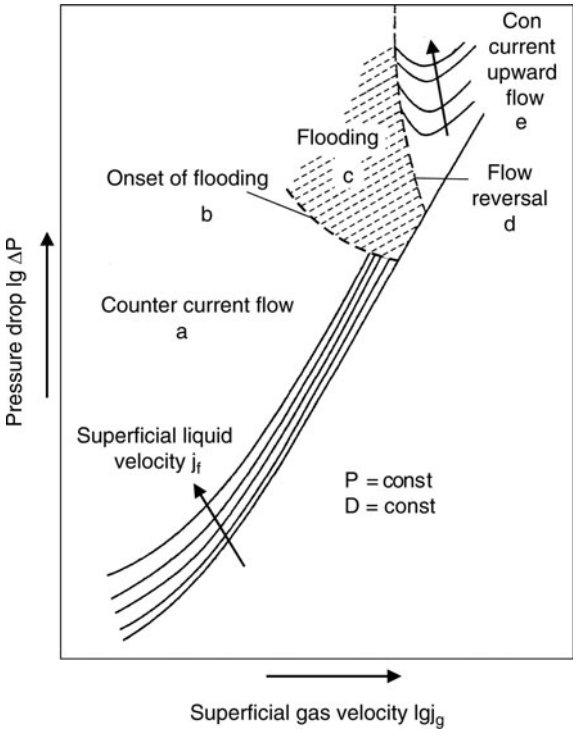
A comparison of results taken from Eq. (2) and measured flooding points is given in Figs. 5 and 6.



L2.5. Fig. 7. Flow transition and pressure drop in gas–liquid flow in vertical pipes.

4 Pressure Drop

The onset of flooding is connected with a strong increase of pressure loss in the gaseous phase flow. In Fig. 7 the measured pressure losses are plotted schematically as a function of the superficial gas velocities. The pressure losses increase already significantly below the flooding point.

The pressure losses are given by three fractions

- The hydrostatic pressure difference
- The friction pressure loss
- The acceleration pressure loss

The last term is omitted for nearly constant film thickness. The other two terms are of equal order as long as the film thickness is constant. If the superficial gas velocity exceeds the flooding point the friction losses become dominant. Slug flow occurs and results in large friction losses. A further increase of gas flow rate exceeding the counter current flow limitation *d*, leads to concurrent upward flow conditions with annular flow *e*, which causes a reduced pressure loss.

Methods for calculation of pressure losses are derived by Zhang [8] and Stephan [9]. They are based on the numerical solution of the momentum transport equations for both phase flows and rely on closure equations empirically derived from experiments. A similar approach is described by Guedes de Carvalho and Talaia [11] by assuming laminar flow in the liquid and turbulent flow in the gaseous phase.

In conclusion there are no methods available for the calculation of pressure losses below the flooding point that lead to more accurate results than those predicted by Feind [2]. This is due to the predominant effect of the exit geometry on flooding and the momentum transfer of dispersed liquid droplets from entrainment effects at the wavy film surface.

5 Example

The water volume flow of 0.14 m^3/h is fed as liquid film into a vertical pipe with 40 mm diameter. Which volume flow of gas marks the onset of flooding?

Densities: $\rho_F = 997\ kg/m^3$ and $\rho_g = 1.17\ kg/m^3$

Superficial liquid velocity	$j_f = \frac{4\dot{V}_l}{\pi D^2} = 0.03\ m/s$
Superficial gas velocity	$j_f^* = j_f \left(\frac{\rho_F}{(\rho_f - \rho_g) D_g}\right)^{1/2} = 0.048$
Superficial gas velocity at the onset of flooding	$j_g^{*1/2} = -0.418 j_f^* - 0.078 j_f^{*1/2} + 0.578 = 0.54$ $j_g^* = 0.29\ m/s$
Superficial gas velocity	$j_g = j_g^* \left(\frac{\rho_g}{(\rho_f - \rho_g) D_g}\right)^{-1/2} = 5.4\ m/s$
Gas volume flow	$\dot{V}_g = j_g \frac{\pi D^2}{4} = 24 m^3/h$

The experimental results give values about 18 m^s/h. The difference is due to the special inlet and outlet conditions of the pipe considered in the experiments.

L2.6 Pressure Drop and Flooding in Packed Towers

Alfons Mersmann
Technische Universität München, Munich, Germany

1 Application of Columns with Packings

Columns with packings are used as heat exchanger and mass transfer apparatus. Arranged-type packings (fabric, stacked packing elements) and dumped-type packing elements are the two types of packings used. In the case of separation processes like distillation and absorption, the gas or the vapor, and the liquid are moving in countercurrent flow. With respect to the design of such columns, it is necessary to calculate the pressure drop of the gas either in the absence or in the presence of a downward liquid flow and the maximum throughput. This chapter is restricted to the pressure drop and the flooding point of arranged-type packings and also of dumped-type packings in which the gas or the vapor is flowing upward in countercurrent to the liquid. The most known packing elements are Rasching rings and Pall rings, and also Berl, Intalox, Novolox, and Torus saddles. Their sizes are between 5 and 200 mm. The elements are made of stoneware, porcelain, glass, stainless steel, and plastic. Often, packing elements with a grill or lattice structures are used.

2 Scheme of a Column; Pressure Drop of Packed Columns

The packing is supported by a plate with holes. The percentage of the total hole area of this plate should approximately be the same as the voidage of the packing. With respect to the liquid flow to the wall, packings are subdivided into sections with heights between 1 and 3 m in order to redistribute the liquid. In the case of high-efficiency distributors and packing elements with a poor tendency of liquid flow to the wall the ratio 8 of the height to the diameter of the column can be chosen.

If the packed column is used as a mass transfer apparatus (rectification, stripping, absorption and desorption), the number of irrigation points should be approximately 250 openings/m^2 in the case of 50 mm packing elements [34]. The horizontal adjustment of trough distributors with holes is very important when the dripping flow is caused by gravity (see Fig. 1).

Distributors operated under pressure are less sensitive with respect to maldistribution; however, cleaning can be a problem.

Principally speaking, it is reasonable to distinguish between dry, wetted, and irrigated packings.

2.1 "Dry" Pressure Drop

When a gas or vapor is passing through a dry packing with the surface $a_t = 6(1 - \psi)\ d_p$ and the height H the so-called dry pressure Δp_t is given by

$$\Delta p_t = \xi \frac{\rho_G\ u_G^2}{2} \frac{(1-\psi)H}{\psi^3 d_p}$$

where ξ = friction factor of the packing

ψ = voidage or porosity of the packing
u_G = superficial gas velocity
ρ_G = density of the gas
d_P = particle diameter of an element according to

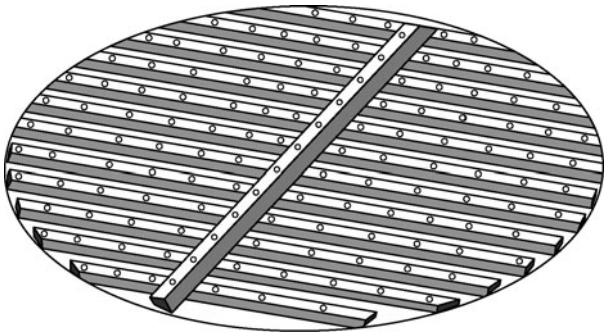
$$d_p = \frac{6 \text{ Volume of an element}}{\text{Surface of an element}}$$

Data of ψ and d_p are listed in Table 1. The exact voidage ψ is mostly a result of the filling procedure of the elements in the column. According to Eq. (1), the pressure drop is mainly dependent on the factor $(1 - \psi)/\psi^3$ or $(1 - \psi)/\psi^{4,65}$ [18]. Since the exact data of the voidage of a column under discussion are not known, it is understandable that "dry" pressure drops in columns with the same packing elements can be found in a certain range.

The friction factor ξ of different packing elements is plotted against the Reynolds number Re_G of the gas according to

$$Re_G = \frac{u_G d_p}{(1-\psi)\nu_G}$$

ν_G is the kinematic viscosity of the gas. The lines in Figs. 2 and 3 are valid for different types of elements shown in Figs. 4 and 5. Spheres, saddles, and cylinders are the basic types.



L2.6. Fig. 1. Trough distributor.

In Fig. 2, the friction factor ξ is plotted against the Reynolds number for the basic types: spheres and cylinders, and special corresponding forms. The friction factor decreases slightly with the Reynolds number and values can be found between 2 and 10 for $Re_G > 10^4$. In the case of saddle-type elements, it is reasonable to plot the friction factor ξ against a modified Reynolds number for which the hydraulic diameter $d_h = \psi\ d_P/(1-\psi)$ in Eqs. (1) and (2) is replaced by the diameter d_P of a sphere with the same volume as the element. In Fig. 2 friction factors for saddles can be found. The values in this modified plot are in the range between 3 and 10 for large Reynolds numbers. All these data are taken from the literature and there are fluctuations between ±25% and even 30% depending on the filling procedure. In the case of full elements, granules, long and very short cylinders and tablets the Ergun equation can be used:

$$\xi = \frac{300}{Re_G} + 3.5.$$

This equation can also be applied for elements with an inner voidage if the diameter d_P is replaced by the ring diameter multiplied by a factor which depends on the voidage ψ_R of the packing of Raschig rings. More information is available in several works [4–7, 9–11].

2.2 Pressure Drop in An Irrigated Packing

The hold-up of the liquid in an irrigated column increases with the superficial velocity or the liquid flow rate based on the unit of the cross-section area. As a consequence, the voidage of the dry packing is reduced with the result that the pressure drop is increased for a given gas flow rate. Even in the case where the packing is wetted only with some stagnant liquid, the pressure drop can be up to 20% higher in comparison with a completely dry packing.

In Figs. 6a and 6b, the pressure drop in an irrigated packing and the liquid hold-up, respectively, are plotted against the so-called F-factor with $F_V = u_G\ (\rho_G)^{1/2}$ for 50 mm Hiflow rings and three different superficial liquid velocities [19] (system air/water). The liquid hold-up is independent of the gas velocity below the loading range but increases with rising liquid velocities. In the gas velocity range above the so-called loading range the hold-up rises with the gas factor F_V. At the flooding point the downward liquid flow is blocked to a certain degree with the result that the hold-up is increased according to $h_L \rightarrow \psi$.

3 Operating Ranges of Packed Columns

3.1 Flooding Point

The higher the superficial liquid velocity the smaller is the superficial gas velocity at the flooding point. The diagram in Fig. 7 can be used for arbitrary gases, liquids, and packings in wide ranges of pressure and temperature in order to calculate the flooding limit. The accuracy of the lines in this diagram is approximately ±25%. This is understandable because the accuracy of the pressure drop of a gas flowing in a dry dumped-type packing is approximately the same as has been outlined already. According to Engel [33], the flooding limit can be calculated by the equation

$$\frac{\Delta\rho_t}{\rho_L g H} = \Delta\rho^*_{t,Fl} = C_{1,Fl} + C_{2,Fl}(B^*)^{C_{3,Fl}}$$
$$C_{1,Fl} = 2.92,\ C_{2,Fl} = -30.809$$
$$C_{3,Fl} = 0.01.$$

An even more accurate calculation of the flooding limit is difficult because the term flooding point is used for the description of two different physical phenomena:

In the case of small packing elements made of stoneware or ceramics with a high wettability and water (σ_L high) the voidage of the packing is filled with liquid for u_L = const but increasing u_G with the result that the downward flow of the liquid is hindered ($h_L \rightarrow \psi$).

Dealing with large elements made of plastics and with organic liquids (σ_L small) drops are formed and their number increases with the irrigation rate. Rising gas velocities lead to entrainment of the liquid. The importance of this phenomenon is increased by the following ratio:

$$\frac{\text{Drop diameter } d_T}{\text{Effective hydraulic diameter } d_{h,eff}} \text{ or}$$
$$\frac{d_T}{d_{h,eff}} = 0.61\ \frac{a_t}{\psi - h_L}\sqrt{\frac{\sigma_L}{(\rho_L - \rho_G)\times g}}$$
$$\text{with } h_L = \frac{\text{Liquid volume}}{\text{Total volume of the packing}}$$

The flooding limit is the result of numerous data published in the literature valid for elements within the following ranges:

$0.7 < \psi < 0.98$

$60\ m^{-1} < a_t < 300\ m^{-1}$

$0.01\ m < d_N < 0.09\ m.$

Reichelt [13] investigated the flooding limit of ceramic elements with the ratio of the column diameter based on the element diameter between 2 and 10. According to his recommendation the following hydraulic diameter should be used:

$$d_{hw} = \frac{\psi d_p}{\frac{3}{2}(1-\psi) + \frac{d_p}{D}}$$

This diameter takes into account the surface provided by the column wall. In addition, based on results obtained by Gieseler [14] and Billet [15] the flooding limit can be predicted with more accuracy in the case of viscous liquids when the dimensionless liquid velocity B^* is multiplied by the factor

$(\nu_G/\nu_L)^{0.1}$. This means that the exponent of the liquid viscosity is only 0.233 instead of 0.333. Later, in Sect. 3.4, it will be shown that this exponent decreases with the liquid Reynolds number $u_L/(a_t\,\nu_L)$ and disappears for $\nu_L{}^2 a_t{}^3/g \to 0$.

Arranged-type packings are used for distillation and absorption columns in order to reduce the pressure drop of the vapor or the gas. According to Fig. 2, the pressure drop in such packings is approximately only 50% in comparison to the most favorable dumped-type elements. The flooding of arranged-type packings can be calculated as has been outlined earlier.

3.2 Loading Limit

The loading limit is defined as the superficial gas velocity at which the liquid hold-up increases for a given superficial liquid velocity. This limit can be taken from Fig. 7; however, this limit cannot be predicted very accurately because of the uncertainties of the voidage ψ caused by differences of the filling procedures of the elements. According to Engel [33] the loading limit can be calculated from

$$\Delta\rho^*_{t,\mathrm{Load}} = C_{1,\mathrm{Load}} + C_{2,\mathrm{Load}}(B^*)^{C_{3,\mathrm{Load}}}$$
$$C_{1,\mathrm{Load}} = 0.57576,\quad C_{2,\mathrm{Load}} = -0.63288$$
$$C_{3,\mathrm{Load}} = 0.017.$$

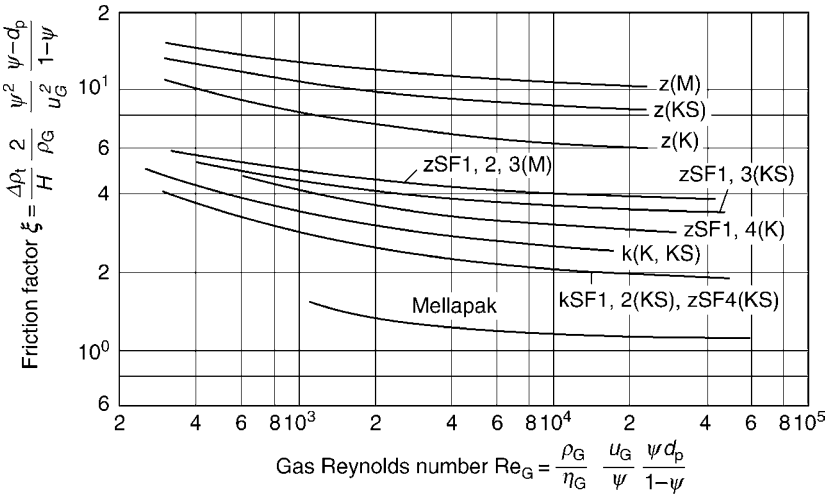
3.3 Other Operating Points

Figure 7 is a tool in order to calculate other operating points. Approximately, the simple relationship $u_G{}^0 = 0.65\ u_{G,Fl}$ is valid for the loading limit. According to Engel [32] the parameter in Fig. 7 can be described by the following equations:

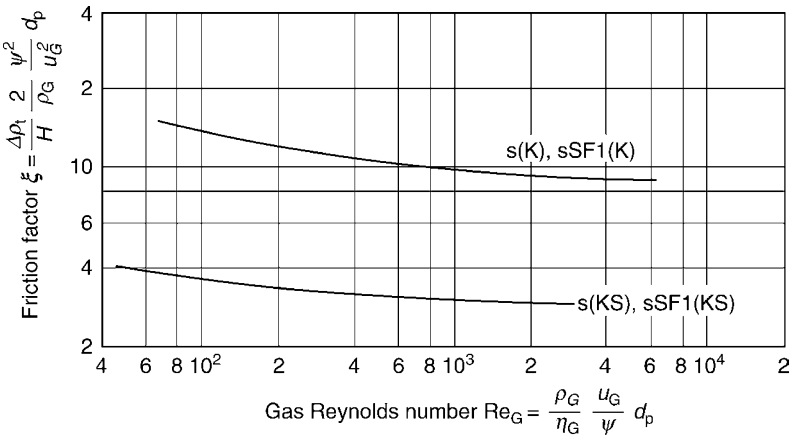
$$\Delta p^*_t = C_1(\Delta p^*) + C_2(\Delta p^*)\cdot[C_3(\Delta p^*) + B^*]^{0.04}$$
$$C_1(\Delta p^*) = -4.3513\times10^{-6} + 8.6424\cdot\Delta p^* - 58.1789\cdot(\Delta p^*)^2 + 170.255\cdot(\Delta p^*)^3.$$
$$C_2(\Delta p^*) = -2.8884\times10^{-4} - 10.6464\cdot\Delta p^* + 71.4375\cdot(\Delta p^*)^2 - 210.7186\cdot(\Delta p^*)^3.$$
$$C_3(\Delta p^*) = +2.4758\times10^{-4} + 5.517\times10^{-3}\cdot\Delta p^* + 0.03503\cdot(\Delta p^*)^2 - 0.069512\cdot(\Delta p^*)^3.$$

3.4 Hold-Up

The total liquid hold-up is composed of the static hold-up and the dynamic hold-up which is important for mass transfer. In the case of large packing elements and low viscous irrigation liquids the dynamic contribution is dominant. Below the loading limit the liquid hold-up increases with the superficial liquid velocity and the superficial gas velocity plays no role. Experimental results of numerous authors [7, 18, 20, 27, 28, 31] are the basis of the following calculation procedure. In Fig. 8, the liquid hold-up $h_L{}^0$ below the loading point is plotted against the Froude number $(u_L{}^2 a_t/g\psi^4)^{1/3}$ with the expression $(\nu_L{}^2 a_t{}^3/g)$ as parameter. This diagram has been chosen because the most important equations valid for $h_L{}^0$ can be transformed into special equations with the possibility to compare them (see Table 2). According to Fig. 8, the liquid hold-up increases with rising values of the irrigation Froude number and the viscosity parameter. The higher the liquid viscosity and the larger the volume-based surface of a packing element, the smaller is the slope of the parameter in Fig. 8. Modern packing elements with outer sizes between 25 and 35 mm, voidages above 0.97 and small volume-based surfaces lead to viscosity parameters between 10^{-6} and 10^{-8} for low viscous liquids (distillation at normal and high pressure). The equations in Table 2 are developed for this case. In the equation of Stichlmair [18] there is no influence of the liquid viscosity, and the proportionality $h_L{}^0 \sim (u^{2/3}{}_L)$ is the steepest slope in Fig. 8. This can be expected for high Froude numbers. Billet, Mackowiak, and Kim [27] have derived an equation which takes into account the liquid viscosity. The relationship $h_L{}^0 \sim u_L{}^{0.5}$ can be expected for small and medium Froude numbers. Based on numerous experimental results, Bornhütter and Mersmann [20, 31] obtained the relationship $h_L{}^o \sim u_L{}^{0.5}$, which is reasonable for operating ranges applied in industrial columns. In the case that the viscosity parameter is above 10^{-4} the exponent of the superficial liquid velocity u_L is smaller $(u_L{}^{0.46})$. This corresponds to an equation published by Gelbe [18, 29] valid for very small packing elements. However, in this case the static hold-up can be dominant. The influence of the liquid surface tension σ_L is poor in packings with large elements; however, this liquid property plays an important role for the static hold-up and the liquid attached to the packing after stopping the irrigation. The hold-up at the flooding point can be described by the ratio $u_L/u_{G,Fl}$.



L2.6. Fig. 2. Friction factor of the basic type cylinder (z) and sphere (k) against the Reynolds number of the gas [16].



L2.6. Fig. 3. Friction factor of the basic type sphere (s) against the Reynolds number of the gas [16].

In the case of large packing elements ($\psi > 0.8$; $a_t < 200\ m^{-1}$) the authors recommend

$$\frac{h_{L,Fl}}{\psi} = 0.83 \cdot \left[\frac{u_L}{u_{G,Fl}} \cdot \left(\frac{\sigma_L}{\Delta\rho g}\right)^{1/2} \frac{a_t}{\psi}\right]^{1/3}$$

and for small elements ($\psi < 0.8$; $a_t > 200\ m^{-1}$)

$$\frac{h_{L,Fl}}{\psi} = 0.62 \cdot \left[\frac{u_L}{u_{G,Fl}} \cdot \left(\frac{\sigma_L}{\Delta\rho g}\right)^{1/2} \frac{a_t}{\psi}\right]^{1/4}$$

with an accuracy of ±20%. In the region between the loading and the flooding limit the hold-up is approximately

$$h_L = h_L^0 + (h_{L,Fl} - h_L^0) \cdot \left(\frac{u_G}{u_{G,Fl}}\right)^7.$$

Example

Calculate the pressure drop Δp of a gas which is flowing through a packing of 50 mm Hiflow rings with the height $H = 1$ m. The superficial velocities are

$$u_G = 2.36\ m/s \text{ and } u_L = 5.55\ 10^{-3} m^3/(m^2 s)$$

Data

Density of the gas $\rho_G = 1{,}2\ kg/m^3$
Density of the liquid $\rho_L = 1{,}000\ kg/m^3$
Kinematic viscosity of the gas $\nu_G = 13^*10^{-6}\ m^2/s$
Kinematic viscosity of the liquid $\nu_L = 10^{-6}\ m^2/s$
Voidage of the packing $\psi = 0.926$
Volume based surface $a_t = 90.7\ m^2/m^3$

1. Dimensionless irrigation rate

   $B^* = (\eta_L/(\rho_L g^2))^{1/3}(1-\psi)\ u_L/(\psi d_P) = 0.000198$
2. F-factor

   $F = u_G(\rho_G)^{1/2} = 2.59(Pa)^{1/2}$
3. Particle diameter

   $d_P = 6(1-\psi)/a_t = 0.00489\ m$
4. Friction factor at the operating point

L2.7 Pressure Drop and Operating Limits of Trays

Johann Stichlmair
Technische Universität München, Garching, Germany

1 Fundamentals

The pressure loss of a gas (or vapor) flowing through a tray column results from the sum of the dry pressure loss Δp_d and the pressure loss Δp_L due to the hydraulic head of the tray:

$$\Delta p = \Delta p_d + \Delta p_L \tag{1}$$

The dry pressure loss can be predicted from the equations presented in Subchap. L1.7. The pressure loss Δp_L is primarily caused by the static head of the liquid in the froth on the tray. The influence of other mechanisms such as formation of bubbles, lateral mixing of liquid, and entrainment of drops can be neglected at normal operation conditions.

2 Two-Phase Flow on Trays

The theoretical prediction of the pressure loss of a tray requires detailed information about the two-phase flow on the tray. Of special importance are the height of the froth h_f and its liquid hold-up ε_L. The maximum gas load F_{max}, which can be modeled from first principles, is decisive for both quantities.

2.1 Maximum Gas Load of Trays

At high gas loads, there exists a so-called drop regime in the froth on the tray [1, 2]. Here, the gas (or vapor) constitutes the continuous phase, and the liquid constitutes the dispersed phase (droplet phase). The space above the plate consists of a zone of drop formation and a zone of drop entrainment. It is the velocity and not the direction of the gas jets emerging from the orifices (e.g., holes, bubble caps, valves) that determines the size of the droplets in the froth. The gas jets penetrate into the two-phase layer and act like a jet mill. The liquid drops are entrained into the jets, accelerated, and eventually deformed. After having lost their spherical shape, the drops are torn into pieces. Drop stability is described by the ratio of friction and surface forces that constitute the Weber number *We*:

$$\mathrm{We} \equiv \frac{\rho_G \cdot u_{Gh}^2 \cdot d}{\sigma} \tag{2}$$

The maximum size of drops is determined by a critical value of the Weber number We_{crit}.

The equation of continuity formulates a relationship between jet velocity u_{Gh} and superficial velocity u_G:

$$u_G = u_{Gh} \cdot \varphi \tag{3}$$

Here, φ denotes the relative free area of a tray. Combining Eqs. (2) and (3) allows the prediction of drop size in the drop formation zone:

$$d = \mathrm{We}_{crit} \cdot \frac{\sigma \cdot \varphi^2}{\rho_G \cdot u_G^2} \tag{4}$$

In the entrainment zone far above the plate, there exists a uniform gas velocity (i.e., superficial velocity) u_G. A balance of friction, weight, and buoyancy forces yields:

$$\frac{d^2 \cdot \pi}{4} \cdot \zeta_{sp} \cdot \frac{\rho_G}{2} \cdot u_G^2 = \frac{d^3 \cdot \pi}{6} \cdot (\rho_L - \rho_G) \cdot g \tag{5}$$

After rewriting:

$$d = \frac{3}{4} \cdot \frac{\zeta_{sp}}{(\rho_L - \rho_G) \cdot g} \cdot \rho_G \cdot u_G^2 \tag{6}$$

Eliminating the drop diameter from Eqs. (4) and (6) yields:

$$u_{G\,max} \cdot \sqrt{\rho_G} = \left(\frac{4 \cdot \mathrm{We}_{crit}}{3 \cdot \zeta_{sp}}\right)^{1/4} \cdot (\varphi^2 \cdot \sigma \cdot (\rho_L - \rho_G) \cdot g)^{1/4} \tag{7}$$

According to [3] the value of the critical Weber number is:

$$\mathrm{We}_{crit} = 12 \cdot \left(1 + \left(\frac{\eta_L^2}{d \cdot \sigma \cdot \rho_L}\right)^{0.36}\right) \approx 12 \tag{8}$$

For low viscous liquids normally processed in separation columns, Eq. (8) yields a value of 12.

The friction factor of spheres at high Reynolds numbers has a constant value:

$$\zeta_{sp} \approx 0.4 \tag{9}$$

In engineering literature, the gas load is often expressed by the so-called F-factor, which is defined by:

$$F \equiv u_G \cdot \sqrt{\rho_G} \tag{10}$$

Combining Eqs. (8), (9), and (10) delivers a very important relationship for the upper limit of the gas load on a tray [1, 2]:

$$F_{max} \approx 2.5 \cdot (\varphi^2 \cdot \sigma \cdot (\rho_L - \rho_G) \cdot g)^{1/4} \tag{11}$$

Equation (11) is valid for the so-called entrainment flooding. This theoretically derived equation corresponds very well with published experimental data and with the well-known empirical correlation of Fair [4]. It is important to note that the maximum gas load is proportional to $\sigma^{1/4}$ (σ surface tension) and $\varphi^{1/2}$ (φ relative free area). Both dependencies agree very well with experimental findings.

2.2 Liquid Hold-Up in the Froth

The mean liquid hold-up ε_L in the froth is defined as:

$$\varepsilon_L \equiv h_L/h_f \tag{12}$$

There exists a large database for both the clear liquid height h_L and the froth height h_f. All data are well correlated by [1, 2]:

$$\varepsilon_L = 1 - (F/F_{max})^{0.28} \tag{13}$$

This simple equation implies in the term F_{max} several system properties of the liquid and geometrical data of the tray.

