bulk) insulation materials (expanded glass expanded clay, perlite, foam glass, mineral wool) was measured according to [22] in a temperature range from 20°C to 80°C for water contents between 0 and the free saturation water content (u_{fs}).



D6.6. Fig. 2. Comparison of model predictions and agreement with experimental results for the fraction of moistened pores (b); EGG: expanded glass granules 4–8 mm type II; btg: expanded clay 4–8 mm type I.

D6.6. Table 2. Fraction of serial and thus poor conductive layers (a) and corresponding values of the radiation constant (c_{rad}), determined using the Nelder-Mead iteration method

Material	Grain size d (mm)	Density ρ (kg/m^3)	Fraction of poor conductive layers a (–)	Radiation constant c_{rad} (W/(m K^4))	Parameter Eq. (28) m1 (–)	m2 (–)
Expanded glass	4–8	185	0.441	$3.9 \cdot 10^{-10}$	–0.0355	0.9979
Expanded clay	4–8	270	0.297	$1.0 \cdot 10^{-10}$	–0.0033	2.9097



D6.6. Fig. 3. Model predictions and measured data for the thermal conductivity (λ_{eff}) of expanded glass granules 4–8 mm type II (EGG: *left*) and expanded clay 4–8 type I (EC: *right*) as a function of the temperature (ϑ) with normalised water content (u/u_{fs}) as parameter.

The lowest thermal conductivity was measured for expanded perlite with about 0.05 W/(m K) at 20°C. The highest value is 0.10 W/(m K) for expanded clay. All investigated porous bulk materials show a (nearly) linear increase of the effective thermal conductivity with temperature when dry, see [23] for details and further results.

The resulting fraction of serial layers (a) and the corresponding radiation constant (c_{rad}) of expanded glass granules and expanded clay are compared in Table 2.

In Fig. 3 model predictions are compared with measured results for expanded glass granules 4–8 mm type II and expanded clay 4–8 mm type I. Good agreement is obtained in the relevant temperature range. Nevertheless, there are deviations at 80°C. Measurement errors at higher temperatures, which are probably caused by heat losses from the guarded heating plate to the ambient, resulting in a measured value of the thermal conductivity that is too low.

5 Summary

An exponential increase of the thermal conductivity with increasing temperature can be recognised above moisture contents of about 50 kg/m^3 (corresponding to $u/u_{fs} \approx 0.1$). For expanded glass granules, the effective thermal conductivity (λ_{eff}) exceeds the reference value (dry, 10°C) of 0.08 W/(m K) by a factor of five at a temperature of 60°C and a moisture content of about 200 kg/m^3; at 80°C even by a factor of 10. A similar behavior can be recognised in the case of expanded clay.

The suggested model predicts the measured data and trends with good accuracy.

6 Symbols

Latin letters

a	fraction of poorly conductive layers (–)
a	thermal diffusivity (m $\cdot$ s^{-2})
b	fraction of moistened pores (–)
c	approximation factor for b(u), model II (–)
c_{rad}	radiation constant (W $\cdot$ m^{-1} $\cdot$ K^{-1})
d	diameter (m)
D	diffusion coefficient (m^2 $\cdot$ s^{-1})
g	acceleration due to gravity (m $\cdot$ s^{-2})
h_v	latent heat of evaporation (kJ $\cdot$ kg^{-1})
m_1, m_2	empirical parameter for b(u), model III (–)
p	pressure (Pa)
R	gas constant (J $\cdot$ (kg $\cdot$ K))$^{-1}$
T	absolute temperature (K)
u	(absolute) moisture content (kg $\cdot$ m^{-3})
V	volume (m^3)

Greek letters

β	coefficient of expansion (K^{-1})
Δ	difference (–)
ε	emissivity coefficient (–)
η	dynamic viscosity (kg $\cdot$ (m $\cdot$ s)$^{-1}$)
ϑ	Celsius temperature (°C)
λ	thermal conductivity (W $\cdot$ (m $\cdot$ K)$^{-1}$)

ν kinematic viscosity ($m \cdot s^{-1}$)
ρ (bulk) density ($kg \cdot m^{-3}$)
σ surface tension ($N \cdot m^{-1}$)
σ_s Boltzmann constant ($W \cdot m^{-2} \cdot K^{-4}$)
φ relative humidity (–)
χ empirical correction factor (–)
Ψ porosity (void fraction) (–)

D6.7 Thermal Conductivity of Building Materials

Hans Werner[1] · *Martin H. Spitzner*[2]
[1]Hochschule für Angewandte Wissenschaften (FH), München, Germany
[2]FIW München, Gräfelfing, Germany

1 Soil

In a totally dry condition, the porosity (ratio of pore volume to total volume) of a material is by far the most important influencing variable in view of the thermal conductivity. In general, soil is to be considered a granular material with a relatively high porosity. As the densities of the components do not vary within a broad range, the density of the dried soil is an appropriate quantity for evaluating the porosity. In practice, one has to expect water within the pores in most of the cases. Based on the test executed by Krischer [1], one can estimate the thermal conductivity of soil with different moisture contents according to Figs. 1 and 2. Concerning the natural moisture content of solid soil, the following empirical values apply:

Soil	Density kg/m3	Moisture content, in % by volume	
		Range of values observed	Usual condition
Argillaceous, clayey sandy	1,900–2,100	10–28	25
	1,600–1,800	4–14	10

The heat transport results from the thermal conduction in porous material. Here, the thermal conductivity λ is decisive. The dependence on temperatures is a result of the relatively weak and nearly linear part of the molecular thermal conductivity (cf. Fig. 3, characteristics of the thermal conductivity of dry material) and of the part of water vapor diffusion which, due to the virtually quadratic dependence on temperatures of the diffusion coefficient, determines the developing of the effective thermal conductivity in humid soils.

At a temperature of about 60°C the apparent thermal conductivity of the air in the humid material, independent of its water content, corresponds to the molecular thermal conductivity of water λ_w = 0.65 W/(m K) and thus, thermal conductivity of the humid material comes up to a value which corresponds to the total saturation of the pores. At still higher temperatures partially waterlogged material shows a higher thermal conductivity than in the case of the total pore saturation. In Fig. 3, the results of the measurements done on sand by Watzinger et al. [2] are shown. Provided the recorded curves are extrapolated beyond the measurement range up to a temperature of about 60°C, one can, based on what had been said earlier, assume that there is a common intersection point.

2 Wood and Derived Timber Products

If wood is in direct contact with air, the moisture content depends on the relative humidity of the air. The humidity of the wood reached after a certain time is referred to as equilibrium moisture content (The equilibrium moisture content is the average moisture content of a material to be expected during its application in practice. Scientifically, it is defined by the so-called sorption isotherm of 10°C for 80% relative humidity.) previously called practical moisture content (moisture content related to mass).

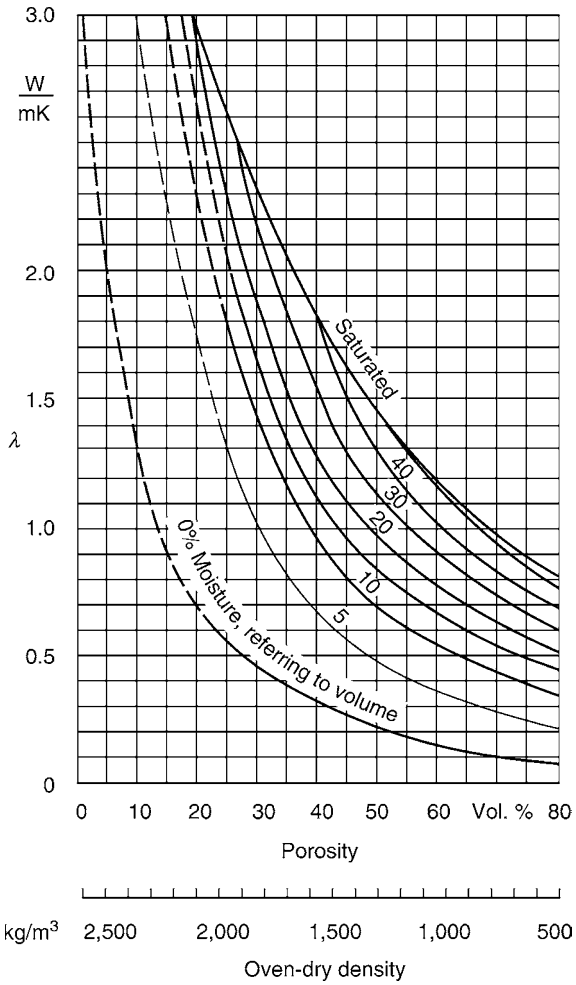
In general, one can assume that, in wood, there are the following relations between relative humidity of the air and equilibrium moisture content:

Relative humidity of air in %	20	40	60	80	100
Equilibrium moisture content at 20°C in % (related to mass)	4	7	11	17	33

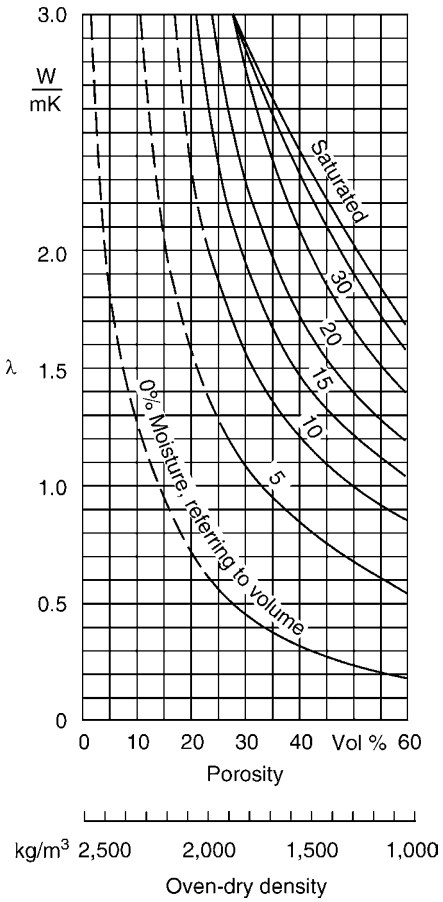
According to DIN 1052-1 [3], the equilibrium moisture content depending on the use categories are as follows:

Use category	1	2	3
Equilibrium moisture content	5–15%[a]	10–20%[b]	12–24%

[a]In most of the coniferous woods, a mean equilibrium moisture content of 12% is not exceeded in use category 1.
[b]In use category 2, a mean equilibrium moisture content of 20% is not exceeded.



D6.7. Fig. 1. Thermal conductivity of soil at a temperature of 20°C.



D6.7. Fig. 2. Thermal conductivity of siliceous sand at a temperature of 20°C.

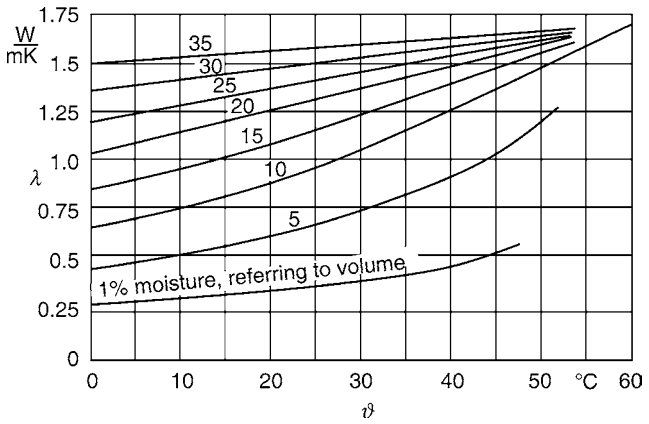
Use categories are identified by equilibrium moisture contents in wood regarding certain application areas. A difference is made between:

Use category 1: Humidities in wood at an air temperature of 20°C and a relative humidity of the ambient air exceeding 65% only during a few weeks per year, e.g., inside all over closed and heated buildings.

Use category 2: Humidities in wood at an air temperature of 20°C and a relative humidity of the ambient air exceeding 85% only during a few weeks per year, e.g., in roofed open buildings.

Use category 3: Climate conditions leading to wood humidities in excess of those mentioned in utilization category 2, e.g., in constructions exposed to outside weather conditions.