2.3 Froth Height

The height of the froth on a tray is primarily determined by the conditions of the flow over the outlet weir. Firstly, the froth height h_f can, at normal operation, be not lower than the weir height h_w. Secondly, the volume flow over the weir contributes significantly to froth height. However, it has to be considered that the volume flow of the two phase mixture $\dot{V}_L/\varepsilon_L$ is the decisive quantity in the weir formula (Francis equation), and not the liquid flow $\dot{V}_L$ alone. Thirdly, the two-phase layer on the tray is additionally increased by elevation forces of the gas flowing upwards through the froth. All tree mechanisms lead to the following relationship [1, 2]:

$$h_f = h_w + \frac{1.45}{g^{1/3}} \cdot \left(\frac{\dot{V}_L/l_w}{\varepsilon_L}\right)^{2/3} + \frac{125}{(\rho_L - \rho_G) \cdot g} \cdot \left(\frac{F - 0.2 \cdot \sqrt{\rho_G}}{1 - \varepsilon_L}\right)^2 \tag{14}$$

At high liquid loads, the second term of Eq. (14) predominates the height of the froth. The third term is significant only at very high gas loads.

In column operation it has to be ensured that the froth height is lower than the tray spacing, which is typically in the rage from 0.3 to 0.6 m. Therefore, the feasible gas load F is in most cases lower than the maximum gas load F_{max}.

3 Pressure Loss of Tray Columns

The total pressure loss Δp of a tray can be easily predicted from Eq. (15):

$$\Delta p = \Delta p_d + h_f \cdot \varepsilon_L \cdot \rho_L \cdot g \tag{15}$$

The quantities in Eq. (15) are evaluated from Eqs. (13) and (14) and from the equations developed in Subchap. L1.7.

Typical values of the pressure loss of a tray are shown in Fig. 1. It should be noted that the general relation $\Delta p \propto \rho \cdot u^2$ holds for the dry pressure drop only. Normally, the pressure drop data are in the rage from 400 to 600 N/m^2 (i.e., 4–6 mbar). Assuming a mass transfer efficiency of a tray of 80% the pressure loss per equilibrium stage is as high as 5–8 mbar. This value is by a factor of 5 higher than the corresponding pressure drop of packed columns.

4 Example

Find the pressure loss of a sieve tray operated with air and water at ambient conditions.

Data: Tray design: $\varphi = 0.125$, $d_h = 5$ mm, $s/d_h = 1$, $h_w = 5$ cm
Tray operation: $u_G = 1.8$ m/s, $\dot{V}_L/l_w = 20$ m^3/(m · h)
System properties: $\rho_G = 1.2$ kg/m^3, $\eta_G = 18 \cdot 10^{-6}$ kg/(m · s), $\rho_L = 1{,}000$ kg/m^3, $\sigma = 0.072$ kg/s^2

4.1 Dry Pressure Loss

Evaluation of the orifice coefficient ζ from Fig. 2 in Subchap. L1.7.

$$Re_h = \frac{d_h \cdot u_h \cdot \rho_G}{\eta_G} = \frac{5 \cdot 10^{-3} \cdot 1.8/0.125 \cdot 1.2}{18 \cdot 10^{-6}} = 4.800$$

Reading from Fig. 2: $\zeta_o \approx 1.7$

Equation (16):

$$\zeta = \zeta_o + \varphi^2 - 2 \cdot \varphi \cdot \sqrt{\zeta_o} = 1.7 + 0.125^2 - 2 \cdot 0.125 \cdot \sqrt{1.7} = 1.39$$

Equation (1):

$$\Delta p = \zeta \cdot \frac{\rho_G}{2} \cdot u_{Gh}^2 = 1.39 \cdot \frac{1.2}{2} \cdot \left(\frac{1.8}{0.125}\right)^2 = 173 \text{ N/m}^2$$

4.2 Total Pressure Loss

Equation (13):

$$\varepsilon_L = 1 - (F/F_{max})^{0.28}$$

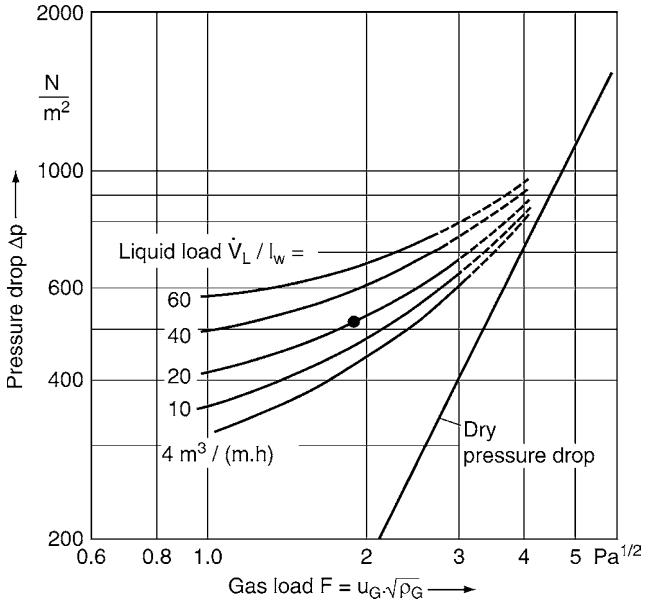
Equation (11):

$$F_{max} \approx 2.5 \cdot (\varphi^2 \cdot \sigma \cdot (\rho_L - \rho_G) \cdot g)^{1/4} =$$
$$2.5 \cdot (0.125^2 \cdot 0.072 \cdot (1.000 - 1.2) \cdot 9.81)^{1/4} = 4.55 \text{ Pa}^{1/2}$$

Equation (13):

$$\varepsilon_L = 1 - (1.8 \cdot \sqrt{1.2}/4.55)^{0.28} = 0.2087$$

Froth height h_f



L2.7. Fig. 1. Pressure loss characteristics of a column tray.

Equation (14):

$$h_f = h_w + \frac{1.45}{g^{1/3}} \cdot \left(\frac{\dot{V}_L/l_w}{\varepsilon_L}\right)^{2/3} + \frac{125}{(\rho_L - \rho_G)\cdot g} \cdot \left(\frac{F - 0.2\cdot\sqrt{\rho_G}}{1-\varepsilon_L}\right)^2$$

$$= 0.5 + \frac{1.45}{9.81^{1/3}} \cdot \left(\frac{20/3,600}{0.2087}\right)^{2/3} + \frac{125}{(1,000 - 1.2)\cdot 9.81} \cdot \left(\frac{(1.8-0.2)\cdot\sqrt{1.2}}{1-0.2087}\right)^2$$

$$= 0.05 + 0.0604 + 0.0624 = 0.173\ \text{m}$$

Total pressure loss:

$$\Delta p = \Delta p_d + h_f \cdot \varepsilon_L \cdot \rho_L \cdot g = 173 + 0.173 \cdot 0.2087 \cdot 1.000 \cdot 9.81$$
$$= 173 + 354 = 527\ \text{N/m}^2$$

This value is marked in Fig. 1.

5 Symbols

d drop diameter (m)

L3.1 Particle Motion in Fluids

Martin Sommerfeld
Martin-Luther-Universität Halle-Wittenberg, Halle (Saale), Germany

1 Introduction

The motion of particles (solids, droplets, and bubbles) in fluids is relevant for a number of processes in chemical engineering, biotechnology, process engineering, and energy conversion. The different forces acting on the particles constitute in many cases the basis for process layout and optimization. Examples of such processes are pneumatic conveying, fluidized beds, sedimentation, dispersion of particles in a stirred vessel, aerodynamic classification of powders, and particle separation in cyclones. Such kind of two-phase flows is termed as "dispersed flows" where individual particles are more or less homogeneously distributed in the continuous phase (i.e., gas or liquid). In dilute dispersed systems, the particle transport is governed mainly by fluid dynamic forces acting on the particle surface in addition to external field forces (e.g., gravity, buoyancy, and electrical forces). On the other hand one finds dense dispersed two-phase flows, e.g., fluidized beds, where additionally fluid dynamic interactions and collisions between particles are of great importance (see for example [1]). In a number of simple design strategies, a quasi-steady particle motion is assumed. Such approaches are for example used to determine the sedimentation velocity of particles, being the basis for determining the size of a sedimentation tank or a sedimentation centrifuge and to calculate the cut size of a cyclone based on a force balance. However, for the design of a number of processes, involving mostly turbulent flows, the full equation of motion for the particles has to be solved in order to obtain for example the particle residence time or better the residence time distribution. In such turbulent flows, the particle transport due to the turbulent eddies has to be accounted for, in addition to the relevant fluid dynamic and external forces. A residence time distribution of particles is for example important for finding the appropriate operational conditions of different multiphase chemical reactors, e.g., stirred vessel, bubble column, or loop reactor. In addition, the knowledge on particle motion and relevant forces is essential for the numerical calculation of dispersed multiphase flows. The two approaches mainly used for technical and industrial multiphase flows are the two-fluid (or Euler/Euler) method [2] and the Euler/Lagrange approach in combination with an appropriate turbulence model [3, 4]. More details about the numerical calculation of dispersed multiphase flow may be found in the publications [5–7].

2 Equation of Motion for Particles

The motion of particles in fluids may be described in a Lagrangian way by solving a set of ordinary differential equations along the trajectory in order to calculate the change of particle location and the linear as well as angular components of the particle velocity. This requires the consideration of all relevant forces acting on the particle. The equation of motion for small spherical particles in a viscous quiescent fluid (i.e., for small particle Reynolds numbers, which is also referred to as Stokes flow) goes back to the pioneering work of Basset, Boussinesq, and Oseen [8–10]. Therefore, the equation of motion is mostly referred to as BBO equation. Numerous publications deal with the extension of the BBO equation for turbulent flows. The thesis of Tchen [11] was probably the first study on particle motion in turbulent flows based on the BBO equation. A rigorous derivation of the equation of motion for small spherical particles in nonuniform flow has been performed by Maxey and Riley [12]. Neglecting the Faxen terms (for details see [3]), the equation proposed by Maxey and Riley [12] for small particle Reynolds numbers is as follows:

$$m_P \frac{d\vec{u}_P}{dt} = \frac{18\mu_F}{\rho_P D_P^2} m_P (\vec{u}_F - \vec{u}_P) - m_F \frac{D\vec{u}_F}{Dt} + 0.5 m_F \left(\frac{D\vec{u}_F}{Dt} - \frac{d\vec{u}_P}{dt} \right) + 9 \sqrt{\frac{\rho_F \mu_F}{\pi}} \frac{m_P}{\rho_P D_P} \int_{-\infty}^{t} \frac{\frac{D\vec{u}_F}{D\tau} - \frac{d\vec{u}_P}{d\tau}}{(t-\tau)^{1/2}} d\tau + (m_P - m_F)\vec{g}. \quad (1)$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_48,

The forces on the right-hand side are the drag force, the fluid inertia (resulting from the pressure term), the added mass, the history force, and the gravity force reduced by the buoyancy. In the following sections, a possible extension of the BBO equation and the involved forces for higher particle Reynolds numbers will be introduced. In addition, other forces, which might be relevant for certain flow conditions, such as for example transverse lift forces, will be introduced and their relevance will be discussed. Neglecting heat and mass transfer phenomena, the calculation of particle trajectories requires the solution of three ordinary differential equations when particle rotation is accounted for. Hence, the differential equations for calculating the particle location and the linear and angular velocities in vector form are given by

$$\frac{\mathrm{d}\vec{x}_\mathrm{p}}{\mathrm{d}t} = \vec{u}_\mathrm{p}, \tag{2}$$

$$m_\mathrm{p}\frac{\mathrm{d}\vec{u}_\mathrm{p}}{\mathrm{d}t} = \sum \vec{F}_\mathrm{i}, \tag{3}$$

$$I_\mathrm{p}\frac{\mathrm{d}\vec{\omega}_\mathrm{p}}{\mathrm{d}t} = \vec{T}, \tag{4}$$

where $m_\mathrm{p} = \pi/6\rho_\mathrm{p}D_\mathrm{p}^3$ is the particle mass, $I_\mathrm{p} = 0.1 m_\mathrm{p} D_\mathrm{p}^2$ is the moment of inertia for a sphere, $\vec{F}_\mathrm{i}$ represents the different relevant forces acting on the particle, and $\vec{T}$ is the torque acting on a rotating particle due to the viscous interaction with the fluid.

Analytical solutions for the different forces and the torque only are available for small particle Reynolds numbers (i.e., Stokes regime). An extension to higher Reynolds numbers is generally based on introducing empirical correlations, which are derived from experiments or nowadays also from direct numerical simulations (DNS). The different forces relevant for particle motion [13] are introduced and discussed in the following sections.

3 Forces Relevant for Translational Motion of Particles

3.1 Drag Force

In most fluid–particle systems, the drag force is dominating the particle motion and consists of a friction and form drag. The extension of the drag force to higher particle Reynolds numbers is based on the introduction of a drag coefficient C_D, which is obtained from measurements of the drag force in a wind tunnel or a sedimentation experiment:

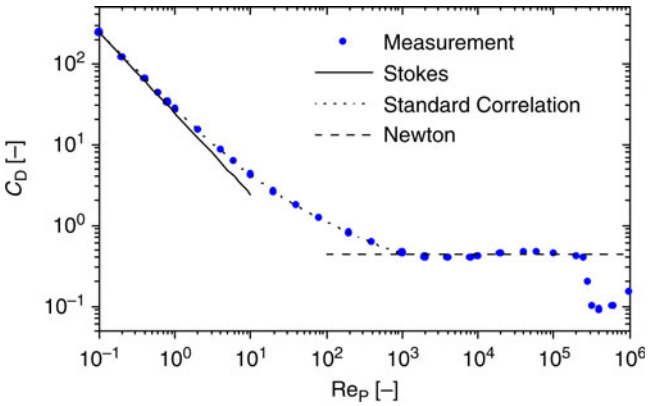
$$C_\mathrm{D} = \frac{F_\mathrm{D}}{\frac{\rho_\mathrm{F}}{2}(\vec{u}_\mathrm{F} - \vec{u}_\mathrm{P})^2 A_\mathrm{P}}, \tag{5}$$

where $A_\mathrm{P} = \pi/4 D_\mathrm{P}^2$ is the cross-section of a spherical particle. The drag force is then expressed by

$$\vec{F}_\mathrm{D} = \frac{3}{4}\frac{\rho_\mathrm{F} m_\mathrm{P}}{\rho_\mathrm{P} D_\mathrm{P}} c_\mathrm{D}(\vec{u}_\mathrm{F} - \vec{u}_\mathrm{P})|\vec{u}_\mathrm{F} - \vec{u}_\mathrm{P}|. \tag{6}$$

The drag coefficient is given as a function of the particle Reynolds number, defined as the ratio of inertial force to friction force:

$$\mathrm{Re}_\mathrm{P} = \frac{\rho_\mathrm{F} D_\mathrm{P}(\vec{u}_\mathrm{F} - \vec{u}_\mathrm{P})}{\mu_\mathrm{F}}. \tag{7}$$



L3.1. Fig. 1. Drag coefficient as a function of particle Reynolds number, comparison of experimental data with correlations for the different regimes (the standard correlation corresponds to Eq. (9)).

The dependence of the drag coefficient of a sphere (spherical particle) on the Reynolds number is shown in Fig. 1 based on numerous experimental investigations (see for example [14]). From this dependence, one may identify several regimes which are associated with certain flow characteristics around the sphere.

- For small Reynolds numbers (i.e., $\mathrm{Re_P} < 0.5$), viscous effects are dominating and no separation of the flow around the particle is observed. Therefore, an analytical solution for the drag coefficient is possible as proposed by Stokes [15]:

$$C_\mathrm{D} = \frac{24}{\mathrm{Re_P}}. \tag{8}$$

This regime is referred to as the Stokes regime.

- In the transition region (i.e., $0.5 < \mathrm{Re_P} < 1{,}000$), inertial effects become of increasing importance. Above a Reynolds number of about 24, the flow around the particle begins to separate. Initially, this separation is symmetric [16]. It becomes unstable and periodic above $\mathrm{Re_P} \approx 130$. For this nonlinear regime, numerous correlations have been proposed [3, 16] which fit the experimental data more or less accurate. A frequently used correlation is that proposed by Schiller and Naumann [17], which fits the data up to $\mathrm{Re_P} = 1{,}000$ reasonably well (see Fig. 1):

$$C_\mathrm{D} = \frac{24}{\mathrm{Re_P}}(1 + 0.15\ \mathrm{Re_P^{0.687}}) = \frac{24}{\mathrm{Re_P}} f_\mathrm{D}. \tag{9}$$

- Above $\mathrm{Re_P} \approx 1{,}000$, the flow is fully turbulent and the drag coefficient remains almost constant up to the critical Reynolds number, since wake size and structure is not considerably changing. This regime is referred to as Newton regime with:

$$C_\mathrm{D} \approx 0.44. \tag{10}$$

- At the critical Reynolds number ($\mathrm{Re_{crit}} \approx 2.5 \cdot 10^5$), a drastic decrease of the drag coefficient is observed, being caused by the transition from a laminar to a turbulent boundary layer around the particle. This results in a decrease of the particle wake size.

- In the super-critical region (i.e., $Re_P > 4.0 \cdot 10^5$), the drag coefficient again increases continuously. For most practical particulate flows, however, this region is not relevant.

The drag coefficient may be altered by numerous other physical effects, such as turbulence of the surrounding flow, surface roughness of the particle, particle shape, wall effects, compressibility of the fluid, rarefaction effects, and particle concentration effects. All these effects can in general only be accounted for by empirical correction factors or functions being derived from detailed experiments.

The *turbulence level of the ambient flow* essentially causes a reduction in the critical Reynolds number as shown by Torobin and Gauvin [18]. With increasing turbulence intensity, the transition from laminar to turbulent boundary layer, i.e., the critical Reynolds number is shifted toward smaller particle Reynolds numbers.

A *surface roughness* on a spherical particle causes a reduction in the critical Reynolds number [19] since this is also associated with a modification of the boundary layer. The increasing effective surface area should however also yield an increase of the drag coefficient.

The *particle shape* has a strong influence on the drag force but also the transverse lift forces and the moment exerted on a particle. Additionally, a profile lift is acting on nonspherical particles. Naturally, the drag coefficient depends on the orientation of a nonspherical particle with respect to the instantaneous relative velocity vector. In order to account for the shape effect, this requires solving additionally for the particle rotational motion. For the Stokes regime, the hydrodynamic forces on ellipsoidal particles were analytically determined by Brenner [20] and the hydrodynamic torque by Jeffery [21]. The importance of considering particle shape effects also in technical processes, e.g., biomass burners, where the particle Reynolds number is mostly much larger than one was emphasized by Rosendahl [22]. However, in such a situation, data is required, which describes the drag coefficient (and the resistance coefficients of the transverse lift forces) as a function of the particle orientation. Such data for the drag coefficient are very rare. Regarding transverse lift forces almost no information is available on the particle shape effect. One attempt in creating such data was undertaken by Hölzer and Sommerfeld [23] by using the Lattice Boltzmann method for simulating the flow across differently shaped particles. Also, there is very little known about particle shape effects in the other forces, such as added mass and Basset force.

For most practical computations, where the particles are considered as point-particles anyway, the calculation of the change in particle orientation is not feasible. However, it is possible to approximately account for particle shape effects on the drag coefficient using a simplified approach on the basis of the correlations proposed by, e.g., Haider and Levenspiel [24], Thompson and Clark [25]. These correlations were evaluated on the basis of numerous experimental data obtained for particles fixed in a wind tunnel or from sedimenting particles. Hence, the drag coefficient is obtained for a given particle orientation. This is also the case in a sedimentation analysis since the particles will sediment in a more or less stable orientation for which the drag coefficient is maximized, i.e., discs will sediment horizontally aligned. The correlation proposed by Haider and Levenspiel [24] has the form:

$$C_D = \frac{24}{Re_P}\left(1 + A\ Re_P^B\right) + \frac{C}{1 + \frac{D}{Re_P}}. \tag{11}$$

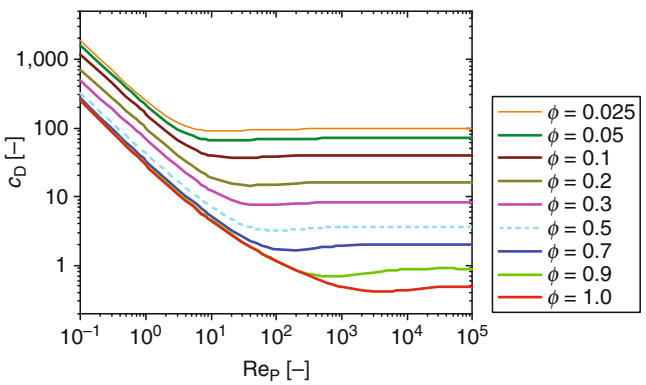
The coefficients A–D are depending on the sphericity of the particle, which is defined as the ratio of the surface area of a volume equivalent sphere to the surface area of the considered nonspherical particle.

$$\phi = \frac{S_V}{S_{Particle}}. \tag{12}$$

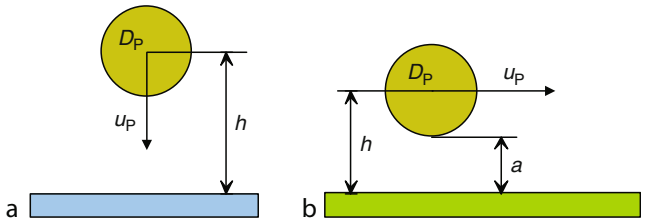
The correlation coefficients A–D are

$$\begin{aligned} A &= \exp\left(2.3288 - 6.4581\phi + 2.4486\phi^2\right), \\ B &= 0.0964 + 0.5565\phi, \\ C &= \exp\left(4.905 - 13.8944\phi + 18.4222\phi^2 - 10.2599\phi^3\right), \\ D &= \exp\left(1.4681 + 12.2584\phi - 20.7322\phi^2 + 15.8855\phi^3\right). \end{aligned} \tag{13}$$

These correlations were obtained from experimental data for isometric nonspherical particles (i.e., cube octahedrons $\phi = 0.906$, octahedrons $\phi = 0.846$, cubes $\phi = 0.806$, and tetrahedrons $\phi = 0.67$) and disc-like particles with sphericities of $\phi = 0.026$, 0.043, 0.123, and 0.230. The drag coefficient according to Eq. (11) is plotted in Fig. 2 as a function of particle Reynolds number, defined with the volume equivalent diameter, with the sphericity as a parameter. This result reveals that the drag coefficient is increasing with decreasing sphericity. This increase is smaller in the Stokes regime compared to the Newton regime where the drag coefficient increases by several orders of magnitude. Moreover, the transition to the Newton regime (fully turbulent regime) is shifted to smaller particle Reynolds numbers with decreasing sphericity. Additionally, the width of the intermediate regime (i.e., between laminar and turbulent) is reduced. It should be noted that the sphericity is not the only possible parameter to characterize the particle shape. This parameter becomes meaningless when particles with rough surfaces



L3.1. Fig. 2. Drag coefficient of nonspherical particles as a function of particle Reynolds number with the sphericity as a parameter according to Eq. (11) [24].



L3.1. Fig. 3. Illustration of wall effects: (**a**) motion normal to a wall; (**b**) motion parallel to a wall.

are considered whereby the sphericity approaches very small values. Therefore, also other parameters are used for shape characterization, such as aspect ratios, roundness, and a hydrodynamic shape descriptor called scruple [25].

The drag correlation proposed by Ganser [26] is based on using a Stokes- and Newton-shape factor, which are combined with the particle Reynolds number to give a generalized parameter $Re_P \cdot K_1 \cdot K_2$. Both shape descriptors are obtained as functions of the sphericity and the projected area in the direction of motion. Hence, this correlation includes the influence of particle orientation with respect to the relative flow.

The *motion of particles in the vicinity of a rigid wall* results in an increase of the drag coefficient and is additionally associated with a transverse lift force. Analytic solutions for the wall effect are again only available for very small particle Reynolds numbers. The particle motion normal to a wall (Fig. 3a) was for example considered by Brenner [27] and a wall-parallel motion (Fig. 3b) was analyzed by Goldman et al. [28, 29]. The first-order solution for a spherical particle moving toward a wall, which is valid for large distances from the wall, is given by [27]:

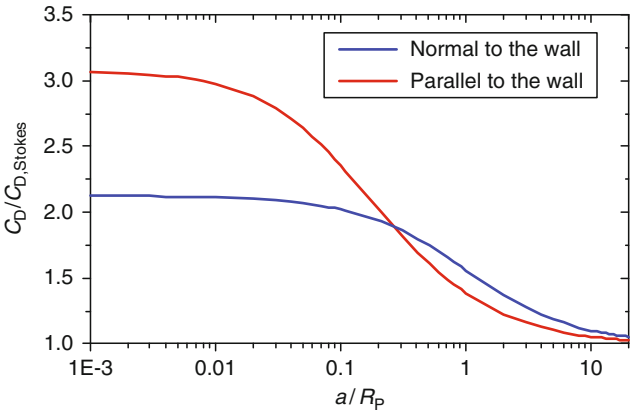
$$\frac{C_D}{C_{D,Stokes}} \cong 1 + \frac{9}{8}\frac{R_P}{h} + \left(\frac{9}{8}\frac{R_P}{h}\right)^2. \tag{14}$$

For a nonrotating spherical particle moving parallel to a wall in a quiescent fluid the increase of the drag is predicted by an asymptotic solution proposed by Faxen (see Goldman et al. [28]) for large distances from the wall:

$$\frac{C_D}{C_{D,Stokes}} = \left[1 - \frac{9}{16}\left(\frac{R_P}{h}\right) + \frac{1}{8}\left(\frac{R_P}{h}\right)^3 - \frac{45}{256}\left(\frac{R_P}{h}\right)^4 - \frac{1}{16}\left(\frac{R_P}{h}\right)^5\right]^{-1}. \tag{15}$$

The two results are shown in Fig. 4 as a function of the normalized gap between particle and wall (i.e., a/R_P). For large wall distance, the curves approach unity and a finite value is obtained for $a/R_P \to 0$. It should be noted that wall effects will be additionally influenced by particle rotation and a shear flow in the vicinity of the wall [28, 29].

Rarefaction effects become of importance in a low pressure environment or when the particles are very small (e.g., nanoparticles). In such a situation, the flow around the particle cannot be regarded as a continuum, instead the particle motion is induced by collisions of gas molecules with the particle surface. This implies that the no-slip condition at the particle surface is not anymore fulfilled. Rather, a partial or full slip is



L3.1. Fig. 4. Modification of drag coefficient for a particle moving normal and parallel to a wall (Eqs. (14) and (15)).

found at the surface. This results in a reduction of the drag coefficient. The importance of rarefaction effects may be estimated based on the ratio of the mean free path of the gas molecules to the particle diameter, which is the particle Knudsen number:

$$Kn_p = \frac{\lambda}{D_p}. \tag{16}$$

The mean free path of the gas molecules λ can be calculated according to kinetic theory of gases from:

$$\lambda = \frac{\mu_F}{0.499\overline{c_{Mol}}\rho_F}, \tag{17}$$

where $\overline{c_{Mol}}$ is the standard deviation of the gas molecule velocity distribution (Maxwellian distribution) given by

$$\overline{c_{Mol}} = \left(\frac{8p}{\pi\rho_F}\right)^{1/2}. \tag{18}$$

Here ρ_F and p are the fluid density and the pressure, respectively. For atmospheric conditions (i.e., $p = 1.0$ bar, $T = 293$ K), the mean free path is about 0.06 µm. A classification of the different flow regimes in rarefied conditions or for very small particles may be based on the Knudsen number and is summarized in Table 1. In the Stokes regime which is generally valid for very small particles, the reduction of the drag coefficient may be accounted for by a correction function, the so-called Cunningham correlation [30]:

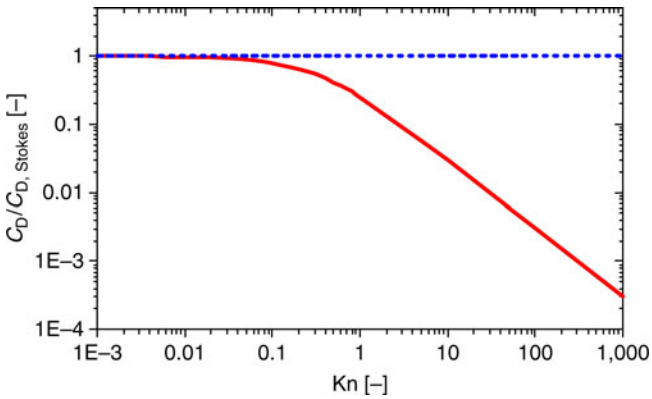
$$C_D = \frac{C_{D,Stokes}}{1 + Kn_P\left\{2.514 + 0.8\exp\left(-\frac{0.55}{Kn_P}\right)\right\}} = \frac{C_{D,Stokes}}{Cu}. \tag{19}$$

This correlation is valid for $0.1 < Kn_P < 1{,}000$ and $Re_P < 0.25$ and is only applicable for low particle Mach numbers. Therefore, it is often used in particle technology, as for example when considering the separation of fine particles from a gas stream.

The Cunningham correction, i.e., 1/Cu, is plotted in Fig. 5 as a function of the Knudsen number. It is obvious that a considerable reduction of the drag coefficient occurs for $Kn_P > 0.012$. At a Knudsen number of one (i.e., $\lambda = D_P$), the particle drag is already reduced by about 75% compared to the continuum regime.

L3.1. Table 1. Different regimes of rarefied flows with respect to particle motion

Flow regime	Range of Knudsen number
Continuum flow	$0 < \mathrm{Kn_P} < 0.015$
Slip flow	$0.015 < \mathrm{Kn_P} < 0.15$
Transition flow	$0.15 < \mathrm{Kn_P} < 4.5$
Free molecular flow	$4.5 < \mathrm{Kn_P} < \infty$



L3.1. Fig. 5. Modification of the drag coefficient due to rarefaction effects (Eq. (19)).

At *higher volume fraction* of the dispersed phase, a reduction of the sedimentation or rise velocity is observed in many technical multiphase flow processes. This phenomenon results mainly from the hydrodynamic interaction between the particles and is termed as hindered settling or rise, as well as swarm effect. A direct consideration of this phenomenon is only possible using DNS with resolving the flow around individual particles. For technical multiphase systems, this is however not feasible and therefore, mainly empirical correlations are being used in engineering computations. A well-known correlation obtained from the sedimentation of a concentrated suspension and the fluidization of a liquid–solid system (solids volume fraction between 1% and 20%) is that of [31]. They provided correlations for the decrease of the sedimentation velocity with increasing solids volume fraction on the basis of a power law with the exponent being dependent on the single-particle Reynolds number. This work was extended by Wen and Yu [32] who found a constant exponent for the entire relevant range of particle Reynolds numbers. The resulting modified drag coefficient for dispersed phase volume fractions up to $\alpha_P < 20\%$ or porosities larger than $\varepsilon > 80\%$ is given by

$$C_{D,sw} = C_D^* \cdot \varepsilon^{-1.65}. \tag{20}$$

Since the studies were performed using a fluidization experiment the single particle drag coefficient C_D^* is defined with the particle Reynolds number calculated on the basis of the superficial fluid velocity U_0, which can be replaced by the product of the relative (slip) velocity and the porosity:

$$C_D^* = \min\left\{\frac{24}{\mathrm{Re}_{P,S}}(1 + 0.15\ \mathrm{Re}_{P,S}^{0.687}), 0.44\right\}, \tag{21}$$

$$\mathrm{Re}_{P,s} = \frac{\rho_F D_P \varepsilon(\vec{u}_F - \vec{u}_P)}{\mu_F}. \tag{22}$$

Due to its simplicity, Eq. (20) is the most frequently applied correlation in the frame of a Lagrangian tracking approach. Other correlations are also provided in the book of Michaelides [7]. For higher dispersed phase volume fractions where mostly an Eulerian model is applied, drag correlations obtained for packed beds have to be used, e.g., the well-known correlation of Ergun [33].

3.2 Pressure Gradient and Buoyancy Force

The local pressure gradient in the flow gives rise to an additional force in the direction of the pressure gradient. Combining the pressure gradient in the fluid with the shear stress one obtains:

$$F_p = \frac{m_p}{\rho_p}(-\nabla p + \nabla\vec{\tau}). \tag{23}$$

From the Navier–Stokes equation of the fluid the pressure gradient and the shear stress can be related to the fluid acceleration and the gravity force:

$$-\nabla p + \nabla\vec{\tau} = \rho_F\left(\frac{\mathrm{D}\vec{u}_F}{\mathrm{D}t} - \vec{g}\right). \tag{24}$$

Hence, the total pressure force is obtained in the following form:

$$\vec{F}_p = m_p\frac{\rho_F}{\rho_p}\left(\frac{\mathrm{D}\vec{u}_F}{\mathrm{D}t} - \vec{g}\right). \tag{25}$$

The first term of Eq. (25) represents the fluid acceleration and the second one is the buoyancy force. It is obvious that in gas–solid flows, the pressure force may be neglected since $\rho_F/\rho_p << 1$. However, in liquid–solid or liquid–gas flows, this force is of importance.

3.3 Added Mass and Basset Force

The acceleration/deceleration of a particle in a fluid also requires accelerating/decelerating a certain fraction of fluid surrounding the particle, this is the so-called added mass. The Basset force is caused by the lagging of the boundary layer development on the particle surface with changing relative velocity (i.e., acceleration or deceleration of the particle and/or fluid) and is often referred to as "history" force. Analytic solutions for both forces are only available for small particle Reynolds numbers (see Eq. (1)). An extension to higher particle Reynolds numbers is only possible by introducing empirical coefficients C_A and C_B similar to the drag coefficient. Based on an experimental study of Odar and Hamilton [34], who examined the motion of a sphere in simple harmonic motion, the added mass and Basset force are expressed as

$$F_A = 0.5 C_A \rho_F \frac{m_P}{\rho_P}\frac{\mathrm{d}}{\mathrm{d}t}(\vec{u}_F - \vec{u}_P), \tag{26}$$

$$F_B = 9\sqrt{\frac{\rho_F\mu_F}{\pi}}\frac{m_P}{\rho_P D_P} \cdot C_B\left\{\int_0^t \frac{\frac{\mathrm{d}}{\mathrm{d}\tau}(\vec{u}_F - \vec{u}_P)}{(t-\tau)^{1/2}}\mathrm{d}\tau + \frac{(\vec{u}_F - \vec{u}_P)_0}{\sqrt{t}}\right\}. \tag{27}$$

The second term in the Basset force accounts for an initial slip velocity at $t = 0$ [35]. The coefficients C_A and C_B were obtained from the experiments of Odar and Hamilton [34] in the following form:

$$C_A = 2.1 - \frac{0.132}{A_C^2 + 0.12}, \tag{28}$$

$$C_B = 0.48 + \frac{0.52}{(A_C + 1)^3}. \tag{29}$$

The parameter A_C is called acceleration number and is defined by

$$A_C = \frac{|\vec{u}_F - \vec{u}_P|^2}{D_P \left| \frac{d|\vec{u}_F - \vec{u}_P|}{dt} \right|}. \tag{30}$$

It is obvious that the Basset force is quite time consuming to solve since it has to be integrated along the entire particle trajectory for each time step of the trajectory calculation. Therefore, this force is often neglected. An approximate solution procedure for the Basset force was introduced by Michaelides [36]. Numerical calculations of Sommerfeld [37] have shown that the consideration of the Basset force increases the computational time by a factor of about 10. An analysis of the importance of the different forces, especially added mass and Basset force, in an oscillatory flow field for different density ratios will be provided below.

3.4 Body Forces

Body or field forces are the gravity-buoyancy force, the Coulomb force, which arises when a particle moves in an electric field, as for example in an electrostatic precipitator or the thermophoretic force, which becomes of importance when a small particle moves in a flow with a high temperature gradient.

The gravity force is

$$\vec{F}_g = m_p \vec{g}. \tag{31}$$

The Coulomb force acting on a particle moving in an electric field with field strength $\vec{E}$ is given by

$$F_C = -q_p \vec{E}, \tag{32}$$

where q_p is the charge of the particle. In an electrostatic precipitator, for example, the particles are charged through an ion-bombardment created by a negative corona discharge in the vicinity of a charging wire. The charging of the particles is caused by two mechanisms, namely field charging and diffusion charging. The relevance of either of these mechanisms depends on the particle size. Field charging is dominant for particles larger than 2 μm while diffusion charging is prevailing for particles smaller than 0.2 μm [38]. In most cases, the temporal evolution of the charging process is not considered, rather the saturation charge or a portion of it is assumed. For the determination of the electrostatic force acting on the particle, additionally the electric field has to be calculated or a certain value may be assumed. More details about particle charging and their motion in an electric field may be found in the book of White [39].

3.5 Slip-Shear Lift Force

Particles moving in a shear layer experience a transverse lift force due to the nonuniform relative velocity over the particle and the resulting nonuniform pressure distribution. The lift force is acting toward the direction of higher slip velocity (Fig. 6). An expression for the slip-shear lift force for a freely rotating particle moving at constant velocity in a two-dimensional shear flow at low Reynolds number was derived from an asymptotic expansion by Saffman [40, 41]:

$$F^y_{LS,Saff} = 6.46 \frac{D_p^2}{4} (\rho_F \mu_F)^{0.5} \left| \frac{\partial u_F}{\partial y} \right| (u_F - u_p). \tag{33}$$

Extending this expression to a three-dimensional flow and introducing a correction function for higher particle Reynolds numbers yields:

$$\vec{F}_{LS} = 1.615 D_p^2 (\rho_F \mu_F)^{1/2} \left(\frac{1}{|\vec{\omega}_F|} \right)^{0.5} \cdot \{(\vec{u}_F - \vec{u}_P) \times \vec{\omega}_F\} f(\mathrm{Re}_P, \mathrm{Re}_S). \tag{34}$$

Here the fluid rotation is obtained from

$$\vec{\omega}_F = \mathrm{rot}\ \vec{u}_F = \nabla \times \vec{u}_F. \tag{35}$$

Introducing now a lift coefficient in Eq. (34) gives the following expression for the slip-shear lift force:

$$\vec{F}_{LS} = \frac{\rho_F}{2} \frac{\pi}{4} D_p^2 C_{LS} D_P ((\vec{u}_F - \vec{u}_p) \times \vec{\omega}_F), \tag{36}$$

with the lift coefficient given as

$$C_{LS} = \frac{2.90805}{\beta^{0.5} \mathrm{Re}_p^{0.5}} f(\mathrm{Re}_P, \mathrm{Re}_S). \tag{37}$$

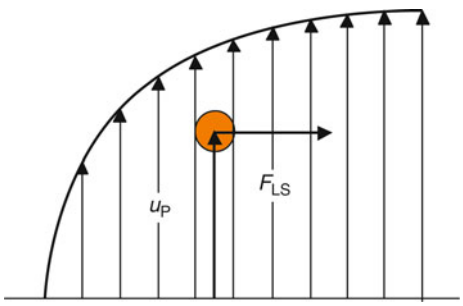
The correction function $f(\mathrm{Re}_P, \mathrm{Re}_S)$ proposed by Mei [42] on the basis of calculations performed by Dandy and Dwyer [43] for a particle Reynolds number in the range $0.1 \le \mathrm{Re}_P \le 100$ is given by

$$f(\mathrm{Re}_P, \mathrm{Re}_S) = \frac{F_{LS}}{F_{LS,Saff}}, \tag{38}$$

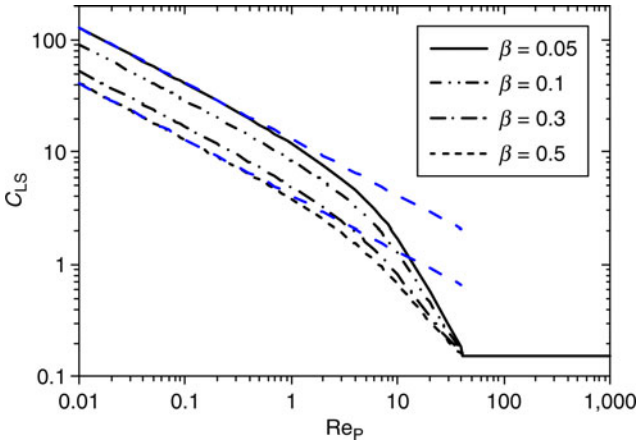
$$f(\mathrm{Re}_P, \mathrm{Re}_S) = \left(1 - 0.3314\beta^{1/2}\right) \exp\left(-\frac{\mathrm{Re}_P}{10}\right) + 0.3314\beta^{1/2} \quad \text{for } \mathrm{Re}_P \le 40$$
$$= 0.0524(\beta\ \mathrm{Re}_P)^{1/2} \quad \text{for } \mathrm{Re}_P \ge 40, \tag{39}$$

with

$$\beta = 0.5 \frac{\mathrm{Re}_S}{\mathrm{Re}_P} \tag{40}$$



L3.1. Fig. 6. Illustration of the action of slip-shear lift force.



L3.1. Fig. 7. Lift coefficient as a function of particle Reynolds number with the nondimensional shear rate β as a parameter. The upper and lower straight lines indicate the lift coefficients according to the Saffman equation, i.e., Eq. (37) with $f(Re_P, Re_S) = 1.0$.

and the particle Reynolds number of the shear flow:

$$Re_S = \frac{\rho_F D_p^2 |\vec{\omega}_F|}{\mu_F}. \tag{41}$$

The dependence of the lift coefficient on the particle Reynolds number with the nondimensional shear rate β as a parameter is shown in Fig. 7. The lift coefficient continuously decreases within the first regime, i.e., from the Stokes limit up to $Re_P = 40$ (Eq. (39)), and then remains constant for higher particle Reynolds numbers. With increasing nondimensional shear rate the lift coefficient is decreasing in the first regime and independent of the shear rate in the second regime (see Eq. (39)). The upper and lower straight dashed lines indicate the result for the Saffman expression, which agree for the considered nondimensional shear rates only with the lift coefficient of Eq. (37) for particle Reynolds numbers up to 0.5. For the smallest shear rate considered a slight kink is found at the transition particle Reynolds number of 40.

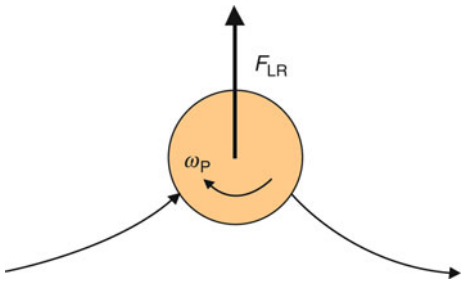
3.6 Slip-Rotation Lift Force

Particles, which are not freely rotating in a flow, may also experience a lift force due to their rotation, the so-called Magnus force. High particle rotations may, for example, be induced by particle–wall collisions frequently occurring in confined flows, such as, pipe or channel flows [44, 45]. The rotation of the particle results in a displacement of the flow field around the particle, associated with a shift of the stagnation points and a transverse lift force (Fig. 8). An analytic expression for the slip-rotation lift force in the case of small particle Reynolds numbers was derived by Rubinow and Keller [46]:

$$\vec{F}_{LR} = \pi R_p^3 \rho_F \left\{ \vec{\Omega} \times \left(\vec{u}_F - \vec{u}_p \right) \right\}, \tag{42}$$

where $\vec{\Omega}$ is the relative rotation given by

$$\vec{\Omega} = \frac{1}{2} \nabla \times \vec{u}_F - \vec{\omega}_p. \tag{43}$$



L3.1. Fig. 8. Illustration of the slip-rotation lift force acting on a stationary particle.

Also, the slip-rotation lift force may be extended for higher particle Reynolds numbers by introducing a lift coefficient [3]:

$$\vec{F}_{LR} = \frac{\rho_F}{2} \frac{\pi}{4} D_p^2 C_{LR} \left| \vec{u}_F - \vec{u}_p \right| \frac{\vec{\Omega} \times \left(\vec{u}_F - \vec{u}_p \right)}{\left| \vec{\Omega} \right|}. \tag{44}$$

For small particle Reynolds numbers, the lift coefficient is obtained according to Rubinow and Keller [46] in the form:

$$C_{LR} = 2\gamma = \frac{D_p \left| \vec{\Omega} \right|}{\left| \vec{u}_F - \vec{u}_p \right|} = \frac{Re_R}{Re_p}, \tag{45}$$

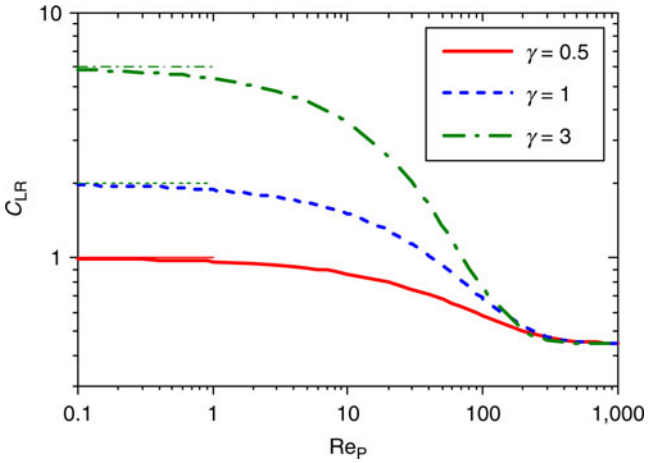
with

$$Re_R = \frac{\rho_F D_p^2 \left| \vec{\Omega} \right|}{\mu_F} \tag{46}$$

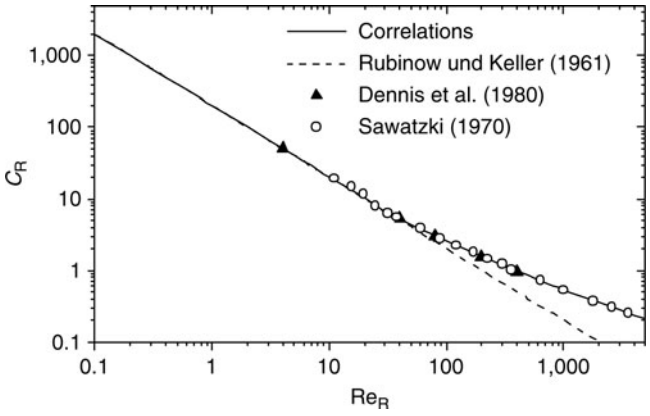
being the Reynolds number of particle rotation and γ the nondimensional relative rate of rotation. A lift coefficient for higher particle Reynolds numbers requires experimental information. Oesterlé and Bui Dinh [47] introduced the following correlation based on available literature data and additional own experiments for $Re_P < 140$:

$$C_{LR} = 0.45 + (2\gamma - 0.45) \cdot \exp(-0.075\gamma^{0.4} \cdot Re_p^{0.7}) \quad \text{for } Re_P < 140. \tag{47}$$

In the publication of Oesterlé and Bui Dinh [47], it is suggested that this correlation may be used up to particle Reynolds numbers of 2,000. The lift coefficient of particle rotation as a function of the particle Reynolds number with the nondimensional relative rate of rotation as a parameter is shown in Fig. 9. With increasing particle Reynolds number, the rotational lift coefficient continuously reduces up to about $Re_P = 500$ and then remains almost constant. In the first regime (i.e., up to $Re_P = 500$), the rotational lift coefficient increases with γ and in the second regime, it is independent of γ. This, however, does not agree with other high Reynolds number results provided in the literature; see for example Sawatzki [48]. Here the rotational lift coefficient increases linearly from $\gamma = 0$ to $\gamma = 1.3$ and then remains constant with a value of $C_{LR} = 0.47$. Hence, further studies are still necessary for obtaining the correct limits at higher particle Reynolds numbers of rotation. The horizontal lines between $0.1 < Re_P < 1.0$ correspond to the result of Rubinow and Keller [46] given by Eq. (45). It is obvious that this expression only holds for small particle Reynolds numbers of translation and rotation.



L3.1. Fig. 9. Lift coefficient of particle rotation as a function of particle Reynolds number with the nondimensional relative rate of rotation γ as a parameter. The horizontal lines correspond to the result of Rubinow and Keller [46] given by Eq. (45).



L3.1. Fig. 10. Coefficient of particle rotation as a function of particle rotational Reynolds number according to Eqs. (50) and (51) and comparison with experiments [50] and numerical calculations [49].

4 Torque on Rotating Particles

The torque acting on a rotating particle due to the interaction with the fluid was also derived by Rubinow and Keller [46] for a stagnant fluid and small particle Reynolds numbers:

$$\vec{T} = \pi \mu_F D_p^3 \vec{\omega}_p. \tag{48}$$

This expression may be extended for a three-dimensional flow and for higher Reynolds numbers by introducing a rotational coefficient:

$$\vec{T} = \frac{\rho_F}{2}\left(\frac{D_p}{2}\right)^5 C_R \left|\vec{\Omega}\right| \vec{\Omega}. \tag{49}$$

From the numerical simulations of Dennis et al. [49] and experimental data of Sawatzki [50], the rotational coefficient for higher particle Reynolds numbers is found to be

$$C_R = \frac{12.9}{Re_R^{0.5}} + \frac{128.4}{Re_R} \quad \text{for } 32 < Re_R < 1{,}000. \tag{50}$$

In the case of smaller particle, Reynolds numbers the result of Rubinow and Keller [46] yields:

$$C_R = \frac{64\pi}{Re_R} \quad \text{for } Re_R < 32. \tag{51}$$

The comparison of the above correlations (Eqs. (50) and (51)) with the simulations [49], and the experiments [50] yields a good agreement as shown in Fig. 10.

5 Particle Response Time and Stokes Number

The particle velocity or momentum response time may be used to characterize the capability of particles to follow a sudden velocity change in the flow, occurring, for example, in large scale vortex structures [51] or turbulent eddies. In order to derive the particle response time, the equation of motion is used by only considering the drag force:

$$m_p \frac{du_p}{dt} = \frac{\rho_F}{2}\frac{\pi}{4} D_p^2 C_D \left|u_F - u_p\right| (u_F - u_p). \tag{52}$$

Dividing by the particle mass and introducing the particle Reynolds number gives:

$$\frac{du_p}{dt} = \frac{18\mu_F}{\rho_p D_p^2}\frac{C_D\, Re_P}{24}(u_F - u_p). \tag{53}$$

The term $C_D\, Re_P/24$ corresponds to the nonlinear term in the drag coefficient f_D (Eq. (9)) and the reciprocal of the first term of Eq. (53) has the dimension of a time, the particle response time:

$$\tau_p = \frac{\rho_p D_p^2}{18\mu_F f_D}. \tag{54}$$

Hence the equation of motion becomes:

$$\frac{du_p}{dt} = \frac{1}{\tau_p}(u_F - u_p). \tag{55}$$

The solution of this equation for a simplified case, namely a jump of the fluid velocity from zero to u_F and an initial particle velocity of zero is

$$u_p = u_F\left(1 - \exp\left(-\frac{t}{\tau_p}\right)\right). \tag{56}$$

From this equation, it is obvious that τ_p is the time required for a particle, released with zero velocity into a flow with u_F, to reach 63.2% of the flow velocity as illustrated in Fig. 11.

In the Stokes regime, where f_D is unity, the particle response time becomes

$$\tau_p = \frac{\rho_p D_p^2}{18\mu}. \tag{57}$$

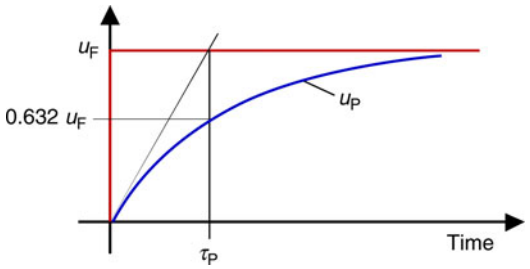
The Stokes number is the ratio of the particle response time to a characteristic time scale of the flow:

$$St = \frac{\tau_p}{\tau_F}. \tag{58}$$

Considering particle motion in a turbulence field, the fluid flow time scale corresponds to the time scale of the energetic eddies, i.e., the integral time scale of turbulence, $T_L \approx k/\varepsilon$. In the case of particle motion in large scale vortices (occurring, for example, in a shear layer), the eddy passage time across a fixed point in space is the relevant fluid time scale [51].

6 Forces Acting on Bubbles

The motion of bubbles in laminar or turbulent flows is much more complex than that of rigid solid particles. First of all, the interface between bubble and fluid is not rigid and hence an internal flow develops inside the bubbles. This implies that the no-slip condition does not apply at the interface. Thereby, the drag coefficient is reduced compared to a solid particle where the no-slip condition applies at the surface. This behavior of bubbles is depicted in the well-known diagram of Clift et al. [16], where the terminal velocity is plotted versus the volume equivalent diameter obtained from a number of experimental data (Fig. 12). Bubbles moving in clean liquid (fluid bubbles) rise considerably faster than those moving in contaminated liquid (rigid bubbles) for a wide range of bubble sizes. The second issue, which considerably complicates the modelling of bubble motion, is the temporal contamination of the bubble surface by surface active substances, e.g., surfactants. This yields eventually a rigid interface and the bubble behaves like a solid particle, whereby the drag coefficient increases (Fig. 14) and the rise velocity decreases (Fig. 12). The third phenomenon affecting bubble motion is bubble deformation and oscillation, which begins for volume equivalent bubble diameters around 1.5 mm for an air water system. Bubble oscillation is triggered by unsteady wake separation and causes the bubbles to rise in a zigzag or spiral manner.