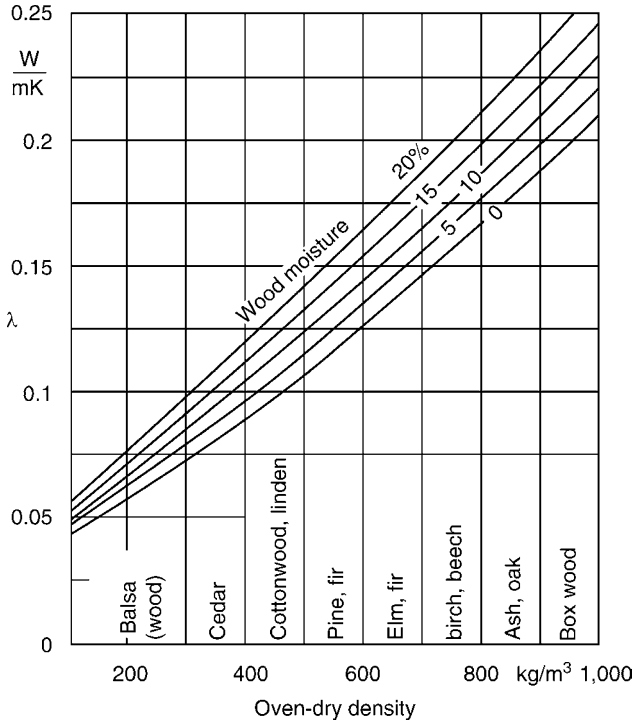
Apart from the moisture content, the thermal conductivity of wood depends above all on the density. Figure 4 shows a diagram made by Koch [4], on which one can see the thermal conductivity perpendicular to the direction of the wood fibers in dependency of the moisture content and density. In the direction of the fibers, the values of the thermal conductivity are twice as high as the ones perpendicular to the direction of the fibers.



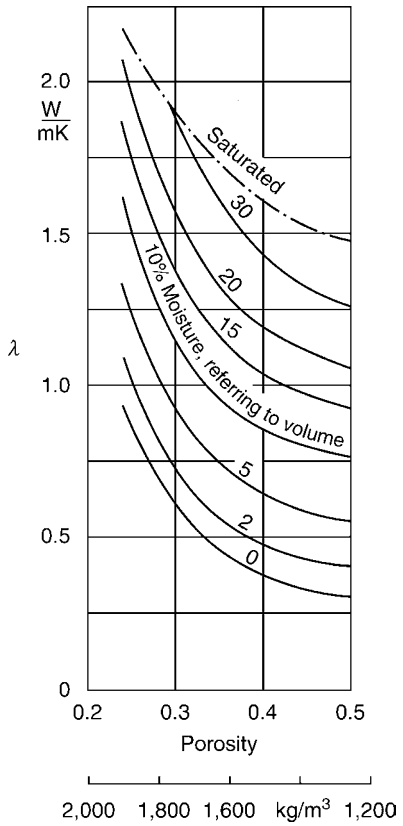
D6.7. Fig. 3. Thermal conductivity of humid sand depending on the temperature.

3 Common Building Materials

Thermal design values of construction material are to be found in DIN V 4108-4 (June 2007, [5]). The values indicated here are referred to as design values of thermal conductivity λ and take into consideration the influence of temperature, moisture



D6.7. Fig. 4. Thermal conductivity of wood perpendicular to the direction of the wood fibers in dependency of moisture content (%) and dry density (kg/m^3) according to [4].



D6.7. Fig. 5. Thermal conductivity of humid bricks depending on the porosity at a temperature of about 20°C according to [8].

D6.7. Table 1. Equilibrium moisture content of building material according to DIN V 4108-4 [5]

Line		Construction material	Moisture content *u* kg/kg
1		Dense concrete with porous aggregate	0.13
2	2.1	Porous lightweight concrete with porous aggregate according to DIN 4226-1	0.03
	2.2	Porous lightweight concrete with porous aggregate according to DIN 4226-2	0.045
3		Gypsum and anhydrite	0.02
4		Melted asphalt and asphalt mastic	0
5		Wood, plywood, fiberboards, reed boards and mats, and organic fiber insulating material	0.15
6		Thermal insulation material out of plant fibers from sea weed, wood, turf, coco, and other fibers	0.15

Further equilibrium moisture contents are listed in Table 6 of DIN 12524:2000-07.

content, variations of the material characteristics, and ageing when applied in the conventional building constructions (cf. scope of DIN V 4108). The moisture content and the condition of application on which the design values are based are to be found in the standards referred to.

Table 1 reproduces the equilibrium moisture content of construction material according to DIN V 4108-4.

In the Tables 2–4, there is an abridged version of DIN V 4108-4 (2007-6) [5], cf. Tables 1 and 2 of this standard. The thermal conductivity of most of the building materials depends largely on their bulk density (mass in relation to the gross volume including all cavities). As most of the industrially fabricated building materials are produced in different apparent densities, thermal conductivity is given in DIN V 4108-4 for different density categories.

All values are only valid for application in conventional building constructions. In case of any other usage condition, there can be variations in view of the given design values.