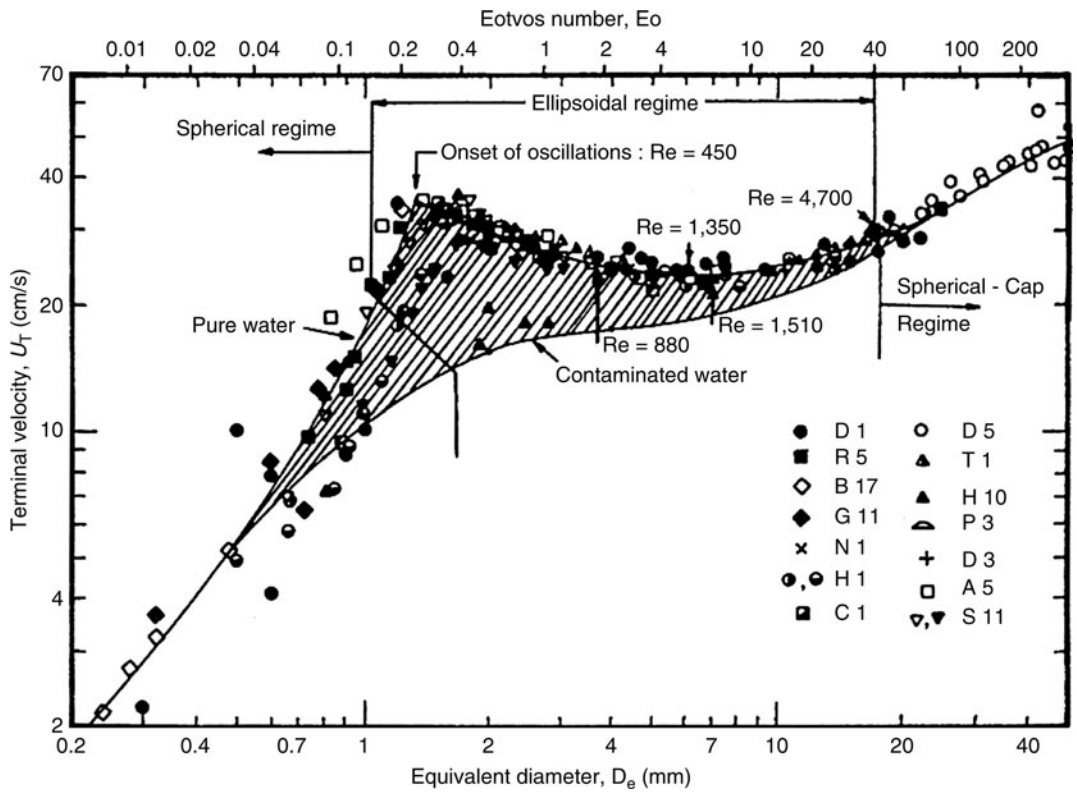


L3.1. Fig. 11. Graphical illustration of the particle response time.

The bubble shape is determined from the relative importance of the fluid dynamic force acting on the bubble to the force due to the surface tension. This ratio yields the Weber number given by

$$\mathrm{We_B} = \frac{|\rho_F - \rho_B| V_B^2 D_e}{\sigma}. \tag{59}$$

In case the Weber number becomes large, the spherical bubble shape cannot be maintained and bubbles become ellipsoidal, wobbling, or spherical-cap. The different bubble shapes can be



L3.1. Fig. 12. Collection of experimental data for the rise velocity of bubbles in different liquids by Clift et al. [16] together with fitting lines for pure and contaminated liquids.

characterized by introducing two additional nondimensional numbers, namely the Eötvös- and Morton-number:

$$\mathrm{Eo} = \frac{\mathrm{We_B}}{\mathrm{Fr_B}} = \frac{g|\rho_\mathrm{F} - \rho_\mathrm{B}|D_\mathrm{e}^2}{\sigma}, \tag{60}$$

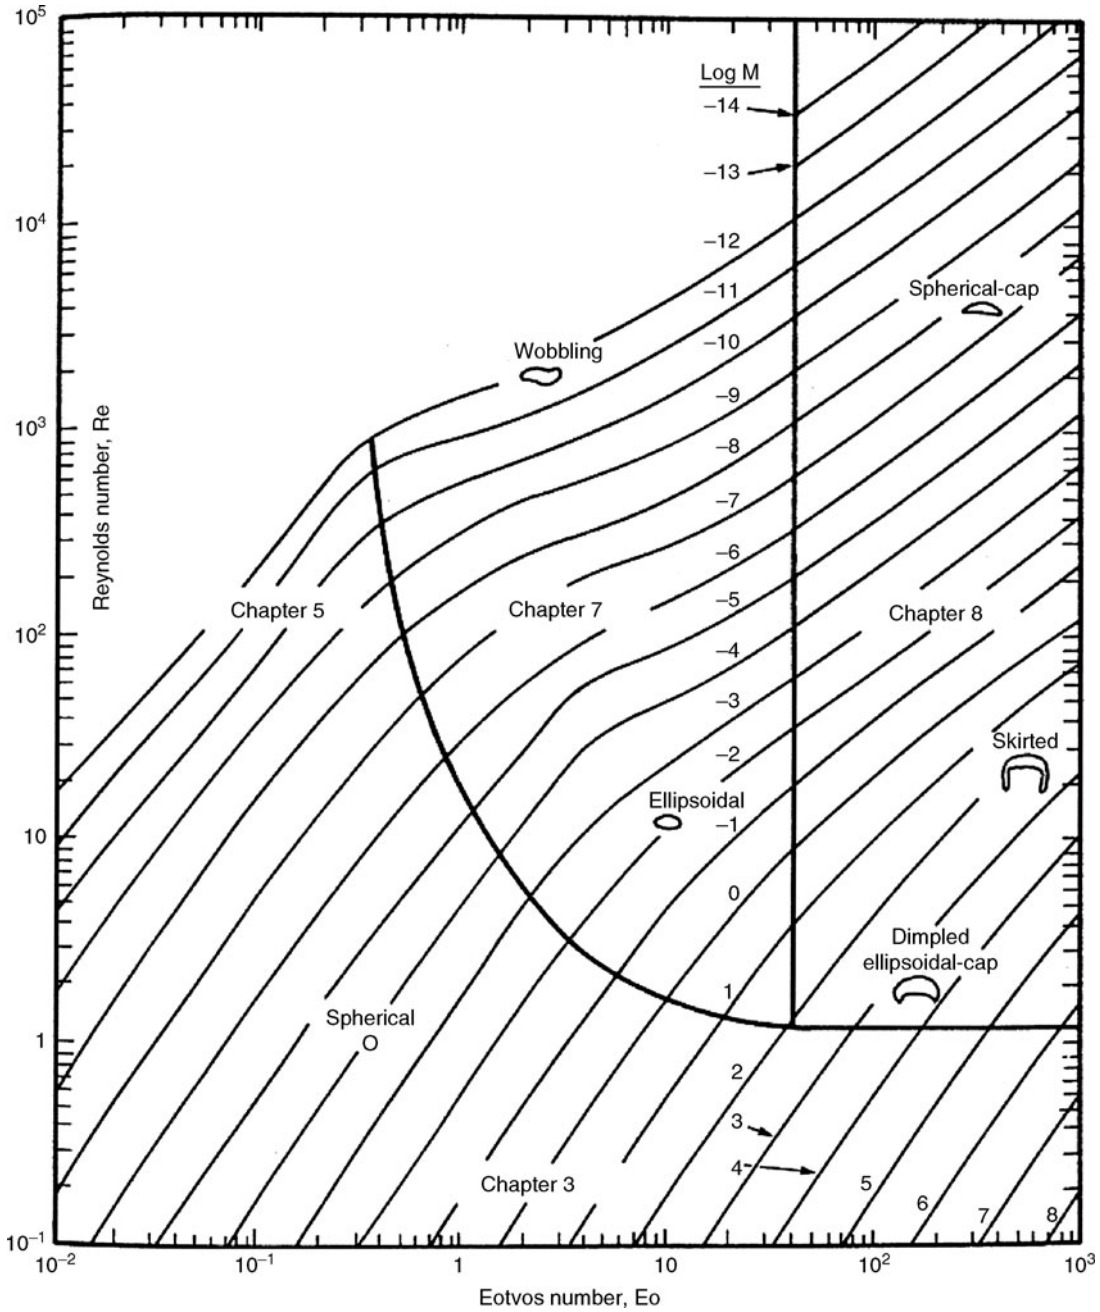
$$\mathrm{Mo} = \frac{g\mu^4|\rho_\mathrm{F} - \rho_\mathrm{B}|}{\rho_\mathrm{F}^2\sigma^3}, \tag{61}$$

where

$$\mathrm{Fr_B} = \frac{V_\mathrm{B}^2}{gD_\mathrm{e}} \tag{62}$$

is the bubble Froude number. These nondimensional parameters are being used to obtain the well-known bubble shape diagram as shown in Fig. 13 [16]. For the numerical calculation of bubble motion, all forces have to be considered such as drag force, pressure force, added mass, Basset force, gravity force, and transverse lift force. The importance of these forces will be discussed below. Nevertheless, the Basset force is neglected in most computational studies due to the considerably increasing numerical effort, which is however not justified for all regimes of bubble size and oscillation frequency of the flow.

Numerous experimental studies are available for the determination of the drag coefficient for different sized bubbles rising in purified or contaminated liquids [52, 53], which were also summarized by Fan and Tsuchiya [54]. These data were obtained my measuring the bubble terminal velocity under



L3.1. Fig. 13. Bubble shape regimes as a function of Reynolds and Eötvös number with the Morton number as a parameter [16].

quasi-steady-state conditions neglecting added mass and Basset forces. In the low Reynolds number regime (including the laminar regime), a clear distinction between bubbles rising in purified and contaminated liquids can be made. In the Stokes regime (and in some cases up to bubble Reynolds numbers larger than 10), contaminated bubbles rise like rigid particles with a drag coefficient of

$$C_D = \frac{24}{Re_B}. \tag{63}$$

Whereas, in purified systems the drag coefficient is lower; namely

$$C_D = \frac{16}{Re_B}. \tag{64}$$

Most critical is the regime of ellipsoidal and wobbling bubbles where the transition of the drag coefficient is extremely affected by the type of liquid considered (see Fig. 14 for $Re_B > 400$). In a contaminated mixture of glycerine and water, for example, this transition is shifted to lower bubble Reynolds numbers if the glycerine content is increased [54].

When the bubble Reynolds number increases beyond about 1530 and the bubbles have a cap-like shape, the degree of contamination of the liquid does not play a role anymore and the drag coefficient approaches a constant value of about:

$$C_D \cong 2.61. \tag{65}$$

In the past, numerous correlations for the bubble drag coefficient as a function of bubble Reynolds number were proposed, mainly to match the transition region most closely for the different types of liquids. A discontinuous correlation for bubbles rising in purified liquid was, for example, proposed by Glaeser and Brauer [55]. Here the drag coefficient in the transition region depends on the Morton number and the bubble Reynolds number. The beginning and the end of the transition region are given by two Reynolds numbers both depending on the Morton number. The Morton number, as given above, is only dependent on the properties of the considered media, i.e., viscosity, density, and surface tension. Several correlations, which are rather easy to use were proposed by Tomiyama et al. [56] for different liquid qualities:

- purified fluids:

$$C_D = \max\left\{\min\left[\frac{16}{Re}\left(1 + 0.15\ Re^{0.687}\right), \frac{48}{Re}\right], \frac{8}{3}\frac{Eo}{Eo + 4}\right\}; \tag{66}$$

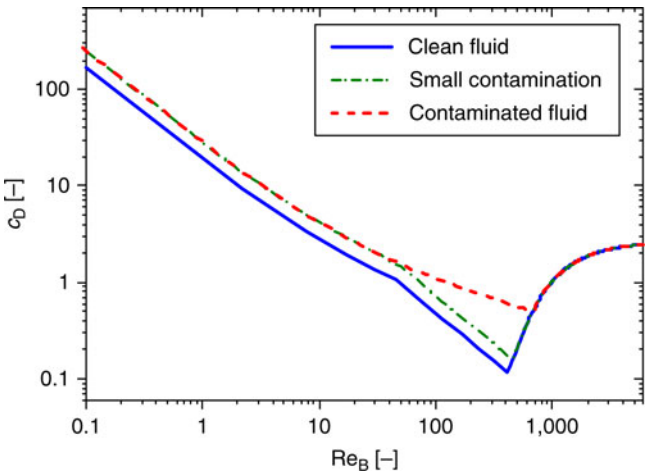
- slightly contaminated fluids:

$$C_D = \max\left\{\min\left[\frac{24}{Re}\left(1 + 0.15\ Re^{0.687}\right), \frac{72}{Re}\right], \frac{8}{3}\frac{Eo}{Eo + 4}\right\}; \tag{67}$$

- contaminated fluids:

$$C_D = \max\left[\frac{24}{Re}\left(1 + 0.15\ Re^{0.687}\right), \frac{8}{3}\frac{Eo}{Eo + 4}\right]. \tag{68}$$

As illustrated in Fig. 14, these correlations, however, do not properly describe the transition region in dependence on the degree of contamination and type of liquid considered as found in numerous experimental studies [54]. Especially in this region, with bubble sizes between 3 and 6 mm for an air/water system, a more accurate description is needed, since such bubble sizes are most important for industrial processes.



L3.1. Fig. 14. Bubble drag coefficient as a function of the bubble Reynolds number for clean and contaminated water according to the correlations of Tomiyama et al. [56] (see Eqs. (66) to (68)).

Hence, so far no generally applicable correlation for the drag coefficient of bubbles is available. Therefore, published results on the hydrodynamics in bubble columns or loop reactors have to be very critically assessed with regard to the drag correlation applied.

In bubbly flows, the added mass force is of great importance since especially wobbling bubbles never exhibit stationary rise behavior, rather they show zigzag or helical rising paths. Additionally, the density ratio ρ_L/ρ_B is considerably larger than one. For spherical bubbles in the Stokes regime the added mass coefficient is 0.5. In the case of ellipsoidal bubbles, the added mass coefficient is a tensor of the form [57]:

$$C_{A,ell} = \begin{Bmatrix} C_{A,h} & 0 & 0 \\ 0 & C_{A,h} & 0 \\ 0 & 0 & C_{A,v} \end{Bmatrix}. \tag{69}$$

For oblate bubbles, an analytic solution for the coefficients in horizontal (h) and vertical (v) direction was provided by Lamb [58] as a function of aspect ratio (i.e., minor axis to major axis, $E = h/b$):

$$C_{A,v} = \frac{E\cos^{-1}E - \sqrt{1-E^2}}{E^2\sqrt{1-E^2} - E\cos^{-1}E} \quad \text{for } E < 1, \tag{70}$$

$$C_{A,h} = \frac{\cos^{-1}E - E\sqrt{1-E^2}}{(2E^{-1} - E)\sqrt{1-E^2} - \cos^{-1}E} \quad \text{for } E < 1. \tag{71}$$

Moreover, transverse lift forces play an important role in the behavior of bubbles. For example, in bubble columns or pipe flows, the void fraction profile shows wall peaking for smaller bubbles (i.e., $D_B < 5.6$ mm in an air/water system under atmospheric conditions) and core peaking is observed for larger bubbles. The latter is also the responsible mechanism for yielding a heterogeneous flow regime in a bubble column as a result of bubble coalescence. The transverse lift force acting on bubbles

may be separated in two contributions, namely due to shear flow and bubble wake effects. Combining these two effects in one lift coefficient yields the following lift force [57]:

$$\vec{F}_L = C_{L,B}\rho_F \frac{\pi D_B^3}{6}(\vec{u}_F - \vec{u}_B) \times \text{rot}\ \vec{u}_F. \tag{72}$$

Here a positive value of $C_{L,B}$ yields a migration of the bubbles toward the wall. For spherical bubbles and for $Re_B >> 1$, the lift coefficient is 0.5 [59]. On the basis of experimental studies in a shear flow and simulations using the VOF (volume-of-fluid) method, Tomiyama et al. [60] suggest the following correlations for the lift coefficient:

$$C_{L,B} = \begin{Bmatrix} \min(0.288 \cdot \tan h(0.121\ Re_B)), f(Eo_h) & \text{for } Eo_h < 4 \\ f(Eo_h) & \text{for } 4 \le Eo_h \le 10.7 \end{Bmatrix}, \tag{73}$$

with

$$f(Eo_h) = 0.00105Eo_h^3 - 0.0159Eo_h^2 - 0.0204Eo_h + 0.474, \tag{74}$$

$$Eo_h = \frac{\rho \Delta\rho D_h^2}{\sigma}; \quad D_h = 2b. \tag{75}$$

For smaller bubbles, the lift coefficient correlates with the bubble Reynolds number (i.e., up to $Re_B \sim 60$) and has positive values (i.e., migration toward the wall of a pipe). If medium sized and large bubbles are considered, the lift coefficient correlates with the Eötvös number based on the volume equivalent bubble diameter [57]. The lift coefficient changes from positive to negative values at about Eo = 6, corresponding to a bubble diameter of 5.6 mm in an air/water system. In both regions (Eq. (73)), the lift coefficient was found to be almost independent of the Morton number. The theoretical studies of Legendre and Magnaudet [61] for a plane shear layer revealed that for bubble Reynolds numbers below about 3, the shear induced transverse lift is dominating and therefore, the lift coefficient will become dependent on the nondimensional shear rate:

$$S_r = \frac{\omega D_B}{|U_F - U_B|}; \quad \omega = \frac{dU_F}{dy}. \tag{76}$$

The correlation for the lift coefficient obtained from these simulations is given by

$$C_{L,B} = \sqrt{\left(\frac{6}{\pi^2}\frac{2.255}{(Re_B\ Sr)^{1/2}(1 + 0.2\ Re_B/Sr)^{3/2}}\right)^2 + \left(0.5\frac{1 + 16/Re_B}{1 + 29/Re_B}\right)^2} \tag{77}$$

and agrees with experiments of Tomiyama [57] up to a bubble Reynolds number of 2.0. For $Re_B > 5$, the influence of the shear rate on the lift coefficient becomes negligible and the correlation of Eq. (73) can be used. A proper transition between the two regimes has not yet been developed.

7 Importance of the Different Forces

In order to estimate the importance of the different forces, especially the importance of added mass and Basset force, acting on a particle in a turbulent flow, Hjelmfelt and Mockros [62] have performed an analysis for an oscillatory flow field. The starting point of their analysis was the Stokes form of the equation of motion given by

$$m_P\frac{du_P}{dt} = \frac{18\mu_F}{\rho_P D_P^2} m_P(u_F - u_P) - m_F\frac{du_F}{dt} + 0.5m_F\left(\frac{du_F}{dt} - \frac{du_P}{dt}\right) + 9\sqrt{\frac{\rho_F\mu_F}{\pi}}\frac{m_P}{\rho_P D_P}\int_{-\infty}^{t}\frac{\frac{du_F}{d\tau} - \frac{du_P}{d\tau}}{(t-\tau)^{1/2}}d\tau. \tag{78}$$

Rearranging this equation results in

$$\frac{du_P}{dt} + a u_P + c\int_{-\infty}^{t}\frac{du_P/d\tau}{(t-\tau)^{1/2}}d\tau = a u_F + b\frac{du_F}{dt} + c\int_{-\infty}^{t}\frac{du_F/d\tau}{(t-\tau)^{1/2}}d\tau, \tag{79}$$

with the coefficients a, b, and c defined by

$$a = \frac{18\mu_F/\rho_F}{(\rho_P/\rho_F + 0.5)D_P^2}, \quad b = \frac{3}{2(\rho_P/\rho_F + 0.5)}, \quad c = \frac{9}{(\rho_P/\rho_F + 0.5)}\sqrt{\frac{\mu_F}{\pi\rho_F}}. \tag{80}$$

The velocities of the particles and the fluid are expressed by Fourier integrals:

$$u_F = \int_0^\infty (\varsigma\cos\omega t + \lambda\sin\omega t)d\omega, \quad u_P = \int_0^\infty (\sigma\cos\omega t + \varphi\sin\omega t)d\omega \tag{81}$$

where ω is the frequency of oscillation. Introducing these Fourier integrals into the equation of motion of the particles (Eq. (79)) yields the amplitude ratio (i.e., amplitude of particle velocity over that of the fluid) and the phase angle (i.e., lag of particle response with respect to fluid) in the following form:

$$\eta = \sqrt{(1 + f_1)^2 + f_2^2}, \quad \beta = \tan^{-1}\left\{\frac{f_2}{1 + f_1}\right\}. \tag{82}$$

The functions f_1 and f_2 are obtained as

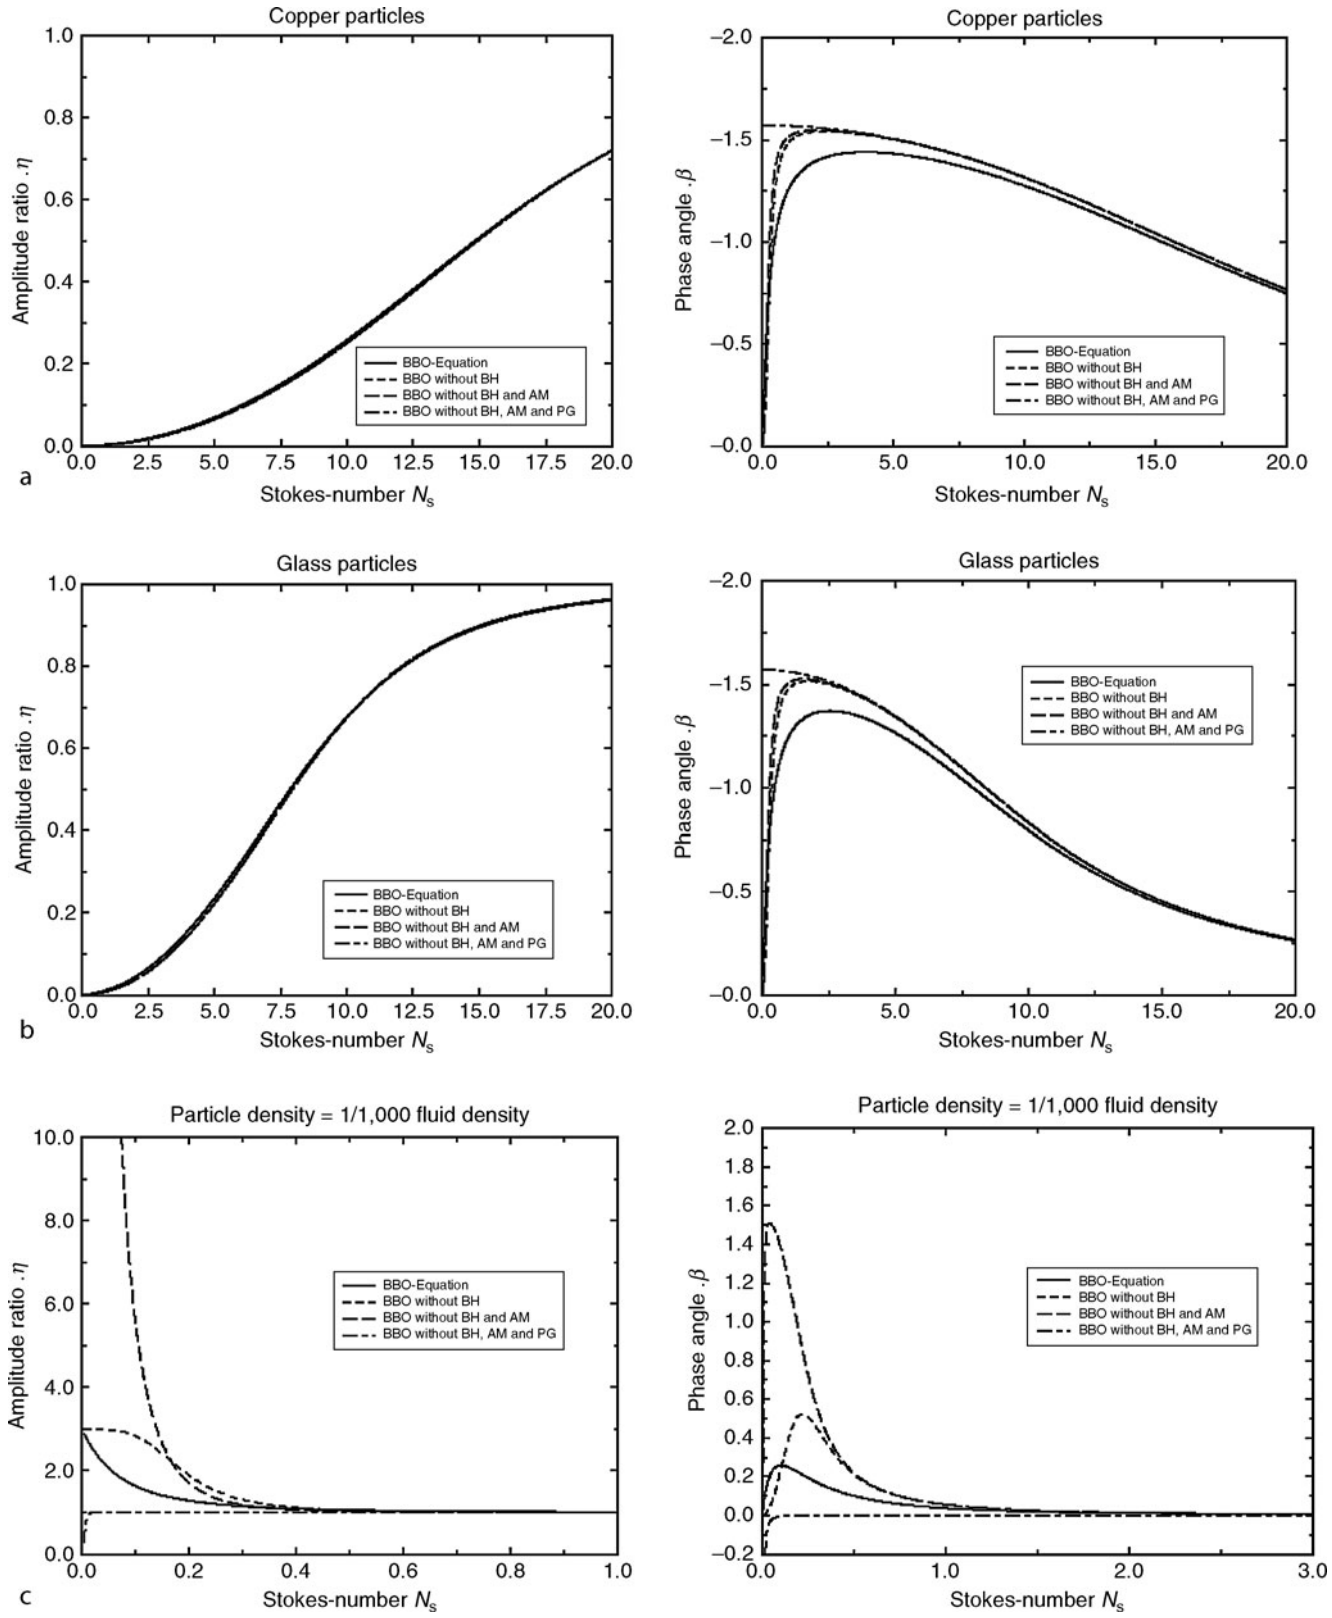
$$f_1 = \frac{\omega(\omega + c\sqrt{0.5\pi\omega})\ (b-1)}{(a + c\sqrt{0.5\pi\omega})^2 + (\omega + c\sqrt{0.5\pi\omega})^2}, \tag{83}$$

$$f_2 = \frac{\omega(a + c\sqrt{0.5\pi\omega})\ (b-1)}{(a + c\sqrt{0.5\pi\omega})^2 + (\omega + c\sqrt{0.5\pi\omega})^2}. \tag{84}$$

The parameter used to characterize the particle response is a modified Stokes number given by

$$N_s = \frac{\mu_F}{\rho_F\omega D_p^2}. \tag{85}$$

The result of this analysis is shown in Fig. 15 for three kinds of particles, namely copper and glass particles in air and air bubbles in water, by considering the different forces. For the three cases, the amplitude ratio and the phase angle is plotted versus the modified Stokes number. It is obvious that for copper particles and glass beads, the added mass, the pressure force, and the Basset term have almost no effect on the amplitude ratio.



L3.1. Fig. 15. Particle response in an oscillatory flow field, influence of the different forces on the amplitude ratio (left column) and the phase angle (right column) for: (**a**) copper particles in air, (**b**) glass beads in air, and (**c**) air bubbles in water.

However, considerable differences are observed in the phase angle for $N_s < 5$, which means for large particles or high frequencies of the oscillatory fluid motion. Only, the added mass is not of great importance and may be neglected without considerable error. Considering a 100 μm particle, the pressure force and the Basset term become of importance for oscillation frequencies larger than about 310 Hz. For bubbly flows, large differences in the response arise for $N_s < 1.0$. However, for this case, the Basset

term may be neglected without introducing too large errors. The added mass and the pressure force on the other hand are of great importance in this region, i.e., for large bubbles and high frequencies of flow oscillation.

In particle-laden flows the drag force is of course the most important fluid dynamic force acting on the particles. The drag however may be affected by a number of physical effects as described above. Wall effects (i.e., particle motion toward or parallel to a wall) become generally only of importance for smaller particle Reynolds numbers. This is achieved for high viscous fluids where obviously the fluid between wall and particle has to be squeezed out. On the other hand, large and inertial particles (i.e., high particle Reynolds number) will not very strongly "feel" the wall before they collide with it and hence fluid dynamic wall effects may be neglected. Rarefaction effects will decrease the drag for very small particles, which is mostly accounted for by the Cunningham correction. Allowing for an error of 5%, rarefaction effects will become important already for particles smaller than about 3 μm for atmospheric conditions. Compressibility effects on the particle drag can be neglected if the particle Mach number is below about 0.5 [4].

The slip-shear lift force in particle-laden flows becomes important if the particles are large and the shear rate is high, as for example in boundary layers or other shear layers. However, this transverse lift force also depends on the slip velocity between particles and fluid. This implies that it might be neglected for smaller particles when the slip is small. For larger particles, the slip-shear lift force should be accounted for. An estimate introduced by Sommerfeld [37] showed that for particles in air, the lift force becomes important for particle sizes larger than about 80 μm and for water, as the continuous phase for sizes larger than about 20 μm. As the shear rate decreases, these sizes are of course shifted to larger values.

The slip-rotation lift force also depends on the slip between the phases and hence becomes less important with decreasing particle size where the slip velocity is also reduced. In addition, small particles will easily follow the rotation of the fluid (freely rotating particle) and therefore, the slip-rotation lift force might be neglected. However, in wall-bounded flows, the particle motion is strongly affected by wall collisions. Thereby, the particles can acquire extremely high angular velocities (e.g., a 100 μm-particle hitting the wall with about 10 m/s will have an angular velocity of $2{\cdot}10^5$ 1/s for a nonsliding wall collision). Therefore, this lift force will strongly affect the particle motion in the vicinity of the wall. With increasing particle size and hence particle inertia, their motion will be more and more affected by the slip-rotation lift force also in regions farther away from the wall. The region of importance may be estimated from the torque acting on the particle. The estimate introduced by Sommerfeld [37] gives, for a higher relative angular velocity, a limiting particle diameter above which the slip-rotation lift force becomes important of 30 μm in water and 90 μm in air.

The transverse lift force in bubbly flows is very important for a correct numerical prediction of the gas volume fraction distribution, such as bubbly pipe flows or in bubble columns. For small bubbles (i.e., $D_B < 5.6$ mm for air–water), this force is directed toward the wall. For larger bubbles, the sign of the lift force changes and thereby the bubbles are driven to the core of a pipe [57]. Therefore, this force is essential for predicting the transition from homogeneous to heterogeneous bubbly flow. The development of a heterogeneous bubbly flow is mainly the result of the transverse lift force, whereby the bubbles are driven to the core, where they will coalesce with other bubbles to form larger bubbles, which are rising in the core of the column. The effect of walls on the behavior of bubbles and the relevant forces is surely quite important. However, up to now, very little knowledge about the modification of forces acting on bubbles in the vicinity of walls and also the direct wall collision process is available.

L3.2 Flow Patterns and Pressure Drop in Fluidized Beds

Karl-Ernst Wirth
Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany

1 Conditions in Fluidized Beds

Fluidization is a technique in which a stream of a gas or liquid flows upward through a bed of particles at a velocity that suffices to loosen the particles and cause the mixture to behave as a liquid.

If the fluid flows at a low velocity, it percolates the bed through the voids without changing the structure of the packing, as is shown in Fig. 1a. The bed with this flow condition is called fixed bed and has a void fraction (porosity) of ψ_{sb} and a height of h_{sb}.

When the velocity is increased, the forces exerted by the fluid on the solid structure become greater. At first, some of the particles commence to move within a restricted range, but most of them remain in prolonged contact to form an expanded solid bed. On a further increase in velocity, all the particles reach a stage in which they are suspended in the fluid and there is no permanent contact with one another. In this state, the pressure drop in the fluid between two horizontal reference planes is in equilibrium with the combined weight of the solids and the fluid per unit area of the planes. This stage is referred to as the onset of fluidization or minimum fluidization and is illustrated in Fig. 1b. The void fraction (porosity) of the bed when it is thus loosened is ψ_L, and the height is h_L. The corresponding fluid velocity is called minimum fluidization velocity.

Beds fluidized by a liquid react toward a further increase in velocity by expanding uniformly. This is known as particulate fluidization, and is illustrated in Fig. 1c.

The behavior of beds fluidized by a gas is entirely different. In this case, the fraction of gas in excess of the flow rate required for minimum fluidization traverses the bed largely in the form of bubbles that are practically free from solids, as is illustrated in Fig. 1d. The void fraction of the bed is then $\psi > \psi_L$, and the height is $h > h_L$. Unless baffles are installed to disperse them, the gas bubbles become larger as they ascend, mainly as a result of coalescence. The fluidized bed is called bubbling fluidized bed.

If the reaction vessel is sufficiently high and narrow, the bubbles finally occupy the total area of the cross section and slugs of gas thus pulse through the fluidized bed, as is indicated by Fig. 1e. This kind of fluidized bed is called slugging fluidized bed.

As long as the bed has a definable upper surface, fluidization prevails in the dense (solid) phase. Once the upward velocity of the fluid becomes the same as the free-falling velocity of the particles, the entire bed will be carried over at the outlet. If the void fraction in gas–solids fluidized beds is large, bubbles will no longer be formed, and the upper surface of the bed will no longer be defined. However, since solid strands are formed, the fluidized bed may be circulated at a superficial gas velocity which is a multiple of the free-falling velocity of the single particles settle, as is shown in Fig. 1f.

2 Onset of Fluidization

The bed is in the most loosely packed state at the onset of fluidization, when the void fraction is ψ_L. It is evident from Table 1 that the numerical value of ψ_L increases with a reduction in the average particle size and a decrease in sphericity φ_s, which is defined by

$$\varphi_s = \frac{\text{Surface area of sphere of same volume as particle}}{\text{Surface area of particle}}.$$

The void fraction at the onset of fluidization also depends on the particle size distribution. This is evident from the figures for "rounded sand $\varphi_s = 0.86$" and "sand mixture (round particles)" in Table 1.

It is only under very restricted circumstances, i.e., a regular arrangement of ideal spheres with few size gradations, that the void fraction of a bed can be predicted [1]. Consequently, if the bed consists of particles of irregular shape and continuous size distribution, the void fraction ψ_L must be estimated from known examples (e.g., Table 1) or determined by experiment. In the following discussion, it is assumed that ψ_L is known. At the onset of fluidization, equilibrium is established between the force of resistance that acts between the fluid and the

solids and the force exerted by the weight of the solids less the buoyancy, i.e.,

$$\Delta pA = Ah_L(1-\psi_L)(\rho_s-\rho_f)g \tag{1a}$$

or

$$\frac{\Delta p}{h_L} = (1-\psi_L)(\rho_s-\rho_f)g, \tag{1b}$$

where Δp is the pressure drop in the fluid in overcoming the resistance of the bed, A is the cross-sectional area of the bed, h_L is the height of the bed at the onset of fluidization, ϱ_s and ϱ_f are the densities of the solid and the fluid, and g is the acceleration due to gravity.

The effect of the void fraction in the $\psi_{sb} \le \psi < 1$ range in predominantly laminar flow through beds of monodispersed spherical particles may be derived from the results of careful measurements [2] and from theoretical considerations [3]. However, the most convenient formulation currently adopted for the pressure drop in polydispersed beds of irregular particles of $\geq$5 µm size packed uniformly at random is that suggested by Ergun and Orning [4], which is valid for the entire range of Reynolds numbers, i.e.,

$$\frac{\Delta p}{h} = kS_v^2\frac{(1-\psi)^2}{\psi^3}\eta u + CS_v\frac{1-\psi}{\psi^3}\rho_f u^2, \tag{2a}$$

where S_v is the specific surface of the particles per unit volume, u is the superficial fluid velocity, η is the dynamic viscosity, and k and C are constants for fitting the experimental results. If it is assumed that the method adopted for the determination of particle size (generally screening) yields at least a rough value for the diameter d_p of spheres of equal volume, the specific surface can be expressed in terms of the mass distribution density $q_3(d_p)$ and the sphericity, which is derived from the particle size measurement and the sphericity which is assumed to be constant, i.e.,

$$S_v = \frac{6}{\varphi_s}\int_{d_{p\,min}}^{d_{p\,max}} d_p^{-1}q_3(d_p)\mathrm{d}(d_p).$$

This relationship defines the average particle size $\bar{d}_p$, which is referred to as the Sauter diameter of the particle size distribution, i.e.,

$$\bar{d}_p = \frac{6}{\varphi_s O_v} = \frac{1}{\int_{d_{p\,min}}^{d_{p\,max}} d_p^{-1}q_3(d_p)\mathrm{d}(d_p)}.$$

Equation (2a) can thus assume the form of

$$\frac{\Delta p}{h} = 36k\frac{(1-\psi)^2}{\psi^3}\frac{\eta u}{(\varphi_s\bar{d}_p)^2} + 6C\frac{1-\psi}{\psi^3}\frac{\rho_f u^2}{\varphi_s\bar{d}_p}.$$

Inserting the numerical values submitted by Ergun [5] for the constants k and C gives

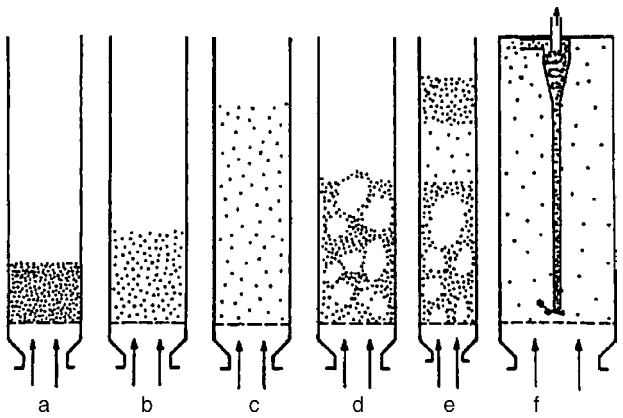
$$\frac{\Delta p}{h} = 150\frac{(1-\psi)^2}{\psi^3}\frac{\eta u}{(\varphi_s\bar{d}_p)^2} + 1.75\frac{1-\psi}{\psi^3}\frac{\rho_f u^2}{\varphi_s\bar{d}_p}. \tag{2b}$$

If allowance is made for the kinematic viscosity $\nu = \eta/\varrho_f$, equating Eqs. (1b) and (2b) yields a correlation for the superficial velocity of the fluid at the onset of fluidization u_L and between the Reynolds number at the onset of fluidization and the Archimedes numbers. The Reynolds number at the onset of fluidization is $\mathrm{Re}_L = u_L\bar{d}_p/\nu$; and the Archimedes number,

$$\mathrm{Ar} = \frac{g(\bar{d}_p)^3}{\nu^2}\left(\frac{\rho_s}{\rho_f}-1\right).$$

Hence,

$$\mathrm{Re}_L = 42.9\frac{1-\psi_L}{\varphi_s}\left[\sqrt{1+3.1\cdot10^{-4}\frac{\varphi_s^3\psi_L^3}{(1-\psi_L)^2}\mathrm{Ar}}-1\right]. \tag{3}$$



L3.2. Fig. 1. Conditions in fluidized beds.

L3.2. Table 1. Experimental values for the void fraction (porosity) at the onset of fluidization [11]

Particles	Average particle size						
	20	50	70	100	200	300	400
Angular sand (φ_s = 0.67)	–	0.60	0.59	0.58	0.54	0.50	0.49
Rounded sand (φ_s = 0.86)	–	0.56	0.52	0.48	0.44	0.42	–
Sand mixture (round particles)	–	–	0.42	0.42	0.41	–	–
Pulverized coal and glass	0.72	0.67	0.64	0.62	0.57	0.56	–
Anthracite (φ_s = 0.63)	–	0.62	0.61	0.60	0.56	0.53	0.51
Activated charcoal	0.74	0.72	0.71	0.69	–	–	–
Fischer–Tropsch catalyst (φ_s = 0.58)	–	–	–	0.58	0.56	0.55	–
Carborundum	–	0.61	0.59	0.56	0.48	–	–

If the data for the solids and the fluid are known, the superficial velocity of the fluid at the onset of fluidization can be determined. Thus if $Re_L \leq 1$, i.e., in the most frequently occurring case of creeping ("laminar") flow through a bed of fine particles, the following applies:

$$Re_L = \frac{1}{150}\frac{\varphi_s^2\psi_L^3}{1-\psi_L}Ar$$

and

$$u_L = \frac{1}{150}\frac{\varphi_s^2\psi_L^3}{1-\psi_L}\frac{g(\bar{d}_p)^2}{\nu}\left(\frac{\rho_s}{\rho_f}-1\right). \quad (4)$$

If $Re > 10^3$, i.e., for predominantly inertia determined ("turbulent") flow through a bed of coarse particles, the relationship is

$$Re_L = \sqrt{\frac{\varphi_s\psi_L^3 Ar}{1.75}}$$

and

$$u_L = \sqrt{\left(\frac{1}{1.75}\right)\varphi_s^2\psi_L^3 g\bar{d}_p\left(\frac{\rho_s}{\rho_f}-1\right)}. \quad (5)$$

The following simple empirical correlation for the determination of the velocity at the onset of fluidization has been submitted by Wen and Yu [6]:

$$Re_L = 33.7(\sqrt{1+3.6\cdot 10^{-5}Ar}-1).$$

The velocity at the onset of fluidization should be determined under actual operating conditions, which may differ considerably from those applicable to a freshly charged bed owing to carryover of fines, agglomeration, and increase or shrinkage in particle size as a consequence of chemical reactions.

3 Expansion of Fluidized Bed

3.1 Homogeneous Liquid–Solids Fluidized Bed

The expansion that ensues when the inlet velocity exceeds that at the onset of fluidization u_L can be very easily expressed in the form of an equation if the liquid–solids fluidized bed is homogeneous. Thus, if ψ is substituted for ψ_L and u for u_L, Eq. (4) could apply for $\psi \leq 0.8$ and Reynolds numbers derived from the particle size, i.e.,

$$Re_p = \frac{u\bar{d}_p}{\nu} \leq 1.$$

This implies that, if flow is "laminar", the structure of a liquid–solids fluidized bed does not differ very much from that of a fixed bed of the same porosity [3].

The simplest relationship for the expansion of these fluidized beds within the entire $\psi_L \leq \psi \leq 1$ range of void fractions and the entire range of Reynolds numbers is that submitted by Richardson and Zaki [7], i.e.,

$$\frac{u}{w_f} = \psi^n, \quad (6)$$

where w_f is the settling velocity of the individual particles in a medium of infinite extent. In practice, when the particle/fluidization vessel diameter ratio is « 1, the index n depends solely on $Re = w_f\bar{d}_p/\nu$. The following numerical values apply:

$n = 4.65$	for	$Re < 0.2$
$n = 4.35\ Re^{-0.03}$	for	$0.2 < Re < 1$
$n = 4.45\ Re^{-0.10}$	for	$1 < Re < 500$
$n = 2.39$	for	$Re > 500$

In particular, Eq. (6) states that if $u = w_f$, i.e., if the settling velocity is attained, the fluidized bed will be carried over.

3.2 Gas–Solids Fluidized Beds

3.2.1 Aggregative Fluidization

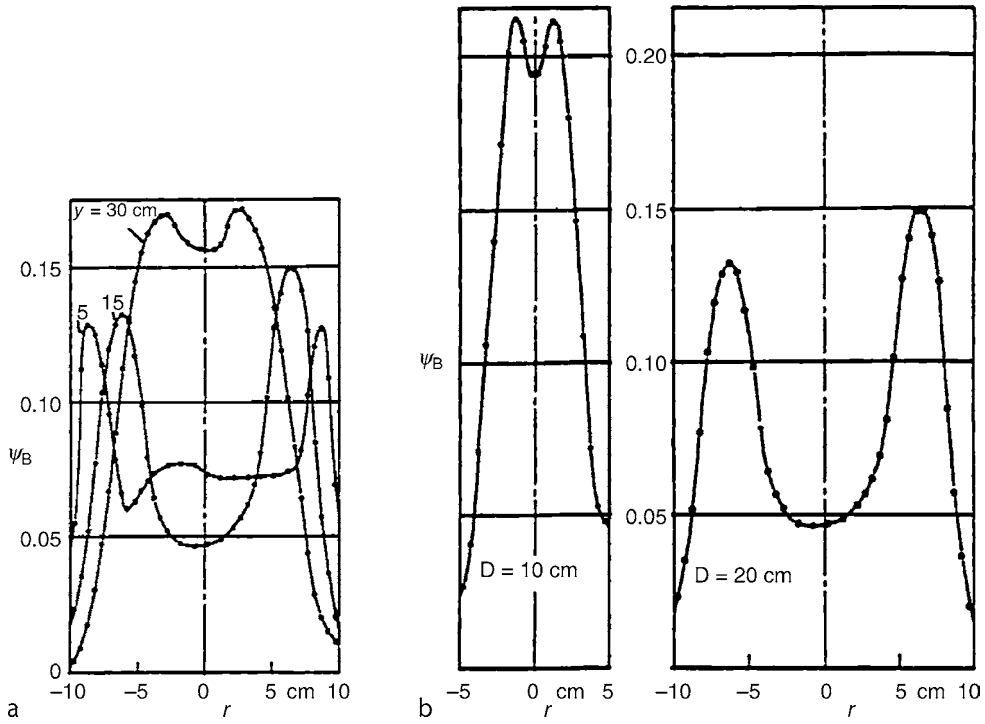
Gas bubbles cause the solids to move violently within the bed. Consequently, fluctuations occur in the height h and thus in the void fraction ψ. These two variables are connected as follows through the data for the system at the onset of fluidization:

$$\frac{h}{h_L} = \frac{1-\psi_L}{1-\psi}.$$

Hence, their numerical values represent averages with respect to time. The void fraction at all points within liquid–solids fluidized beds is practically the same as the porosity ψ, but a quantitative characterization of gas–solids fluidized beds is much more difficult. In a detailed description that has been published [8] on the flow mechanisms concerned, it was assumed that an element of volume within a gas–solids fluidized bed contains a time-averaged fraction ψ_B of gas bubbles and that the loosened bed enclosing the bubbles in the same element of volume has a void fraction ψ_S. As a rule, neither ψ_B nor ψ_S is constant for a given bed. In vessels that are symmetrical about an axis of rotation, they depend on the distance r from the axis and on the distance from the gas distributor, as has been demonstrated in studies with local sensors [8]. Local bubble volume fractions ψ_B measured in various cross sections at different distances from the gas distributor are presented as an example in Fig. 2a. It can be seen that the expansion of a gas–solids fluidized bed is governed in a complicated manner by local fluctuations.

An aggravating factor is that fluidization greatly depends on the diameter of the vessel. Figure 2b shows the local bubble volume fraction ψ_B measured at a distance of 15 cm from the gas distributor in fluidized beds of 100 and 200 mm diameter.

It is evident from these experimental results that no equation of general validity can be quoted for the relationship between the inlet velocity and the bed expansion. Likewise, empirical correlations derived by various authors from bed expansion measurements in laboratory apparatus are valid only for the layout concerned.



L3.2. Fig. 2. (**a**) Local bubble volume fraction ψ_B as a function of the distance r from the axis of a tubular bed for various spacings y from the gas distributor. Diameter of fluidized bed 20 cm; u = 8.94 cm/s. Sand (d_p = 85 μm, u_L = 1.8 cm/s); (**b**) local bubble volume fraction ψ_B as a function of the distance r from the axis of a tubular bed at a spacing of 15 cm from the gas distributor in fluidized beds of various diameters. Sand (d_p = 85 μm, u_L = 1.8 cm/s); u = 8.94 cm/s.

3.2.2 Circulating Fluidized Beds

The feature of circulating fluidized beds is that the superficial velocity are greater than the free-falling velocity of the individual particles, which are generally expressed in terms of $\bar{d}_p$. As a result, a stream of solids is carried over. In order to maintain steady-state conditions, the solids must be separated from the gas stream, e.g., in a cyclone, and returned to the bed.

State and pressure drop diagrams for these beds can be determined mathematically and graphically from simple force and mass balances [9]. Examples in dimensionless form are presented in Fig. 3. The ordinate axis represents the pressure gradient in the plant expressed in terms of that at minimum fluidization. The only values that this dimensionless form of pressure gradient can assume lie between zero and unity. In the former case, no solids are present in the pipe element; and in the latter case, the pipe element is completely filled with solids in a state of minimum fluidization. The axis of abscissae represents the superficial velocity expressed in dimensionless form as the particle Froude number, i.e.,

$$\mathrm{Fr}_p = \frac{u}{\sqrt{\frac{\rho_s - \rho_f}{\rho_f}\bar{d}_p g}}.$$

The parameter is a dimensionless form of the mass flow rate of circulated solids. It is expressed as the ratio of the volume flow rate of solids, as determined from the apparent density at minimum fluidization, to the volume flow rate of gas, i.e.,

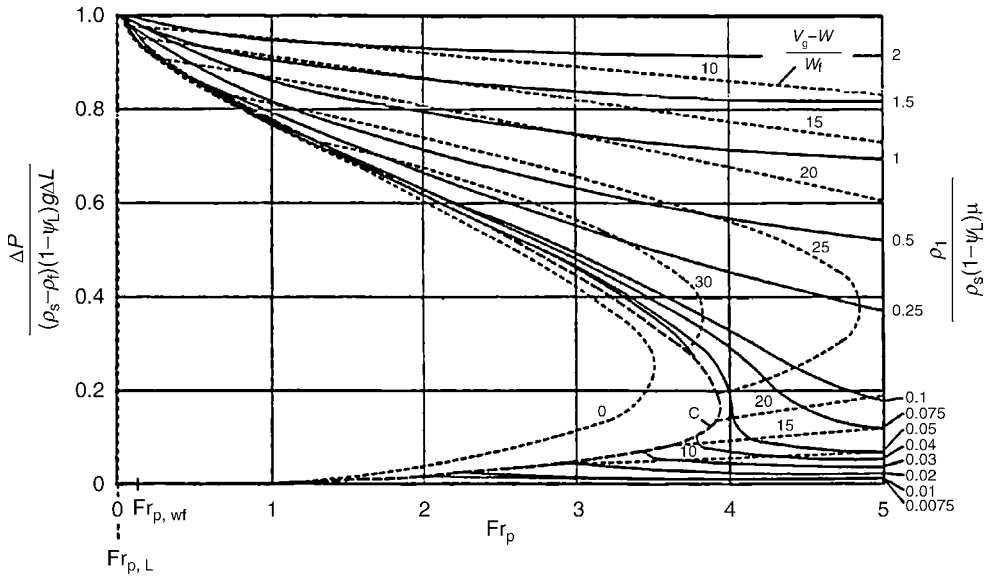
$$\frac{\rho_f}{\rho_s(1-\psi_L)}\mu = \frac{\dot{M}_s}{\rho_s(1-\psi_L)}\frac{\rho_f}{\dot{M}_f},$$

where μ is the solids load in the gas stream, M_s is the mass flow rate of solids carried over, and M_f is the mass flow rate of gas through the bed.

The diagram also includes curves for constant relative velocity ratios, i.e., $(v_g - w)/w_f$, where v_g is the velocity of the gas phase with a low solids content and w is the velocity of the strands. This ratio indicates the factor by which the relative velocity between the gas and the solid aggregate, i.e., strands and clusters, exceeds the free-falling velocity of the individual particles.

A state and pressure drop diagram of this nature is valid only for a given gas–solids system that is characterized by the Archimedes number, which contains only the properties of the gas and the solids and the bed porosity at the onset of fluidization. All the operating points that are likely to occur in a circulating fluidized bed have been included in the diagram.

The solids separated by a cyclone from the gas stream are returned to a point immediately above the gas distributor in the circulating fluidized bed. The construction of the line through which they are returned is responsible for the differences in the



L3.2. Fig. 3. State and pressure diagram for the upward flow of demixed circulating gas–solids fluidized beds (Ar = 10; $\psi_L = 0.4$).

design of the beds, and the individual designs permit only very specific operating points [9]. There are three basic designs, i.e.,

1. Circulating fluidized beds with dosing devices and a pressure lock.
2. Circulating fluidized beds with dosing devices and a pressure feeder with a restricted differential pressure, e.g., a feeder-type fluidized bed and an L-valve.
3. Circulating fluidized beds with siphons.

The most widely adopted design in current practice is that with a siphon in the return line. The bed in this case is of given mass, i.e., the pressure drop in the bed is constant. At high gas velocities, the contents of the bed are uniformly distributed, apart from acceleration effects, over the entire height of the installation. A zone of steady-state conditions and a constant pressure gradient exists in the circulating fluidized bed. The pressure gradient can be calculated from the mass of the bed, i.e., the weight of the solids charged, by means of Eqs. (1a) and (1b). It is independent of the gas velocity as long as the solids remain uniformly distributed over the height of the installation. The corresponding curve in the dimensionless pressure drop diagram is parallel to the axis of abscissae. The relationships are shown schematically in Fig. 4.