An analysis of a multitude of research results concerning the influence of the moisture content onto the thermal conductivity of building and insulating materials is published in a paper by Achtziger and Cammerer [6].

The thermal conductivities of specific products (branded products manufactured by industry) can be found in Germany in the Bauregelliste (list of building rules) or in the Allgemeine bauaufsichtliche Zulassung (technical approval) of that product, both of which are published by the Deutsches Institut für Bautechnik (DIBt, German Institute for building technique).

Further tabulated design values are listed in DIN EN 12524 [3]. These values are used if there is no other data given in the national rules and regulations. There is an abridged version in Table 5.

3.1 Masonry

As a general rule, for masonry the design values according to DIN V 4108-4 [5] (having been determined according to DIN EN ISO 10456 [7]) or according to technical approvals (German Allgemeine bauaufsichtliche Zulassung) are applied. In this case, they are based on the moisture content at 23°C and 80% relative humidity. One has to focus on the fact that, with masonry, not only the thermal conductivity of the masonry blocks is taken into consideration in the design value but also that of the mortar and thus, of the resulting effect of thermal bridges.

Due to larger quantities of condensation water, an insufficient protection against driving rain, ground water, and such-like, the moisture content can be far higher than the equilibrium moisture content. This can lead to a negative effect on the thermal insulation of the masonry.

Figure 5 shows the evaluation of measurements on bricks having different densities at a temperature of about 20°C, according to Krischer and Rohnalter [8]. By means of Fig. 5, the influence of the moisture content onto the thermal conductivity of brick masonry can be estimated. Having evaluated the international literature, Cammerer [9] concludes a mean value determining the moisture influence on thermal conductivity of different construction materials for walls to be applied in practice (Table 6). A summing up of the influence of moisture onto the thermal conductivity of other building material as well is mentioned in Cammerer [10]. In practice, however, these fundamental dependencies are not that important as in DIN V 4108-4 [5] and the equilibrium moisture content has already

been taken into consideration. Moisture contents, in practice which are higher than the equilibrium moisture content, need a testing by specialists. Recommendations concerning the then occurring thermal conductivity cannot be given offhand.

3.2 Specific Thermal Capacity

The specific thermal capacity of building materials is a relatively insignificant factor as it is only to be considered in conditions changing at short term (transient). In DIN V 4108-4 [5] these values are not indicated, as in practice only long-term mean values matter, for which near steady-state conditions apply. Only in DIN EN 12524 [3] specific thermal capacities are indicated. One recognizes that, for most of the building materials including industrially produced building materials out of clay, for mineral wool and air, the specific thermal conductivities are at about 1,000 J/(kg·K). Woods show about 1,600 J/(kg·K) and rigid foams about 1,450 J/(kg·K).

Heat Conduction

E1 Steady-State Heat Conduction

Erich Hahne
Universität Stuttgart, Stuttgart, Germany

1 Introduction

Conduction heat transfer is the transfer of energy caused by interaction between adjacent molecules of a stagnant substance, gaseous, liquid, or solid, subject to a temperature difference between some solid boundaries, which means a difference of molecular kinetic energy. Unless they are confined to small spaces, gases and liquids tend to move when heated and transfer heat by the regime of "natural convection." Thus, heat conduction mostly occurs in solid bodies. The basic equation for the heat flow $\dot{Q}$ (rate of heat transferred) is the Fourier law of heat conduction equation (1):

$$\dot{Q} = -\lambda A \frac{\mathrm{d}T}{\mathrm{d}x}. \tag{1}$$

With λ being the thermal conductivity of the material, A the area of the body normal to the heat flow in the direction of x (one dimensional flow), and $\mathrm{d}T/\mathrm{d}x$ the temperature gradient. If there is no dependence on time, there is a steady flow i.e., steady conduction.

In the following, the temperature distribution as shown in Figs. 1 and 2 can be calculated by the given equations if the contacts between the layers are perfect i.e., there are no inhomogeneities (gaps due to roughness or enclosures) between them. These would cause a "contact resistance" with a temperature jump across the gap.

2 Temperature Distribution for Simple Geometries

Equation (1) can be applied to simple geometries such as plane walls, cylindrical, or spherical walls where the heat flow is one-dimensional. In all these cases, constant thermal conductivity is assumed.