If the volume of the solids return line is neglected and the solids are uniformly distributed, the maximum dimensionless pressure drop in circulating fluidized beds of constant cross-sectional area is equal to the ratio of the height h_L of the bed at the onset of fluidization to the total height of the installation, i.e., equal to the relative height to which the bed is filled with solids, i.e.,

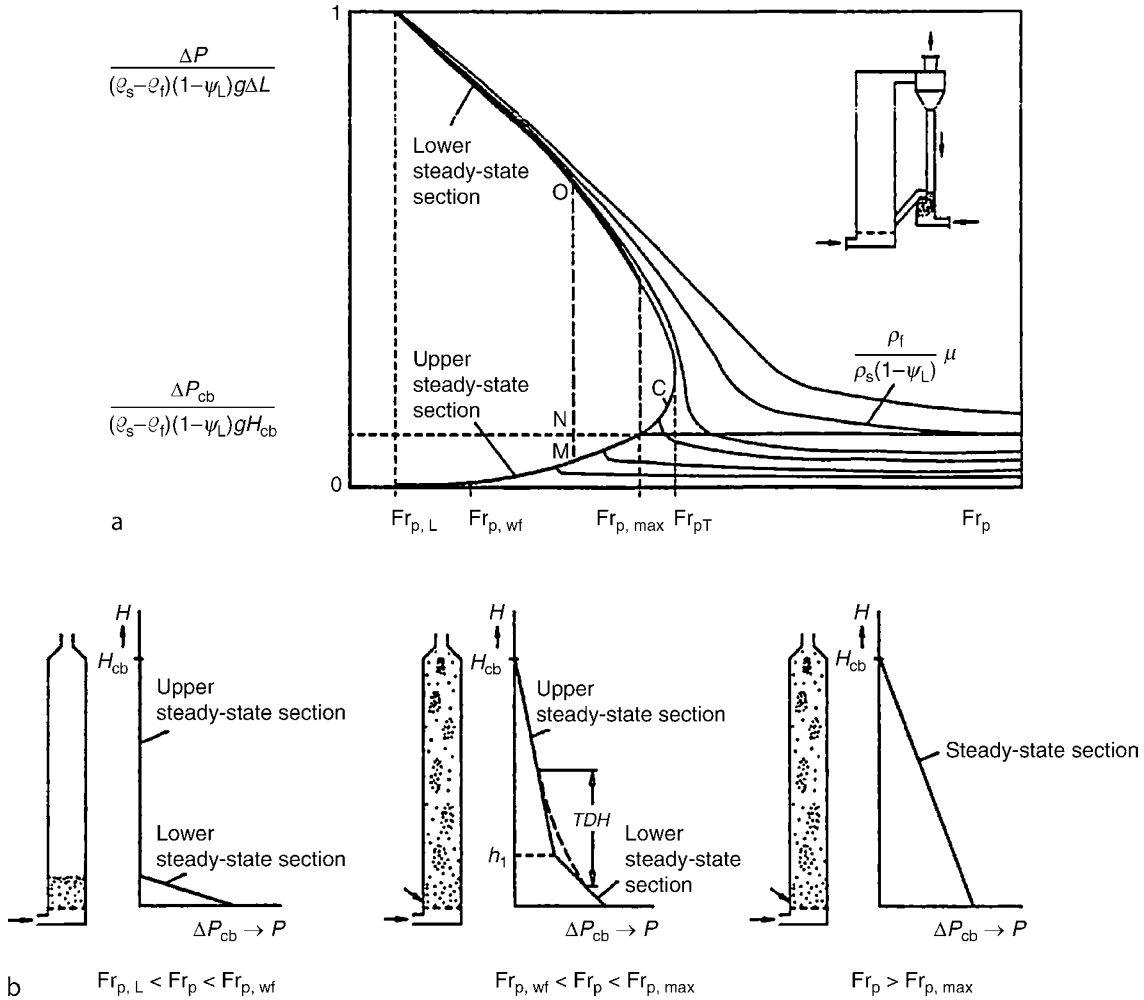
$$\frac{\Delta P_{cb}}{(\rho_s - \rho_f)(1 - \psi_L)gH_{cb}} = \frac{h_L}{H_{cb}},$$

where H_{cb} is the height of the circulating bed.

If the Froude number Fr_p is reduced, the pressure drop curve corresponding to a charge of constant weight meets the boundary curve C at the point $Fr_{p,\,max}$. At values in the range between $Fr_{p,\,max}$ and the particle Froude number derived from the settling velocity of the individual particles $Fr_{p,\,wf}$, there are two pressure gradients in the circulating fluidized bed that correspond to the boundary curve C. Thus, there are two steady-state sections. One of them, with a pressure gradient corresponding to the upper branch of the boundary curve C, exists in the lower part of the circulating bed; and the other, with a pressure gradient corresponding to the lower branch of curve C, in the upper part. Nevertheless, the total pressure drop Δp_{cb} remains constant and continues to be governed by the weight of the charge and the height of the bed at the onset of fluidization. In practice, the transition at the point h_1 between two steady-state sections is not as abrupt as is indicated by the full-line theoretical curve in Fig. 4. It actually takes place gradually, and the height of the zone over which it proceeds is referred to as the transport disengaging height (TDH).

If the Froude number Fr_p is further reduced in the range between that derived from the velocity at the onset of fluidization $Fr_{p,\,L}$ and $Fr_{p,\,wf}$, two steady-state sections again exist in the circulating fluidized bed. Since Fr_p is smaller than $Fr_{p,\,wf}$, which is derived from the settling velocity of the individual particles, no solids can be carried over. Thus, there is a freeboard, and the pressure gradient is delineated by the axis of abscissae, i.e., it is zero. The pressure gradient in the lower part of the bed is fixed by the pressure drop curve for the volume flow rate ratio zero. In this range of Fr_p numbers, an aggregative or turbulent bed is formed – but only immediately above the gas distributor – and the total pressure drop in the circulating fluidized bed ΔP_{cb} again depends solely on the weight of the charge.

The solids concentration is a factor that affects heat transfer, and a knowledge of its axial distribution is therefore of great importance in thermal design. The average $(1 - \psi)$ over the



L3.2. Fig. 4. Diagram of state (**a**) and pressure profile (**b**) for a circulating fluidized bed with siphon.

cross section can be calculated from the dimensionless pressure drop, i.e.,

$$(1-\psi) = (1-\psi_L)\frac{\Delta P}{(\rho_s-\rho_f)(1-\psi_L)g\Delta L}.$$

Thus, the solids concentration in a circulating fluidized bed is proportional to the pressure gradient at a given height. It is constant in the axial direction if $Fr_p > Fr_{p,\,max}$, but depends on height if $Fr_p < Fr_{p,\,max}$. On a reduction of the Froude number Fr_p below $Fr_{p,\,max}$, the solids concentration decreases in the upper part of the bed and increases in the lower part. If $Fr_p < Fr_{p,\,wf}$, there will be a freeboard, i.e., the concentration in the upper part of the bed will be zero. In the lower part of the bed, even in this Fr_p range, the solids concentration continues to increase with a decrease in the Froude number. The maximum value is attained when the particle Froude number Fr_p is equal to that derived from the velocity at the onset of fluidization $Fr_{p,\,L}$, i.e., when fluidization in the circulating bed is a minimum.

The reason for the decrease in solids concentration in the upper part of the bed when Fr_p is reduced to below $Fr_{p,\,max}$ is that the stable solids load that the gas stream can carry is restricted by the boundary curve *C*. In this design of circulating fluidized bed, the mass of the bed remains constant if the Froude number Fr_p is reduced. The law of conservation of mass therefore entails that an axial concentration profile is formed if $Fr_p < Fr_{p,\,max}$. The relative length of the lower steady-state section h_1/H_{cb} is equal to the ratio of the sections NM and MO; and that of the upper steady-state section $(H_{cb} - h_1)/H_{cb}$, to the ratio NO/MO.

Accordingly, if $Fr_p < Fr_{p,\,max}$, the physics of gas flow is responsible for the solids concentration and the pressure gradients in the steady-state sections; and the weight of the charge, only for their relative length. Conversely, if $Fr_p > Fr_{p,\,max}$, the solids charge and thus the method of plant operation will govern the solids concentration and the pressure gradients in circulating fluidized beds with siphons.

If the superficial velocity is less than the settling velocity of the individual particles, expressed in terms of $\bar{d}_p$, the particle size distribution should be divided into as many intervals as possible, and the state and pressure drop diagrams for each should then be separately determined. Afterwards, the flow patterns in the circulating fluidized bed can be obtained from the mass fractions in each interval [9]. An example is given by circulating fluidized bed firing systems, in which the cross

section is usually widened. In this case, the height of the system should be divided into two parts, each of uniform cross-sectional area, and the associated diagrams of state should then be determined [9].

4 Operating Range of Inlet Velocities in Particulate and Aggregative Fluidized Beds

The range of inlet velocities in liquid–solids fluidized beds is restricted, on the one hand, by the velocity at the onset of fluidization u_L and, on the other hand, by the settling velocity of the particles, i.e., $u_L \leq u \leq w_f$. Pronounced inhomogeneities occur in gas–solids fluidized beds, i.e., gas bubbles at low and solid strands at high void fractions. As a consequence, a substantial fraction of the solids may be carried over and returned to the bed via a cyclone [10], as has been described in Sect. 3.2.2. A useful estimation of the operating range, even in aggregative gas–solids fluidized beds, can be obtained from the w_f/u_L ratio if the particles are spheres of the same diameter d_p. The Archimedes number and the Reynolds number derived from the settling velocity of the individual particles are related as follows:

$$\mathrm{Ar} = 3/4\mathrm{Re}_{wf}^2 c_w(\mathrm{Re}_{wf}),$$

in which $c_w(\mathrm{Re}_{wf})$ is the drag coefficient for the individual particles. The unique inverse function is

$$\mathrm{Re}_{wf} = \mathrm{Re}_{wf}(\mathrm{Ar}). \qquad (7)$$

Figure 5 has been derived from Eqs. (3) and (7) for $\varphi_s = 1$. It shows the Archimedes number as a function of the following ratio:

$$\frac{w_f}{u_L} = \frac{\mathrm{Re}_{wf}}{\mathrm{Re}_L} = f(\mathrm{Ar}, \psi_L).$$

The parameter is ψ_L, and the diagram is valid for spherical particles of uniform size.

The following simple expressions can be derived for the two limits – minimum fluidization and settling of the individual particles:

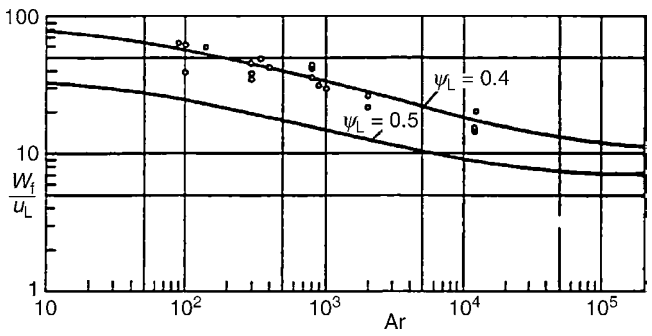
$$\left.\begin{aligned} \left(\frac{w_f}{u_L}\right)_{lam} &= \frac{25}{3}\frac{1-\psi_L}{\psi_L^3} = 78 \\ \left(\frac{w_f}{u_L}\right)_{turb} &= \sqrt{\frac{5.25}{\psi_L^3}} = 9 \end{aligned}\right\} \text{for } \psi_L = 0.4.$$

They apply if both limits are for purely "laminar" or for purely "turbulent" flow. The numerals 78 and 9 were obtained from the results of experiments. Particular attention should be paid to the fact that the operating range for fine particles is wider than that for coarse particles.

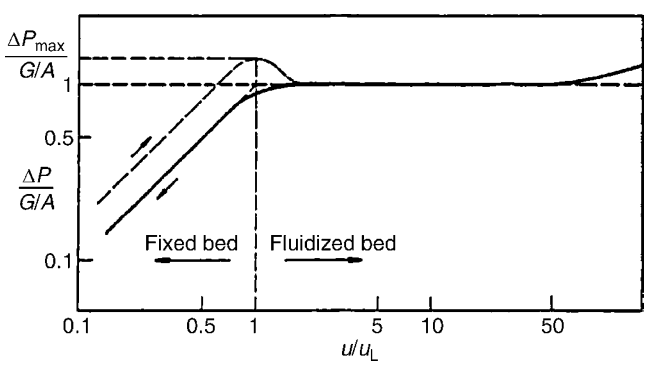
5 Pressure Drop

In a readily fluidizable bed of particles with low cohesion and of almost uniform size, a dimensionless expression for the pressure drop Δp can be obtained from the total weight G and the cross-sectional area A of the bed. It is shown in Fig. 6 as a function of the dimensionless superficial velocity, i.e., u expressed as a ratio of the velocity u_L at the onset of fluidization.

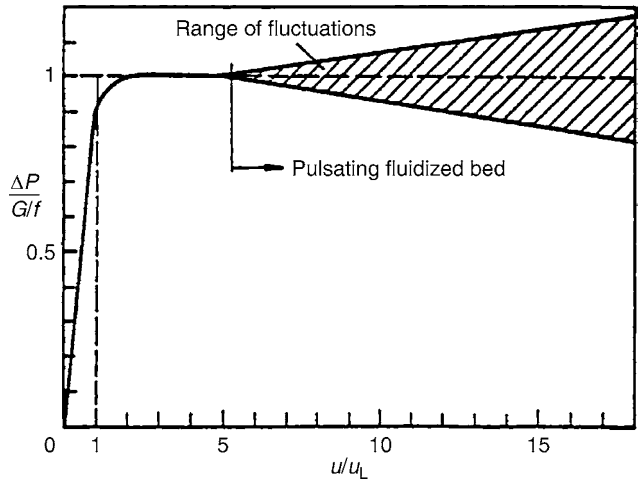
If the particles are sufficiently fine and the flow through the bed is thus "laminar", the slope of the curve is unity. Before the onset of fluidization, a value $\Delta p_{max}(G/A) > 1$ is attained as a result of compaction brought about by the bed's own weight. As fluidization progresses, the initial compaction is overcome, and the pressure drop within the bed falls to the equilibrium value $\Delta p/(G/F) = 1$. It is not until u/u_L » that the pressure drop commences to rise slightly again as a result of the additional losses brought about by the much more intense movement of the solids and the increase in the gas flow rate. If the inlet velocity falls below u_L, the pressure drop becomes less in the bed of loose solids. For this reason, it is advisable to define the onset of fluidization as the intersect of the decreasing inlet velocity branch of the curve for the fixed bed (extrapolated if necessary) and the horizontal curve for the fluidized bed. Whenever possible u_L determined direct by this means should be adopted for design purposes.



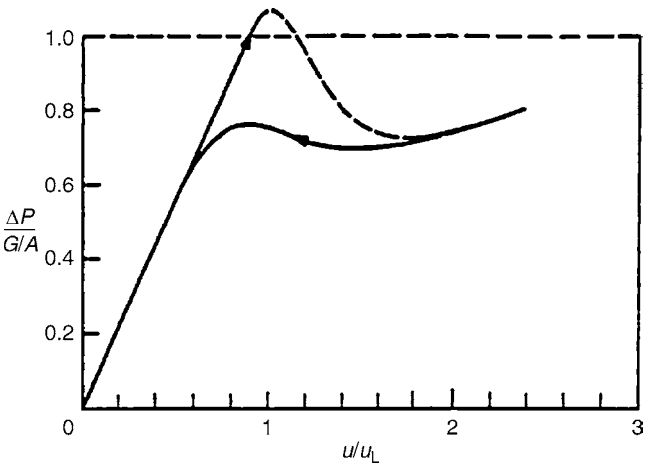
L3.2. Fig. 5. Operating range for particulate and aggregative fluidized beds: Archimedes number as a function of w_f/u_L with ψ_L as parameter. Measurements by [18].



L3.2. Fig 6. Pressure drop curve for a readily fluidizable gas–solids bed.



L3.2. Fig. 7. Fluctuations in pressure in a pulsating fluidized bed.



L3.2. Fig 8. Pressure drop in a channeling fluidized bed.

Pulsation and channeling in fluidized beds must be avoided in practice: pulsation entails undesirable mechanical stresses, and channeling indicates maldistribution. Both can be recognized by peculiarities in the pressure characteristic. Thus pronounced fluctuations in pressure, as is illustrated in Fig. 7, are a sign of pulsation.

Beds of fine particles are particularly cohesive and thus prone to channeling. The gas flows preferentially through the channels, and the surrounding sections of the bed remain largely unfluidized. The pressure drop in channels of comparatively large cross-sectional area is abnormally less than that in a well-fluidized bed, as can be seen in Fig. 8.

The gas distributor contributes substantially to the pressure drop in a bed. The design depends on the application – porous sintered metal, ceramics, plastics panels; fabrics stretched on a supporting grid; beds of material fixed between sheets of wire gauze; perforated sheet metal; or slotted or bubble-cap plates. Experience gained in operating fluidized beds has shown that the pressure drop over the gas distributor should be 10–20% of the pressure drop in the bed or at least about 3,000 N/m^2 if the bed is correspondingly low [11–13].

The void fraction in plates with perforations of a few millimeters diameter is $\varphi_{perf} < 10\%$. Their pressure drop can be determined by the Kneule and Zelfel diagram [14], which is reproduced in Fig. 9. The characteristic K on the axis of abscissae is given by

$$K = \mathrm{Re}_{perf}\left(\frac{d_{perf}}{b}\right)\left(\frac{b}{t}\right)^{0.7} N_{perf}^{0.25}, \tag{8}$$

where $\mathrm{Re}_{perf} = u_{perf} d_{perf}/\nu$ is the Reynolds number applicable to an average gas velocity u_{perf} in perforations of d_{perf} diameter, b is the thickness of the perforated plate, t is the spacing between perforations, and N_{perf} is the number of perforations.

The following relationships exist between φ_{perf}, d_{perf}, N_{perf}, t, and the bed diameter d:

$$\varphi_{perf} = \left(\frac{d_{perf}}{d}\right)^2 N_{perf} = \frac{\pi}{2\sqrt{3}}\frac{d_{perf}^2}{t^2}, \tag{9}$$

$$N_{perf} = \frac{2}{\sqrt{3}}\frac{A}{t^2}. \tag{10}$$

The thickness of the perforated plate is given by [14]

$$b \geq d_{perf}. \tag{11}$$

The measured dimensionless pressure drop ξ_{perf} on the axis of ordinates is defined by

$$\xi_{perf} = \frac{\Delta p_{perf}}{\frac{\rho_g}{2} u_{perf}^2}. \tag{12}$$

If the particles are fine and correspondingly cohesive, adequate fluidization may be ensured by designing the distributor so that the gas jets issuing from the perforations maintain the solids in sufficient motion. The conditions for this, as determined by experiment, are as follows:

$$\frac{\rho_g}{2} u_{perf}^2 = a\frac{G}{f},$$

where $0.5 < a < 0.75$ and

$$u_{perf} = b\sqrt{\frac{G}{f\rho_g}}, \tag{13}$$

where $1 < b < 1.2$.

The void fraction and the (generally higher) pressure drop in the gas distributor can be obtained from the superficial velocity required for fluidization and the diameter selected for the perforations.

Engineers engaged in practice can obtain more detailed information on specialized aspects of fluidization technology from standard works [15–17].

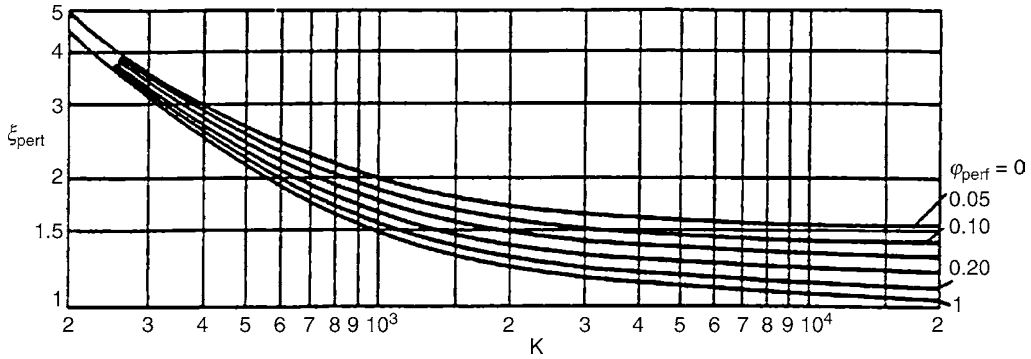
Example

Given

$$\varrho_s = 3\,\mathrm{g/cm^3},\ \bar{d}_p = 100\,\mu\mathrm{m},\ \text{and}\ \varrho_g = 10^{-3}\,\mathrm{g/cm^3}.$$

Fluidized bed diameter $d = 5$ m.

$$\varphi_s = 1, \nu = 15 \cdot 10^{-6}\,\mathrm{m^2/s},\ h_L = 3\,\mathrm{m}, \text{and}\ \psi_L = 0.4.$$



L3.2. Fig. 9. Resistance factor ξ_{perf} for a perforated-plate gas distributor as a function of the characteristic K with the void fraction φ_{perf} as parameter [14].

To be determined

1. Gas velocity $u = 10\,u_L$.
2. w_r/u_L.
3. Pressure drop in fluidized bed and design data for perforated-plate gas distributor.
   (1) If $Re \leq 1$ is assumed, it follows from Eq. (4) that

$$u_L = \frac{1}{150}\frac{1 \cdot 0.4^3}{0.6}\frac{9.81 \cdot 10^4 \cdot 10^{-12} \cdot 3}{15 \cdot 10^{-6} \cdot 10^{-3}} = 1.4 \cdot 10^{-2}\ \text{m/s},$$

$$u = 10 \cdot 1.4 \cdot 10^{-2} = 0.14\ \text{m/s}.$$

   Check

$$Re_L = \frac{1.4 \cdot 10^{-2} \cdot 10^2 \cdot 10^{-6}}{15 \cdot 10^{-6}} = 0.093 = 1.$$

   (2) $$Ar = \frac{9.81 \cdot 10^6 \cdot 10^{-18} \cdot 3}{225 \cdot 10^{-12} \cdot 10^{-3}} = 131.$$

   Reading off against $\psi_L = 0.4$ in Fig. 5 gives $w_f/u_L > 10$. In other words, the conditions lie within the operating range for the fluidized bed.
   (3) Pressure drop in fluidized bed as derived from Eq. (1a)

$$\Delta p = (1 - \psi_L)\left(\rho_s - \rho_g\right) g h_L$$

$$= 0.6 \cdot 3 \cdot 10^3 \cdot 9.81 \cdot 3 = 5.3 \cdot 10^4\ \text{N/m}^2.$$

$$\text{Estimation}: \quad 4\Delta p_{perf} = 0.1\Delta p_{bed} = 5.3 \cdot 10^3\ \text{N/m}^2.$$

Turbulent flow and thus very low void fractions φ_s represent the only means of obtaining high pressure drops of this order. In this case, it follows from Fig. 9 that $\xi_{perf} = 1.5$; and thus from Eq. (11),

$$u_{perf} = \sqrt{\frac{2 \cdot 5.3 \cdot 10^3}{1 \cdot 1.5}} = 84\ \text{m/s}.$$

The equation of continuity yields

$$\varphi_{perf} = \frac{u}{u_{perf}} = \frac{14 \cdot 10^{-2}}{84} = 1.67 \cdot 10^{-3}.$$

A point to observe in selecting the diameter d_{perf} of the perforations is that a large number of perforations N_{perf}, i.e., a narrow spacing t, improves gas distribution by preventing dead spots in the vicinity of the distributor but greatly increases the risk of fouling. Values of t and N_{perf} calculated from Eqs. (9) and (10) are listed against the corresponding values of d_{perf} in the following table. The value for K should be subsequently determined to verify the validity of the assumption $\xi = 1.5$.

d_{perf} (M)	t (m)	N_{perf} (–)	B (m)	K (–)	ξ_{perf}[a] (–)
0.001	0.023	$4.2 \cdot 10^4$	0.004	$5.8 \cdot 10^3$	1.6
0.002	0.047	$1.0 \cdot 10^4$	0.004	$1 \cdot 10^4$	1.5
0.005	0.147	$1.67 \cdot 10^3$	0.005	$2 \cdot 10^4$	1.5
0.010	0.233	418	0.010	$2.8 \cdot 10^4$	1.5

L3.3 Pressure Drop in Pneumatic Conveying Systems

Ulrich Muschelknautz
MK Engineering, Innsbruck, Austria

1 Types of Flow and Functional Diagram

The type of the two-phase flow, which develops in a pneumatic conveying system, depends crucially on the load ratio (solids-to-gas) μ . The load ratio is defined by

$$\mu = \dot{M}_s / \dot{M}_g. \tag{1}$$

Also the pressure drop of a pneumatic conveyor is strongly determined by the solids load. The transport of particles leads to a pressure drop in addition to that caused by the pure gas flow.

In thermal engineering applications, e.g., cooling, heating, drying, or incineration, the load ratio is typically $\mu = 0.05$–2, the gas velocities in the pipe are 15–30 m/s, and the average particle size d_{50} lies between ca. 50 µm and 2 mm. Under these operating conditions, the particles are usually uniformly distributed over the pipe cross section. This state of pneumatic conveying is referred to as fully suspended flow. The short routes which the particles have to traverse in pneumatic conveyor dryers of the type shown in Fig. 1 consist of frequent turns and changes in the cross section. In this case, the pressure drop is mainly caused by acceleration of the particles at the feeding point and behind the bends.

If the conveyor is intended solely for transportation, as is shown in Fig. 2, bends are avoided whenever possible. Under these circumstances, the weight and wall friction of the solids are primarily responsible for the additional pressure drop.

A fully suspended flow is feasible if the load ratio in a horizontal pipe remains less than the limited load ratio μ_{lim} [1–4]:

$$\mu_{lim} = (0.02...0.04) \cdot \left[\frac{\lambda_g v^3}{g D w_s} k + \frac{2}{\sqrt{\frac{a}{d_s}}} \frac{c^2}{gD} (1-k) \right]. \tag{2}$$

A load ratio μ, which is not more than about 10% greater than the limited load ratio μ_{lim}, does not create any problem for fully suspended flow. The smaller constant in Eq. (2) is valid for narrow particle size distributions and for approximately spherical particles, the larger constant has to be applied for broader particle size distributions and for particles with irregular but compact shape. Equation (2) is valid for conveying pipes with an inner diameter larger than 70 mm.

At higher solids load and/or lower gas velocity, a part of the product moves along the wall in the form of strands and the strand type conveying is achieved.

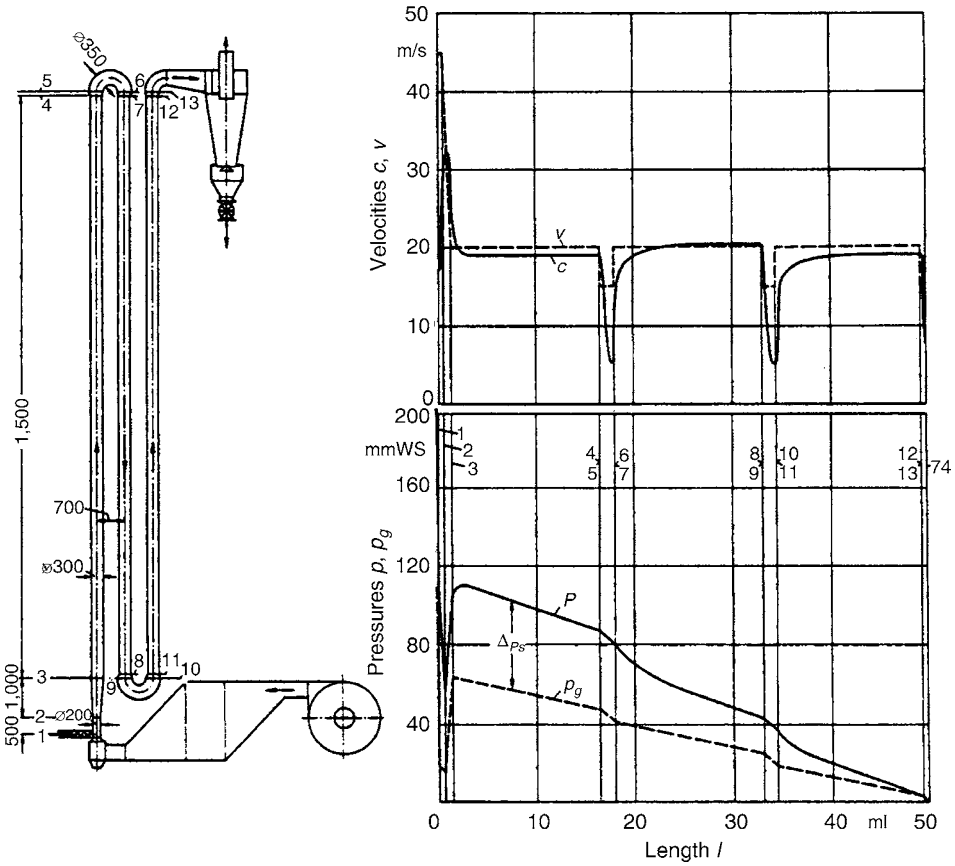
At high solids mass flow rates, direct transition from strand type conveying to plug flow occurs for solids with large particle sizes and, in the case of finely grained particles, blockage of the system develops. Plug flow conveying is frequently resorted in order to save energy in pure transportation tasks.