2.1 Plane Walls

For plane and multilayered walls with surface A and n layers (Fig. 1), the Fourier equation is transformed into

$$\dot{Q} = \frac{A(T_1 - T_{n+1})}{\frac{s_1}{\lambda_1} + \frac{s_2}{\lambda_2} + \cdots + \frac{s_n}{\lambda_n}}. \tag{2}$$

The temperature distribution in any of the layers, e.g., the kth layer is

$$T = T_k - \frac{\dot{Q}}{A\,\lambda_k}(x - x_k). \tag{3}$$

(Note that $x > x_k$)

The temperature at the end of the kth layer is

$$T_{k+1} = T_k - \frac{\dot{Q}}{A\,\lambda_k} s_k, \tag{4}$$

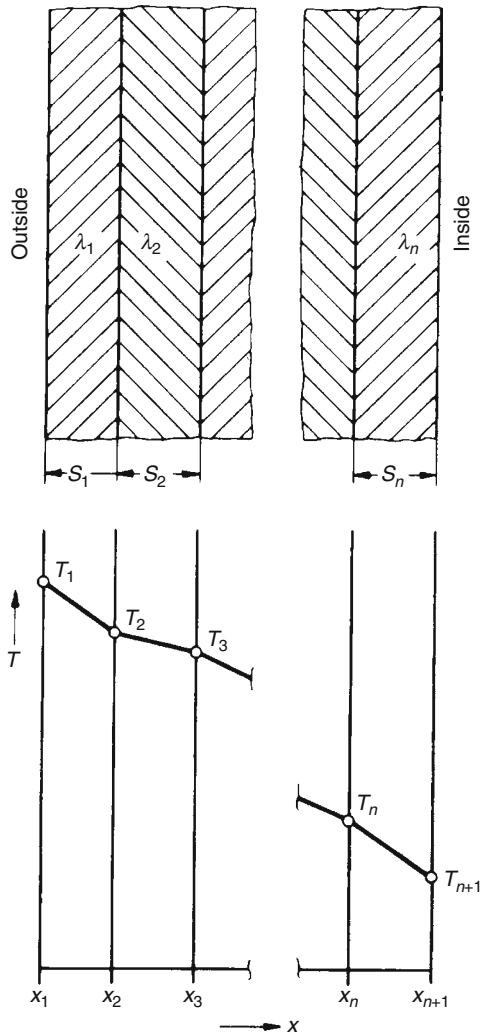
with $x_{k+1} - x_k = s_k$.

2.2 Hollow Cylinders (Pipes)

In single- or multi-layered (e.g., insulated) pipes of length l, with n layers, (Fig. 2) the heat flow is

$$\dot{Q} = \frac{2\pi l(T_1 - T_{n+1})}{\frac{1}{\lambda_1}\ln\frac{r_2}{r_1} + \frac{1}{\lambda_2}\ln\frac{r_3}{r_2} + \cdots + \frac{1}{\lambda_n}\ln\frac{r_{n+1}}{r_n}}. \tag{5}$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_16,



E1. Fig. 1. Temperature distribution in plane walls.

The temperature distribution in any of the layers, e.g., the kth layer is

$$T = T_k - \frac{\dot{Q}}{2\pi l \lambda_\kappa} \ln \frac{r}{r_k}. \tag{6}$$

The temperature at the end of the kth layer is

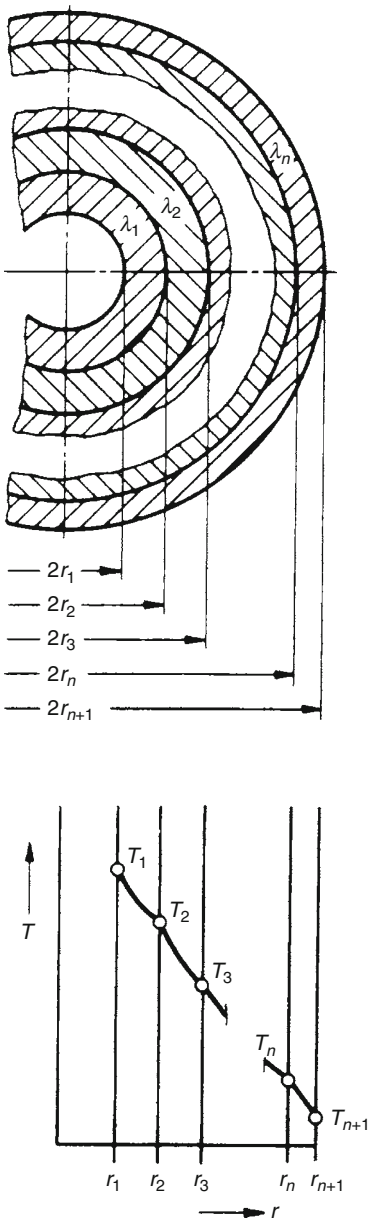
$$T_{k+1} = T_k - \frac{\dot{Q}}{2\pi l \lambda_\kappa} \ln \frac{r_{k+1}}{r_k}. \tag{7}$$