Typical data for the three types of conveyance are given in Fig. 3.

Plug flow conveyance may also be controlled. In this case, bypasses are usually installed by means of which the columns or plugs are restricted to given lengths [5, 6].

By itself, v is the superficial velocity, but in the term c/v it is the effective velocity.

The functional diagram in Fig. 4 shows on the right-hand side at the top the fully suspended flow at load ratios of



L3.3. Fig. 1. Schematic diagram of a pneumatic conveyor dryer with gas velocity v, average particle velocity c, pressure p_g of the pure gas, and pressure p of the loaded gas stream along the path through the pipe.

μ = 5–10. At higher load ratios and lower gas velocities, strands and plugs developed at weakly increasing pressure drop. If the solids mass flow rate $\dot{M}_s$ is further increased, there is a small velocity range in which dunes are conveyed. No stable pressure drop occurs; at leftmost in the diagram the conveyance is again regular at very high loadings and very small velocities. The pressure drop of this type of conveyance is again stable. The limit is achieved when an almost continuous, fluidized column of product is slowly pressed through the pipe. The flow power which has to be expended is for isothermal expansion

$$N = \dot{V}_1 \cdot p_1 \cdot \ln\frac{p_1}{p_2} = \dot{V}_2 \cdot p_2 \cdot \ln\frac{p_1}{p_2}. \qquad (3)$$

If before an adiabatic compression has been applied, the power of the fan has to be increased by a factor of about 1.33, including the efficiency factor.

2 Fully Suspended Flow

2.1 Particle Size Distribution

Measurements obtained e.g., by light scattering, laser diffraction, image analysis, screening, sedimentation or wind sifting are plotted in an RRSB net to determine the particle size distribution in the form of retained fraction $R(d)$ or a cumulative pass fraction $D(d) = 1 - R(d)$ curve [7], Fig. 5. They are described by

$$R(d) = \exp\left[-\left(\frac{d - d_{\min}}{d' - d_{\min}}\right)^{n}\right] \quad \text{for } d_{\min} < d < d', \qquad (4a)$$

$$R(d) = \exp\left[-\left(\frac{d_{\max} - d'}{d_{\max} - d}\right)^{0.1} \cdot \left(\frac{d}{d'}\right)^{n}\right] \quad \text{for } d' < d < d_{\max}, \qquad (4b)$$

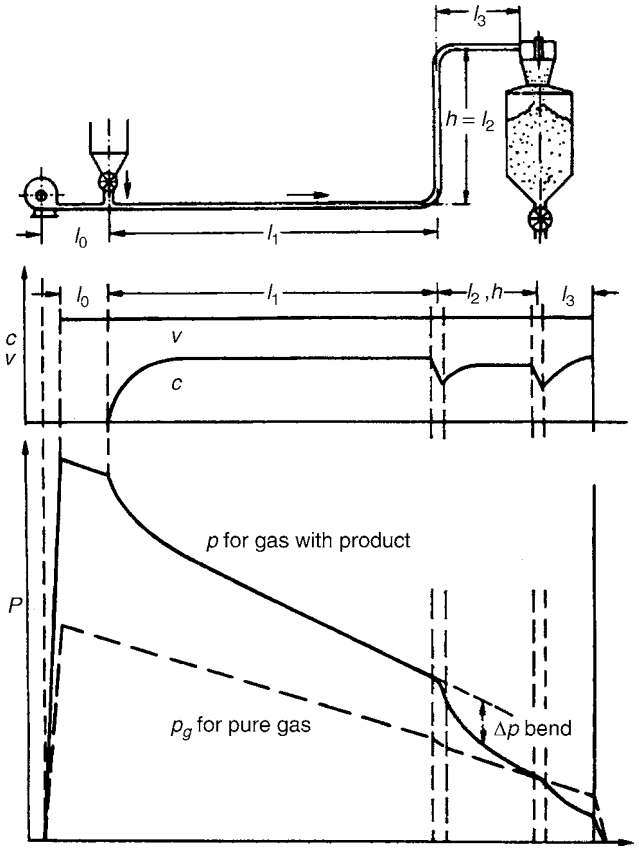
where d' is the particle size corresponding to $R = 1/e = 0.36$, $d_{\min}$ is the minimum particle size, and $d_{\max}$ is the maximum particle size. The exponent n determines the slope of the distribution curve at d' and thus its width.

The courses of the velocities in Fig. 2 show that the velocity of coarser particles remains substantially below the gas velocity. Further preliminary estimates can be made from the velocity ratios $C = c/v$ in Fig. 3. If the entire particle size distribution at a given load ratio μ is expressed by the average diameter d_{50} at R = 0.5, the ratio of the mutual spacing a between the particles to the size of the particles d is given by

$$\frac{a}{d} = \left(\frac{\pi/6\rho_S/\rho_g \; c/v}{\mu}\right)^{1/3}. \qquad (5)$$

Spacings calculated according to Eq. (5) are listed in Table 1 for pulverized coal with the particle size distributions given in Fig. 5 at a load ratio of μ = 1. The first row of Table 1 shows the result

for the average particle size of the distribution. A spacing of 8.7 d_{50} = 244 µm characterizes the cloud of particles only very roughly. If, however, the distribution in Table 1 is divided into three classes, viz. 25% of fine, 50% of average, and 25% of coarse particles, quite different spacings are obtained: 1,100 µm for the coarse particles, 300 µm for the average particles, and 62 µm for the fine particles. Since the small particles move more rapidly than the large ones, frequent overtaking and collisions of particles occur. In the following discussion, these collisions are ignored. Research along these lines was recommenced in 1959 [6] and has since then been resumed. With respect to the pressure drop, collisions of particles with the wall are by far more important, because the associated velocity of impact is very much greater than that between the particles. At load ratios above $\mu = 2$ the mixture described earlier or a similar mixture behaves approximately like a collective of particles with the uniform particle size d_{50}, due to the numerous collisions between the particles. It is for this reason that the average particle size is resorted to for the analysis.



L3.3. Fig. 2. Conveying system with fully suspended flow. Shown are the gas velocity *v*, the mean particle velocity *c*, and the pressure of the pure gas flow as well as the pressure of the loaded gas flow along the path through the conveyor.

2.2 Equation of Motion and Velocity Ratio

In a fully suspended flow the forces acting on the particles of a cloud parallel to the direction of conveying are the drag force F_W, the component of weight parallel to the conveying direction F_G, the frictional force due to weight F_R, and the wall impact friction force due to particle impact at the wall F_S.

From the momentum balance it follows for the product mass M_S in a pipe section of length Δl

$$M_S c \frac{dc}{dl} = F_W + F_G + F_R + F_S. \quad (6)$$

2.2.1 Drag Force

According to [8, 9], the drag force of the product cloud is conveniently expressed in terms of its weight in a section of length Δl of the conveyor

$$M_S g = \dot{M}_s \frac{\Delta l}{c} g \quad (7)$$

	μ	d_{50} mm	v m/s	c/v	Δp/100 m bar
a	1–10	0.1 1 10	20 30 40	0.8 0.65 0.5	0.15–0.5
b	10–50	0.01 0.1 0.5	20 25 30	1 0.3 0.4	0.75–2
c	20–50	0.01 0.1 1	15 20 25	1 0.3 0.5	0.4–0.8

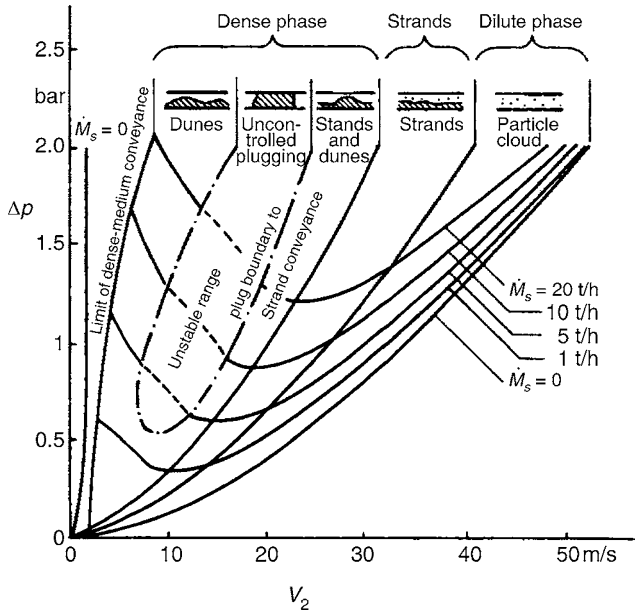
L3.3. Table 1. Particle spacings a for pneumatic conveying of pulverized coal represented in Fig. 5, calculated according to Eq. (5)

		μ	d_{min} µm	d_{50} µm	d_{max} µm	a µm
I	One class	1	2	28	150	244
II	Three classes	0.25	2	4.5	17	62
		0.5	17	28	52	300
		0.25	52	80	150	1,100

I For the average particle size d_{50} and $\mu = 1$ for the total amount
II For three classes with different size fractions and solids loadings



L3.3. Fig. 4. Functional diagram for pneumatic conveyance with typical operating data for a plant with $D = 150$ mm, air at 1.5 bar, and free-flowing product with particle sizes greater than 10 µm.

and the average settling velocity w_S of the solid particles [1]:

$$F_W = \mathrm{sgn}(v - c) M_S g \left(\frac{|v - c|}{w_S} \right)^{2-k}. \tag{8}$$

The drag force impels or retards if $v > c$ or $v < c$.

The settling velocity w_S in Eq. (8) has been adopted for practical reasons.

For a single particle with arbitrary shape the settling velocity depends on the drag coefficient c_w as follows:

$$w_{s0} = \left(\frac{(V_S/(d_S A_S)) \Delta\rho_{s,g} g d_s^{1+k}}{c_w \mathrm{Re}_S^k \eta_g \rho_g^{1-k}} \right)^{1/(2-k)}. \tag{9}$$

In Eq. (9) A_S and d_S denote the maximum cross section and the maximum particle diameter of the particle perpendicular to the direction of the flow onto the particle, respectively, V_S the particle volume, g the acceleration due to gravity, $\Delta\rho = \rho_s - \rho_g$ the density difference between particle and gas, η_g the gas viscosity, and

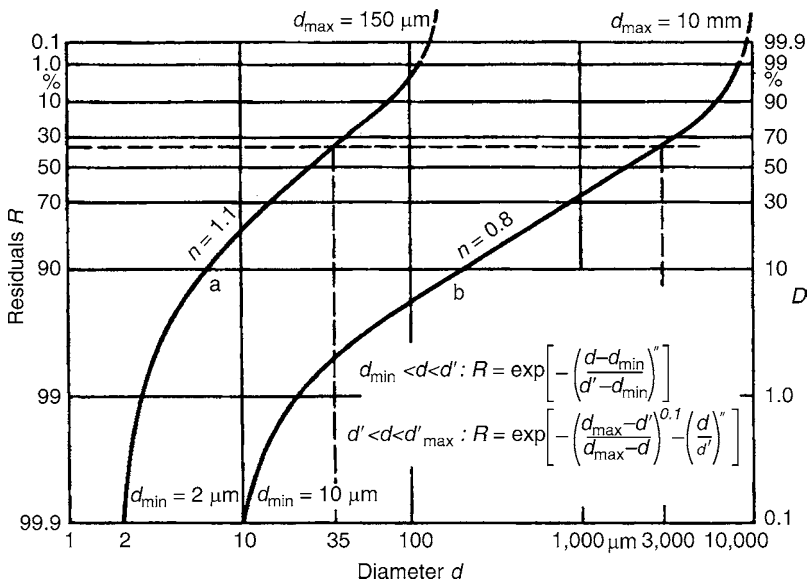
$$\mathrm{Re}_S = \frac{|v - c|\, d_S \rho_g}{\eta_g} \tag{10}$$

the Reynolds number for the flow around the particle.

The drag coefficient can be described for a wide range of particle Reynolds numbers ($0.5 < \mathrm{Re} < 1{,}000$) by a three-term approximation

$$c_w = \frac{A}{\mathrm{Re}_S} + \frac{B}{\mathrm{Re}_S^{0.5}} + C. \tag{11}$$

The values A, B, C depend on the particle shape and are listed in Table 2. The values given there are valid for the range $0.5 < \mathrm{Re}_S < \mathrm{Re}_G$. Values for Re_G vary depending on the particle shape, Table 2. For $\mathrm{Re}_S < \mathrm{Re}_G$ approaching Re_G the drag coefficient approaches the limit $c_{w,G}$, Table 2.



L3.3. Fig. 5. Size distribution curves plotted in a RRSB net with minimum and maximum particle sizes. (**a**) Pulverized black coal fed to burners, (**b**) Run-of-mine coal fed to roller mill.

L3.3. Table 2. Constants in Eq. (11) and values for limits c_{wG} for different particle shapes

	A	B	C	Re_{lim}	$c_{w,lim}$
Sphere	21.5	6.5	0.23	1,000	0.46
Compact angular	24	6	0.35	800	0.60
Cube	27	4.5	0.65	400	0.98
Cylinder	23	6	0.5	600	0.80
Elliptic grain	25	6	0.4	800	0.65
Elliptic lenses	28	6.5	0.7	150	1.4

For limited ranges of Reynolds numbers the settling velocity can be obtained by linearization in the c_w (Re_S) diagram:

$$c_w = \frac{K}{Re_S^k}. \tag{12}$$

The constants K and k are obtained by drawing the tangent to the c_w (Re_S) curve for any desired Re_S number.

From Eq. (11) it follows

$$k = \frac{A + 0.5B\sqrt{Re_S}}{A + B\sqrt{Re_S} + C\sqrt{Re_S}}, \tag{13}$$

$$K = \frac{A}{Re_S^{1-k}} + \frac{B}{Re_S^{0.5-k}} + C\,Re_S^k. \tag{14}$$

For the case of single particles with spherical shape, it is $V_S = (\pi/6)\,d_S^3$ and $A_S = (\pi/4)\,d_S^2$. Thus, it follows from Eqs. (9) and (12):

$$w_{S0} = \left(\frac{(4/3)\Delta\rho_{s,g} g d_S^{1+k}}{K \eta_g^k \rho_g^{1-k}}\right)^{1/(2-k)}. \tag{15}$$

Approximations for w_{S0}

The exponent k depends on the Re_S number. For laminar flow around the particle, it is $k = 1$. If the flow is in the transition region, it is $k = 0.5$ and if it is turbulent, it is $k = 0$. Should a first approximation suffice, Stokes' law may be applied for approximately spherical particles and Reynolds numbers up to $Re_S = 10$

$$w_{S0,Stokes} = \frac{\Delta\rho_{S,g} g d_S^2}{18\eta_g} \tag{16}$$

and in the transition region $Re_S = 10$–10^3 with the linearization according to Eq. (11)

$$w_{S0,Ü} = \frac{\left(\Delta\rho_{S,g} g\right)^{2/3} d_S}{4.3\left(\eta_g \rho_g\right)^{1/3}} \tag{17}$$

and in the turbulent region at $Re_S > 10^3$

$$w_{S0,N} = \sqrt{\frac{4}{3}\frac{\Delta\rho_{S,g} g}{\rho_g c_W} d_S} \tag{18}$$

with $c_w = 0.5$–0.7 depending on the particle shape.

Equation (15) or the approximations in Eqs. (16–18) give the settling velocities of single particles with spherical shape without allowance for the effects exerted by neighboring particles, agglomerates, or accumulations of small particles in the lee of the larger ones.

According to measurements of [10] for Re_S numbers between 50 and 1,000, the following dependence of the settling velocity on the solids load is obtained:

$$\frac{w_S}{w_{S0}} = 1 + (0.25 + k) \cdot \mu^{0.25}. \tag{19}$$

2.2.2 Weight and Friction due to Weight

It is

$$F_G + F_R = -M_S g(\sin\,\alpha + f\,\cos\,\alpha) \tag{20}$$

with the angle of slope of the conveying pipe α against the horizontal and with the coefficient of friction f, which is identical with the coefficient of sliding friction f_{sl}. Typical values are given in Table 3.

2.2.3 Force due to Wall Impact Friction

It is

$$F_S = -M_S g \frac{c^2}{Dg}\frac{\lambda_S^*}{2}. \tag{21}$$

The wall impact friction factor λ_S^* indicates the number of collisions on the wall per unit area, the intensity of impact, and the attendant loss in impetus of the particles. Comprehensive studies on actual and simulated weightlessness have revealed that, with respect to fluid dynamics, it depends on a modified Barth number,

$$Ba^* = \frac{\nu^k w_S^{2-k}}{Dg(1 - v_{Ba}^*/v)^{2-k}}, \tag{22}$$

and, with respect to mechanics, on the number of collisions S

$$S = \frac{d_S}{s}\frac{E_W}{E_S}\frac{\rho_S}{\rho_W} \tag{23}$$

and the load ratio μ [11–13]. In Eq. (23), s is the wall thickness of the conveyor. To calculate the Ba^* number, the velocity at the distance $y^* = d_S/2$ from the wall is used. It can be obtained quite accurately from the *Prandtl* one-seventh power law, i.e.,

$$v_{Ba}^* = 1.05\nu\left(\frac{d_S}{D}\right)^{1/7} \tag{24}$$

or from the general profile shown in Fig. 6 [14].

Guide values for the modulus of elasticity of the wall and the particle material E_W and E_S required to determine the expression for the number of collisions S are listed in Table 4.

The relationship between the impact friction factor λ_S^* and the load ratio μ is given by

$$\lambda_S^* = \frac{\lambda_S^*}{(1+\mu)^{0.25}} \tag{25}$$

The reference variable λ_{S0}^* for small load ratios μ which tends to zero can be obtained from the diagrams in Figs. 7 and 8 or from original works [11–13].

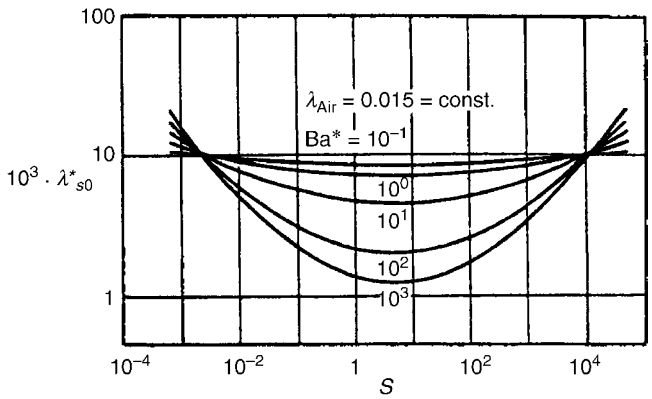
L3.3. Fig. 7. Minimum impact friction coefficient as a function of modified Barth number Ba* for a constant impact number $S = 5.5$ and a constant wall friction coefficient $\lambda_g = 0.015$ for the unladen flow, cf. Sect. 2.3.1.



L3.3. Fig. 8. Impact friction coefficient as a function of the impact number S and the modified Barth number Ba* for a constant wall friction coefficient $\lambda_g = 0.015$ for the unladen flow, cf. Sect. 2.3.1.

the Barth number

$$\mathrm{Ba} = \frac{v^k w_S^{2-k}}{Dg}, \tag{29}$$

the dimensionless length

$$L = \frac{gl}{v^k w_S^{2-k}} \tag{30}$$

and the velocity ratio

$$C = \frac{c}{v} \tag{31}$$

the equation of motion can be expressed in a dimensionless form as [3, 8]

$$\frac{dC}{dL} = \mathrm{sgn}\,(1-C)\,\frac{(|1-C|)^{2-k}}{C} - \frac{B\cdot\beta}{C} - C\,\mathrm{Ba}\,\frac{\lambda_S^*}{2}. \tag{32}$$

By means of this equation the change in velocity during acceleration $C(L)$ or $c(l)$ and the velocity ratio obtained in steady-state operation C_e at $dc = 0$ can be determined for all states of fully suspended flow.

In Fig. 9a–c the terminal velocity ratio C_e has been plotted as a function of the following characteristic

$$\frac{v/w_S}{\beta^{1/(2-k)}} \tag{33}$$

according to Eq. (27) $\beta = 1$, if the conduit leads vertically upward. In this case no conveyance is possible if $v/w_S = 1$. The curves with the upward slope demonstrate that conveyance is feasible at velocity ratios of about 0.5, if $v/w_S = 3$ or higher. Below 0.5, a fully suspended flow conveyance in the classical sense is not possible. At high values of $\mathrm{Ba}\cdot\lambda_S^*/2$ (on the right-hand border of the diagram) the velocity ratio remains low; at low values ratios of almost unity are reached when the values on the axis of abscissa are increased. Cases of this nature arise if the diameter D of the pipe is large and the settling velocity w_S is low or if the wall impact friction factor λ_S^* is small.

If the conduit leads vertically downward, $\beta = -1$, the force of gravity acts downward together with the drag, and a final velocity equal, at the most, to twice the gas velocity is attained at an abscissa value of unity. However, if the wall impact friction factor λ_S^* is high and the conduit diameter is small, the velocity ratio may also fall below unity. If the values on the axis of abscissa are high, the curves which slope downward in Fig. 9 terminate in the curves for the pipes that lead vertically upward whenever the weight is no longer of any significance in conveying.

2.3 Pressure Drop

According to [8, 9] the general rule is applied that the total pressure drop Δp is the sum of the pressure drop Δp_g due to the wall friction of the gas, and the additional pressure drop due to the solids transport Δp_s:

$$\Delta p = \Delta p_g + \Delta p_Z. \tag{34}$$

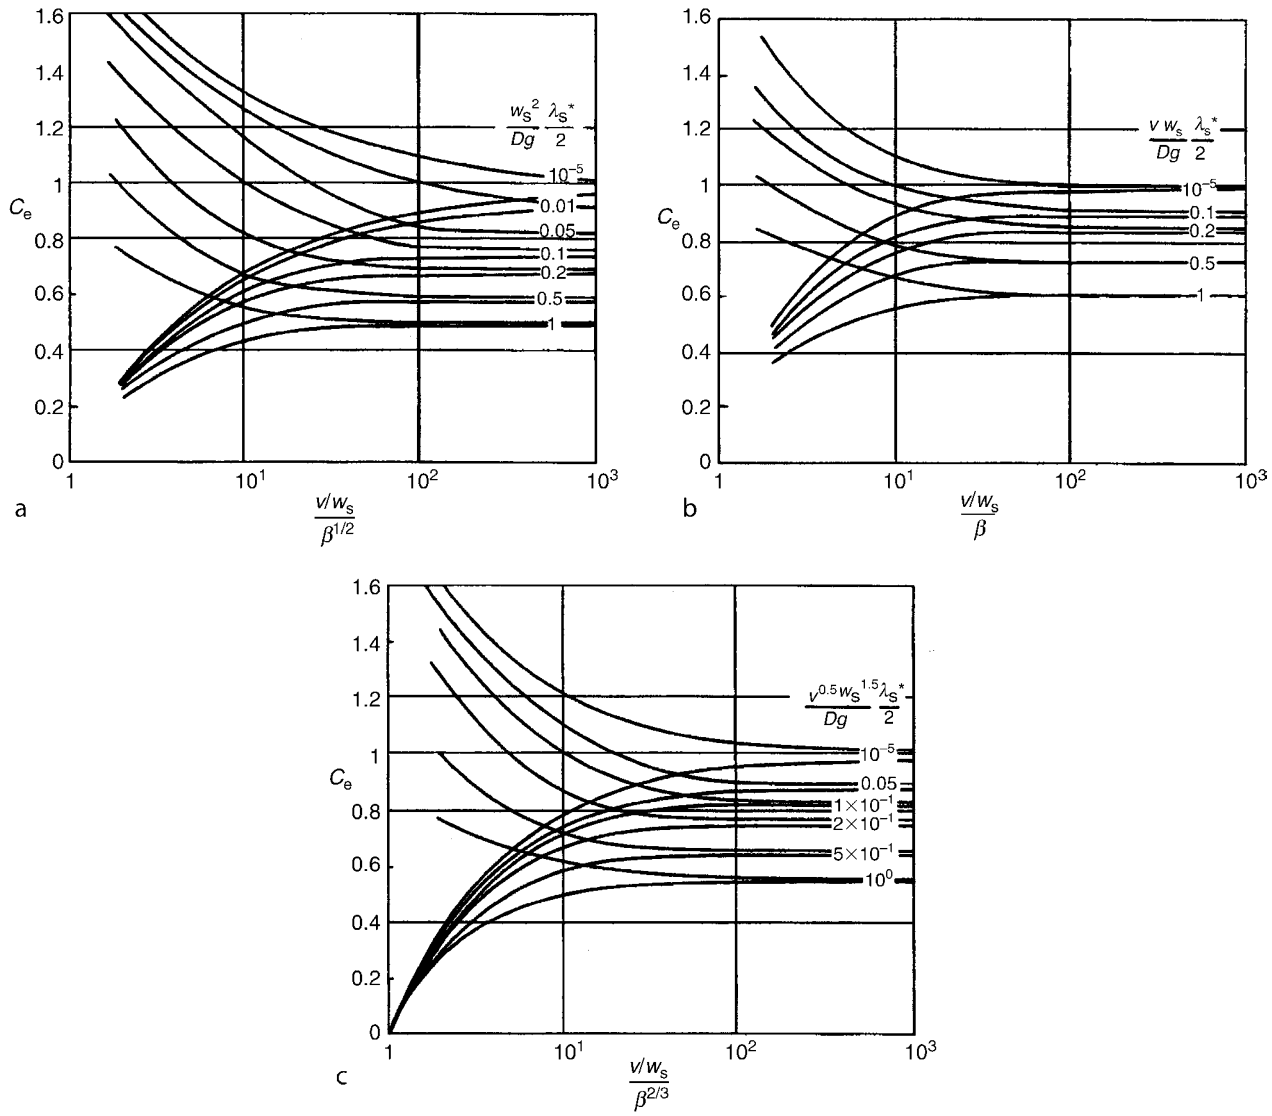
2.3.1 Pressure Drop of the Pure Gas Flow

The component Δp_g is determined in the same way as that for pure gas. In the fully suspended flow, the total surface area of the particles of the pulverized coal represented in Fig. 5 is 10–20 times greater than the area of the wall in the tubular section in which the particles are conveyed. Under these conditions, the inertia of the solids slightly suppresses turbulence, and the velocity profile thus becomes flatter [15]. Figure 10 shows the profile of the pure gas flow and a sectional view of the conditions in the immediate vicinity of the wall. The general profile of the pipe flow can be seen in Fig. 6 in a dimensionless form. The shear stress acting between the wall and the pure gas flow is given by $\tau = \lambda_g/4\rho_g/2\overline{v}^2$, and the rate of shear by $v^* = \sqrt{\tau/\rho_g}$. The associated pressure drop is given by

$$\Delta\rho_g = -\left(\lambda_g\,\frac{\Delta l}{D} + \sum\xi\right)\,\frac{\rho_g}{2}\,v^2. \tag{35}$$

The coefficient of wall friction λ_g for a smooth pipe is

$$\lambda_g = 0.006 + \frac{0.55}{\mathrm{Re}_D^{1/3}}. \tag{36}$$



L3.3. Fig. 9. Terminal velocity ratio $C_e = c_e/v$: (**a**) $k = 0$, (**b**) $k = 1$, and (**c**) $k = 0.5$.

Thus, it depends solely on the Reynolds number for the pipe flow

$$\mathrm{Re_D} = \frac{vD\rho_g}{\eta_g}. \tag{37}$$

Pressure drop coefficients of bends are $\xi = 0.10$–0.15 if the radius of curvature has the usual value of $R = 10D$.