2.3 Hollow Spheres (Spherical Shells)

In single- or multi-layered (n layers) spherical shells (Fig. 2) the heat flow can be obtained from Eq. (8)

$$\dot{Q} = \frac{4\pi (T_1 - T_{n+1})}{\frac{1}{\lambda_1}\left(\frac{1}{r_1} - \frac{1}{r_2}\right) + \frac{1}{\lambda_2}\left(\frac{1}{r_2} - \frac{1}{r_3}\right) + \cdots + \frac{1}{\lambda_n}\left(\frac{1}{r_n} - \frac{1}{r_{n+1}}\right)}. \tag{8}$$

The temperature distribution in any of the layers e.g., the kth layer is



E1. Fig. 2. Temperature distribution in hollow cylinders and spheres.

$$T = T_k - \frac{\dot{Q}}{4\pi \lambda_\kappa}\left(\frac{1}{r_k} - \frac{1}{r}\right). \tag{9}$$

The temperature at the end of the kth layer is

$$T_{k+1} = T_k - \frac{\dot{Q}}{4\pi \lambda_\kappa}\left(\frac{1}{r_k} - \frac{1}{r_{k+1}}\right). \tag{10}$$

2.4 Examples

Example 1

A plane wall tempering furnace with an inside temperature of $T_1 = 1500°C$ is insulated with three layers: magnesite ($\lambda_1 = 2.9\,W/m\,K$), fireclay ($\lambda_2 = 0.8\,W/m\,K$), each 250 mm

thick, and diatomaceous earth ($\lambda_3 = 0.14\,\mathrm{W/m\,K}$) 150 mm thick (Fig. 3). The outside surface temperature was measured as $T_4 = 84°\mathrm{C}$.

What is the temperature distribution in the wall?

Since the temperature distribution is linear and perfect contact is assumed, it is enough to calculate the temperatures at the layer boundaries.

The transferred heat flux $\dot{Q}/A$ according to Eq. (2) is

$$\frac{\dot{Q}}{A} = \frac{1500 - 84}{\frac{0.25}{2.9} + \frac{0.25}{0.80} + \frac{0.15}{0.14}}\,\mathrm{W/m^2} = 963\,\mathrm{W/m^2}.$$

According to Eq. (4)

$$T_2 = \left(1500 - \frac{963}{2.9}0.25\right)°\mathrm{C} = 1417\,°\mathrm{C},$$

$$T_3 = \left(1417 - \frac{963}{0.80}0.25\right)°\mathrm{C} = 1116\,°\mathrm{C},$$

$$T_4 = \left(1116 - \frac{963}{0.14}0.15\right)°\mathrm{C} = 84\,°\mathrm{C}\text{ as given.}$$

Example 2

The outside temperature of an iron pipe with inside/outside diameter 37/40 mm is 600°C (Fig. 4). The pipe is insulated with two layers.

Layer 1: kieselguhr bricks 25 mm thick, $\lambda_1 = 0.14\,\mathrm{W/m\,K}$.

Layer 2: slag wool 45 mm thick, $\lambda_2 = 0.06\,\mathrm{W/m\,K}$

The outside surface temperature of the insulation is $T_3 = 35°\mathrm{C}$.

The temperature distribution should be calculated and drawn. According to Eq. (5) the heat flow per m length is

$$\frac{\dot{Q}}{l} = \frac{2\pi\,(600 - 35)}{\frac{1}{0.14}\ln\frac{0.09}{0.04} + \frac{1}{0.06}\ln\frac{0.18}{0.09}}\,\mathrm{W/m} = 205\,\mathrm{W/m}.$$

For the first layer, the temperature distribution is obtained according to Eq. (6)

$$T = 600°\mathrm{C} - \frac{205}{2\pi\,0.14}\ln\left(\frac{r}{0.02}\right)°\mathrm{C};\ \text{temperature distribution}$$

r in m	0.020	0.025	0.030	0.035	0.040	$0.045 = r_2$
T in °C	600	548	505	469	438	$411 = T_2$

For the second layer with $T_2 = 411°\mathrm{C}$ the temperature distribution is

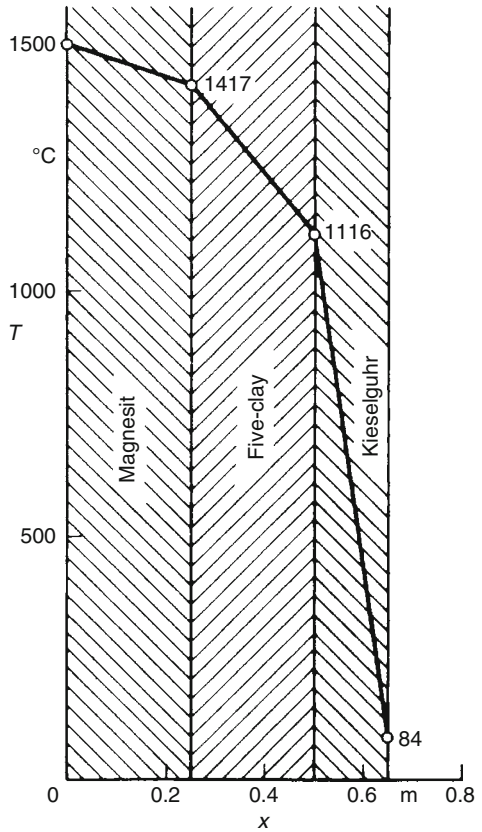
$$T = 411°\mathrm{C} - \frac{205}{2\pi\,0.06}\ln\left(\frac{r}{0.045}\right)°\mathrm{C};\ \text{temperature distribution}$$

r in m	0.045	0.050	0.060	0.070	0.080	$0.090 = r_3$
T in °C	411	354	255	171	99	$35 = T_3$

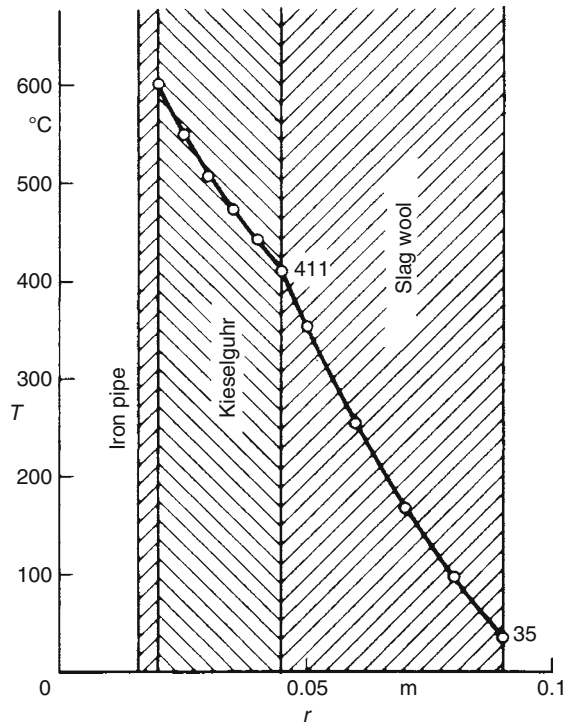
3 Variable Thermal Conductivity

If the thermal conductivity depends on temperature, Eqs. (2), (5), and (8) can still be used, when the thermal conductivity between two temperatures T_k and T_{k+1} can be taken as a mean value according to Eq. (11)

$$\lambda_{k,k+1} = \frac{1}{T_k - T_{k+1}} \int_{T_{k+1}}^{T_k} \lambda\,(\Theta)\,\mathrm{d}\Theta. \qquad (11)$$



E1. Fig. 3. Temperature distribution in an insulated plane wall (example 1).



E1. Fig. 4. Temperature distribution within the insulation around an iron pipe (example 2).

In this case, the temperature distribution in a plane wall is no longer linear. If the temperature dependence of λ is linear

$$\lambda = \lambda_0 + aT. \tag{12}$$

Eq. (11) becomes

$$\lambda_{k,k+1} = \lambda_0 + a\frac{T_k + T_{k+1}}{2}. \tag{13}$$

This means in order to obtain the mean thermal conductivity of a layer, the arithmetic mean of the boundary temperatures has to be introduced.

The equation for the temperature distribution usually cannot be solved for T.

For an arbitrary temperature dependence of thermal conductivity one obtains for plane walls