2.3.2 Additional Pressure Drop Caused by Conveying Solids

The additional pressure drop caused by conveying solids has two components:

$$\Delta p_Z = \Delta p_S + \Delta p_{SB}. \tag{38}$$

The pressure drop component caused by weight and impact friction Δp_S is determined by a relationship similar to Eq. (35) for Δp_g, i.e.,

$$\Delta p_S = -\lambda_S \frac{\Delta l}{D} \mu \frac{\rho_L}{2} v^2. \tag{39}$$

A more accurate breakdown [11, 12] yields

$$\lambda_S = \frac{2\beta}{C\,\mathrm{Fr}} + C\,\lambda_S^*, \tag{40}$$

where Fr is the Froude number in the 10^2–10^4 range, i.e.,

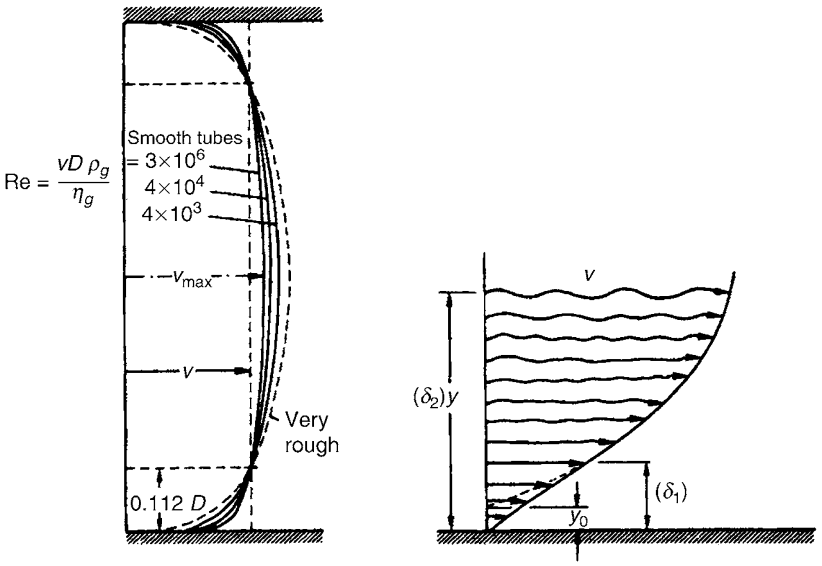
$$\mathrm{Fr} = \frac{v^2}{gD}. \tag{41}$$

The term β is defined by Eq. (27), which contains the coefficient of friction f. The first summand in Eq. (40) represents the additional pressure drop caused by the weight directly and by friction, and the second summand stands for friction by wall impact.

The additional pressure drop Δp_{SB} occurs during acceleration by Δc at the feeding point and behind the bends. It is obtained from the conservation of momentum, i.e.,

$$\Delta p_{SB} = -\mu\rho_g v \sum \Delta c. \tag{42}$$

This is the main component of the total additional pressure drop if the product is conveyed over short distances and through numerous bends. In this case, mostly the other components are



Re = $\frac{vD\rho_g}{\eta_g}$	2,320	10^4	10^5	10^6	10^7	10^8
λ Smooth tube	0.0472	0.0309	0.0180	0.0112	0.0081	0.0059
$\overline{v}/v_{max}$	0.776	0.811	0.849	0.877	0.893	0.908

L3.3. Fig. 10. Velocity profiles of a pure gas flow in a pipe.

not even taken into consideration. The subject is dealt with in the literature [16–21].

At the feeding point, it is $\Delta c = c_e$. Behind a bend, it is $\Delta c = c_e - c_2$. Here, c_e is the terminal particle velocity after the feeding point or after the bend and c_2 is the velocity, onto which the particles are decelerated within the bend. According to [20], it can be assumed in a first approximation that $c_2 = c_e/2$. A more accurate calculation allows for the dependency of the velocity c_2 on the angle at which the gas stream is diverted and for the length of section where a strand is accelerated until it is fully dissolved after the bend, cf. Sect. 2.3.3.

2.3.3 Deceleration in Bends and Reacceleration

Figure 11 shows the length of the path required for the particles to be accelerated or decelerated in relation to the terminal velocity. When the product is blown through bends, it immediately segregates owing to insufficient gas turbulence and slides in the form of almost motionless strands along the walls of the bend. As a rule, the weight of the strands and the motion imparted by the stream are neglected. Then the following relation can be applied on changes of direction through an angle ε (in radians) according to [23]

$$c_2 = c_1 \exp(-f\varepsilon). \tag{43}$$

The decrease of velocity from the value c_1 at the inlet to the bend to the value c_2 at the outlet of the bend is independent of the radius of curvature: The friction in a narrow bend is very high but does not last long, and the converse applies in wide bends.

Figure 12 shows how the product segregates in the bend to form strands. Some interval of time or length of path is required for a strand to disintegrate completely. The length of the path through which a strand has to be accelerated until it has entirely disintegrated is given by

$$l_{Str} = l_0\left[1 + K\left(\frac{\mu^{0.25} gD}{\nu^k w_S^{2-k}}\right)\right], \tag{44}$$

where l_0 is the length through which individual particles have to be accelerated. Numerical values for the extension factor K are listed in Table 5.

2.3.4 Calculation for High Pressure Drops

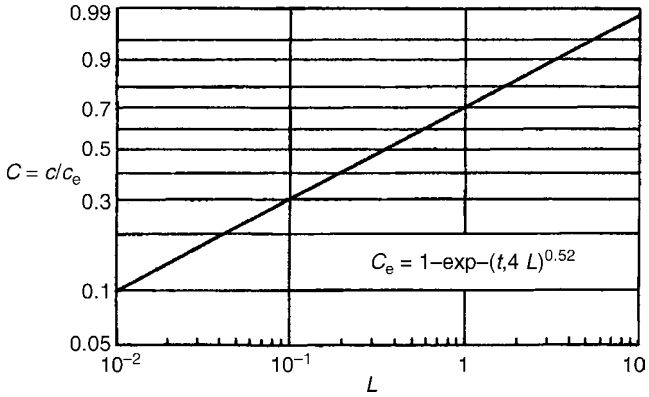
If the pressure drop Δp is more than 10% of the absolute pressure p, iteration must be resorted to and isothermal conditions are assumed. The gas density ρ_g and the gas velocity v are determined at the mean pressure, i.e.,

$$p_m = \frac{p_1 + p_2}{2}. \tag{45}$$

Parameters, which are independent of the pressure in the entire conduit, are the load ratio μ and, if the diameter of the pipe is constant, Re_D and λ_g as well. As a first approximation, the same applies to the second part of λ_S. The mean Froude number is taken for the first part, i.e.,

$$Fr_m = \frac{v_1 v_2}{Dg}. \tag{46}$$

If the pressure drops by more than 40%, the conduit must be divided from back to front into stages, in each of which the pressure ratio is 1:1.5–1:2. This can be achieved by reducing the pipe diameter in a ratio of approximately 1:0.9–1:0.85. In a fully suspended flow, the load ratio at the beginning of each stage



L3.3. Fig. 11. Velocity ratio C during acceleration as a function of the dimensionless length L (cf. Eq. (30)).

On the vertical tube wall	15
On the lower tube wall	30

should be checked by means of Eqs. (1) and (2) to ensure that it does not lie below the limited load ratio.

Example 1 (Fully suspended flow)
The pneumatic conveying system shown in Fig. 13 conveys fine, medium, and coarse granules of polyester over a length of $l = 100\ \text{m} + 75\ \text{m} = 175\ \text{m}$ and through a height of $h = 25$ m.

The limited load ratio μ_{lim} for the fine particles is much higher than the value of 5 listed in Table 6. The limited load ratio for the particles of medium size is roughly the same as the design value; and that for the coarse particles is slightly less. Particles larger than 1 mm bounce mechanically at right angles to the pipe and do not require turbulence.

The Reynolds number Re_S and the settling velocity w_S of the fine particles lie at the lower limit of the transition range; and that for the coarse granules, at the upper limit. The increase in w_S effected through the load ratio is considerable in the former case, but slightly in the latter. A rough estimate in the light of the guide values listed in Fig. 3 suffices for determining the range of Reynolds numbers for w_S and k. The three particle sizes span the entire range of Barth numbers Ba^*, from the smallest to the largest, and correspond to velocity ratios of $C \approx 1$ to $C \approx 0.6$. In view of the great differences that exist in the relationships between the particles and the wall, the number of collisions S may be considerable greater or less than the figures quoted in the table of Fig. 3. The fine particles are mainly arrested aerodynamically in the layer next to the wall, against which the coarse particles impinge. The figures for λ_S^* and λ_S representing impact friction and additional pressure drop are correspondingly higher or lower. In all the cases the decrease in velocity at the bends is approximately the same. Coarse particles are conveyed more readily than fine particles, because they are comparatively slower and have very small λ_S^* values.

If the most that is required is a rough estimate it would suffice to take $\lambda_S^* \approx 0.0075$, $\beta \approx 0.6$, and $C_e \approx 0.8$ for all three cases in the example. They are responsible for a substantial part of the pressure drop if there are more than two bends. In this case it is expedient to determine only the terminal velocity ratio C_e or velocity c_e by setting $dC = 0$ in Eq. (32) and to determine the decrease in velocity in two bends by means of Eq. (42). Thus,

$$\begin{aligned}\sum \Delta c \approx c_e + 2c_e/(2\Delta p) &= -\left[\lambda_g + \mu\left(\frac{2 \cdot 0.6}{\text{Fr}} + 0.8 \cdot 0.0075\right)\right] \\ &\cdot \frac{l+h}{D} \cdot \frac{\rho_g}{2} v^2 - \mu\rho_g\, v\,(c_e + 2c_e/2) \\ &= (-34{,}000 - 7{,}000)\ \text{Pa} = -41{,}000\ \text{Pa}.\end{aligned}$$

The vertical section of the pipe is taken here as an example to illustrate the calculation of the length l_{Str} required for disintegration of the strands and reacceleration in case 2:

$$\begin{aligned}c_2 &= 22.5 \cdot \exp\left(-0.5 \cdot \frac{\pi}{2}\right) \\ &= 10.26\ \text{m/s}, \\ c_2/c_1 &= 10.26/21.5. \\ &= 0.47 \quad \text{at } L = 0.3.\end{aligned}$$

It can be derived from Fig. 11 that a dimensionless length of $\Delta L = 5.7$ is required up to a value of $c_3/c_e = 0.95$.

Example 2 (Fully suspended flow)
Plastic powder with a particle size of 150 µm and a particle density of $\rho_S = 1{,}000\ \text{kg/m}^3$ should be conveyed over a distance of 800 m with a gas mass flow rate of $M_g = 1{,}680$ kg/h at a load ratio of $\mu = 4.8$. Figure 13 shows the conduit. After one

iteration, two sections each with a length of 400 m are obtained. The data of the two sections are listed in the following table. The pressure drops from 3 bar to 1.7 bar at the end of Part A and to 1 bar at the end of Part B. The average densities ρ_g and the average velocities v are given in the table. The settling velocity w_{SO} is always calculated according to Eq. (17) at the average pressure. With λ_g, v, and w_S the limited load ratio is determined at the average pressure. The velocity ratio $C = c_e/v$ is 0.95. The calculation is performed with f = 0.5 and $\lambda_S^* = 0.005$. The

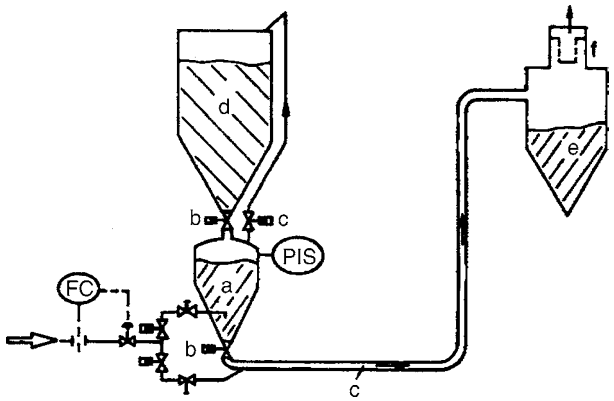
pressure drops Δp_g, Δp_S, Δp_{SB} and the pressure drops at the bends Δp_{Kr} are calculated according to Eqs. (35), (39), and (42).

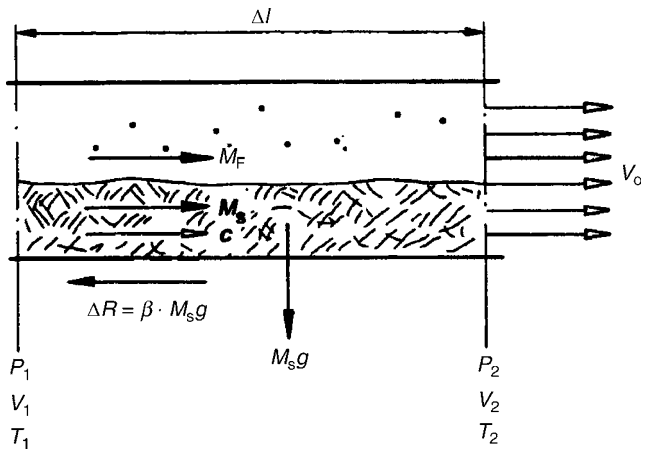
In [2, 3, 8, 9], calculated data of numerous pneumatic conveying plants can be found.

3 Dense-Phase Conveying

If the throughput is larger than 5 ton/h and pressure drops as high as 1–6 bar are feasible, this method of conveyance is adopted to reduce gas requirements and to avoid wear of the conduit and abrasion of the product conveyed. The load ratio μ can be increased to 10–150. The superficial gas velocities are



L3.3. Fig. 14. Dense-phase conveying. (**a**) Pressure vessel, (**b**) Valves and controllers, (**c**) Conduit, (**d**) Feed hopper, (**e**) Bunker, and (**f**) Bunker filter.

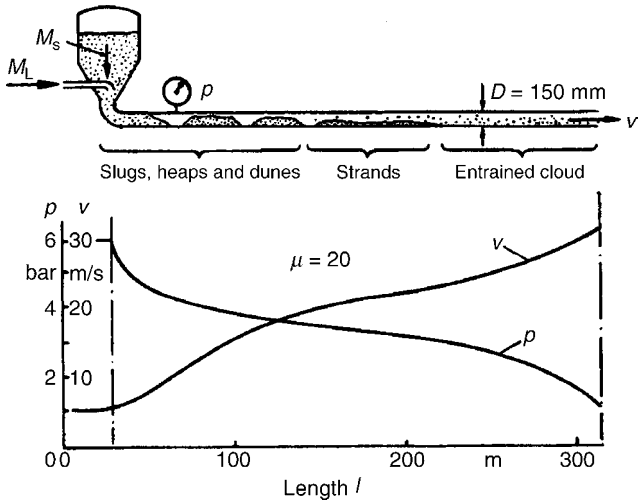


L3.3. Fig. 15. Pressure drop due to friction along a strand of bulk material.

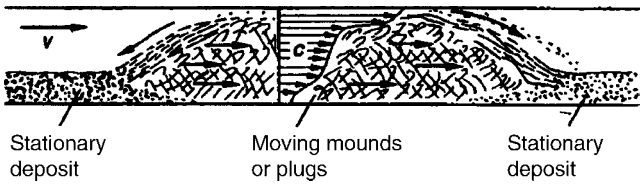
merely 2–15 m/s and are often less than the settling velocity. The diameter of the pipe varies between 50 and 300 mm. Almost all products with particle sizes between 1 μm and 10 mm can be conveyed [24–26]. Figure 14 shows an installation for dense-phase conveying.

3.1 Movement of Particles in Pipes

If the gas velocity is not high enough, the particles are deposited on the lower surface of the conduit until the velocity in the remaining cross section is again sufficiently high to convey the increased load. Large differences in concentration thus occur in the cross section. The moving particles impart a large component of their momentum to the deposits on which they impinge. As a result, the growing deposits finally commence to move with the aid of the pressure gradient and pore flow. Conveyance of strands by moving particles and currents in this manner is often quite stable. However, if fluctuations occur, large plugs and conglomerates are formed and finally preponderate. The main resistance to conveyance is the force of friction caused by the weight of solids [2]



L3.3. Fig. 16. Gas velocity and pressure along the conveyor for dense-phase conveyance of 2-mm plastics granules.



L3.3. Fig. 17. Movement of a plug of loose material (Drawing made from a photograph).

$$dR = \frac{\dot{M}_S g dl}{c}(\sin\alpha + f\cos\alpha) = \frac{\dot{M}_S g dl}{c}\beta \qquad (47)$$

The coefficient of friction is f = 0.3–0.8. The force of friction includes the wedging forces at right angles to the wall.

Figure 15 shows the conditions for a strand section.

At the inlet of long pipes of uniform diameter, there are high pressures, low velocities, high pressure drops, and large concentrations of conglomerates (Fig. 16). The mass flow rate of solids $\dot{M}_s$ and the load ratio μ remain constant over the entire length. As the pressure increases, the velocities c and v increase, the close succession of conglomerates loosen, and the pressure gradient becomes less. Toward the end of the pipe, strands and (frequently) individual particles are conveyed at higher velocities, with the result that the pressure drop increases again. In order to avoid this, the pipe is often widened in two to three stages.

3.2 Simplified Calculation

A heap of loose material is shown in Fig. 17. It pushes against a stationary deposit and bulldozes it ahead. The bulk of the air streams through the small free cross section above the mound and thus entrains the particles at a load ratio of about 5–10. As a result this bypass current flows against a high pressure gradient, and the heap of loose material is thus pushed forward. The pressure drop is also responsible for (usually laminar) pore flow in a heap of length Δl and void fraction ε.

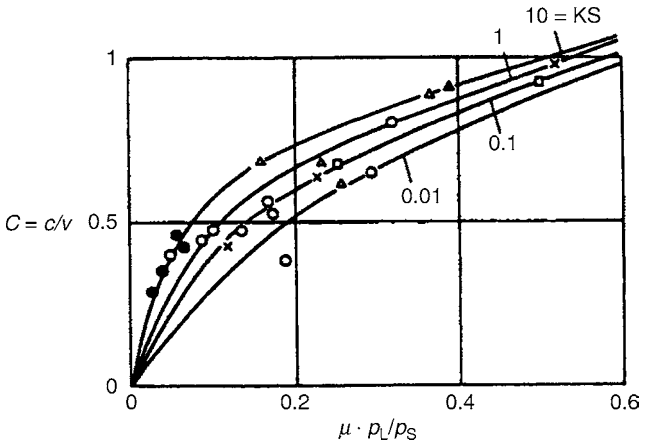
In Eq. (47) the mass flow rate of solids is

$$\dot{M}_S = \mu \dot{M}_g = \mu A \rho_g v_0 \tag{48}$$

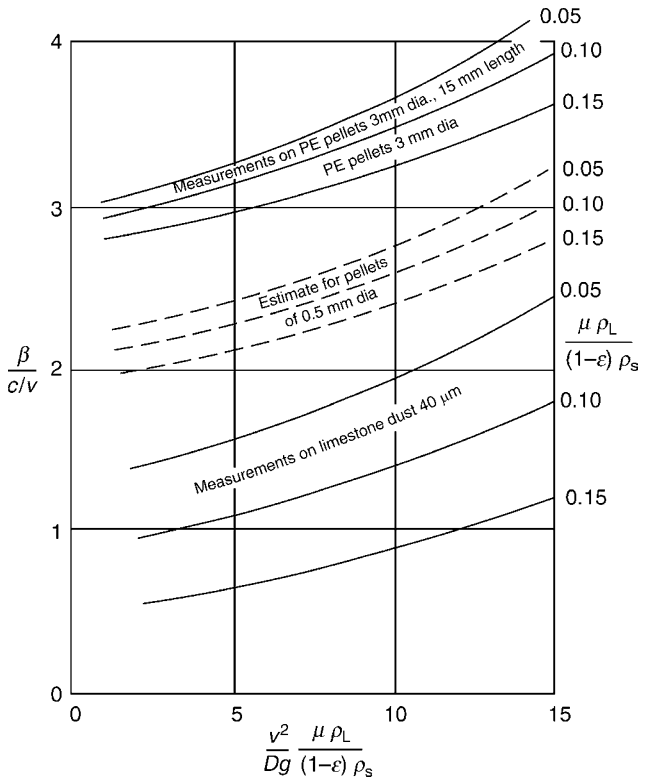
with the superficial velocity v_0. With $C = c/v_0$ and Eq. (47) it follows

$$dp_S = \frac{dR}{A} = \mu \rho_g g \; dl \frac{\beta}{C} \tag{49}$$

Even if the pressure drop in the dense-phase conveying is high, the pressure is released at almost constant temperature T. Hence [2]



L3.3. Fig. 18. Comparison of measured and calculated velocity ratios C for the conveyance of strands of sand (25 μm) in a pipe of 50 mm diameter [2]. KS is the number of strands (cf. Eq. (30) in [2]).



L3.3. Fig. 19. Empirical values for β/C.

$$\rho_g = \frac{p}{RT}. \tag{50}$$

The pressure at the inlet 1 and outlet 2 of a conduit is

$$p_1 = p_2 \exp\left(\frac{\mu g \Delta l}{RT} \frac{\beta}{C}\right). \tag{51}$$

The expression in brackets should not exceed 0.8. If it is higher, the conduit should be divided into a number of sections and the value of Δl of each section should be separately determined backward against the direction of conveyance. Figure 18 shows calculated and measured values of the velocity ratio C as functions of the modified density ratio $\mu\rho_g/((1-\varepsilon)\rho_S)$. In practice, the ratio β/C is usually obtained from tables, e.g., Table 7. If the velocity ratio is unknown, resort may be taken to empirical values such as those shown in Fig. 19.

The void fraction ε of the moving plug is 1.5–3 times greater than that of the stationary deposit. As can be seen from Fig. 20 the void fraction of fine dust depends considerably on the particle size.

The pressure drop along the plug is also responsible for (usually laminar) pore flow in the inner of the plug. The volume flow rate of that flow, however, is negligible compared to that of the main flow. For laminar pore flow through a heap of length Δl with the void fraction ε, the pressure loss along the heap is [28]

$$\Delta p = 165 K^2 \cdot \frac{(1-\varepsilon)^2}{\varepsilon^3} \cdot \frac{\eta_L \mu_0 \Delta l}{d_S^2} \tag{52}$$

where u_0 is the superficial velocity of the seepage flow.

If the Reynolds number for the seepage current is

$$\mathrm{Re} = \frac{u_0 \, d_S}{K(1-\varepsilon)\nu} > 20, \tag{53}$$

then

$$\Delta p = 80 K^{1.5} \frac{(1-\varepsilon)^{1.5}}{\varepsilon^2} \cdot \frac{\sqrt{\eta_g \, \rho_g \, u_0^{1.5} \, \Delta l}}{d_S^{1.5}}. \tag{54}$$

The shape factor for spheres is $K = 1$, for granules $K = 1.2$, and for very irregular particles $K = 2$.

4 Injectors for Solids Feeding

Instead of rotary feeders injectors are also used to feed solids into pneumatic conveyers with fully suspended flow. In dryers, the injectors split coarse blocks of wet product into small agglomerates with sizes between 100 and 500 μm. In jet mills, a pre-fragmentation takes place in the interior of the injector at motive gas velocities up to 500 m/s for air and up to 1,000 m/s for steam [29]. The following remarks bear on [10].

4.1 Pressure Buildup

Figure 21 shows an injector for solids feeding with the pressure and velocity profile along the injector. The motive gas in front of the nozzle has the pressure p_T and is expanded in the entrance

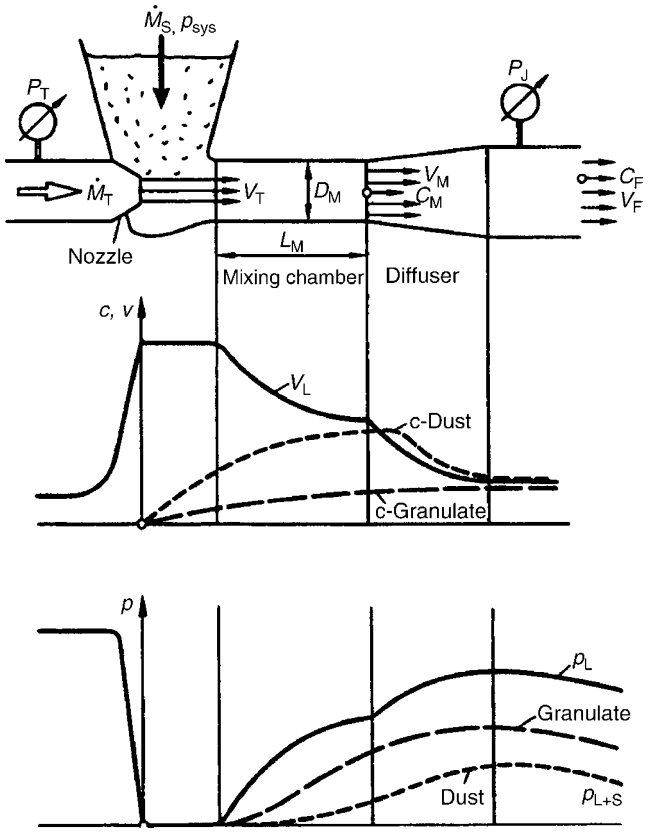
L3.3. Fig. 20. Void fraction of bulk ε of quartz according to measurements [27].



L3.3. Fig. 21. Injector for solids feeding with velocity and pressure profile.

zone of the feed onto the pressure p_{Sys}. In the zone of the free gas jet between the nozzle and the mixing chamber the velocity profile of the jet changes strongly due to momentum exchange. In the mixing chamber, the gas jet is decelerated on the mean velocity v_M, which is determined by the diameter D_M at the end of that section. This leads to an increase of the static pressure. When particles are fed in, an additional considerable momentum exchange with the solids occurs leading to a reduction of the pressure generation in the mixing chamber. The pressure reduction is stronger for fine particles than for coarser ones since the gas accelerates fine particles more strongly than coarser particles. In the following diffuser the static pressure is further increased due to the deceleration of the gas flow with the velocity v_F in the conveying pipe.

Depending on the pressure ratio of the nozzle, three types of injectors for solids feeding are differentiated according to Table 8.

At a pressure difference $\Delta p = p_T - p_{Sys} < 0.2$ bar the velocity of the motive gas can be calculated by assuming an incompressible gas. Up to a pressure of the motive gas of $p_T = 1.9 p_{Sys}$, the calculation can be performed by the average gas density

$$\bar{\rho}_{g,M} = \frac{(p_T + p_{Sys})/2}{RT}, \qquad (55)$$

L3.3. Table 8. Differentiation of injectors for solids feeding according to pressure ratios with guiding values for pressure generation at p_{Sys} = 1 bar, d_S = 100 µm, ρ_S = 2,650 kg/m^3, L_M/D_M = 4, η_{Diff} = 0.85

		Low pressure injector		Medium pressure injector		High pressure injector	
p_T/p_{Sys}		1.2		3		11	
v_T	m/s	175		400		500	
D_M/D_T		1.5	2	2	4	2.5	4
$\Delta p_{J,max}$ (μ = 0)	Pa	1,100	7,000	50,000	15,000	150,000	65,000
µ (for $\Delta p_J = 0.5 \times \Delta p_{J,max}$)		1.5	3	3	6	2	4

$$T = \sqrt{\frac{2\,(p_T - p_{Sys})}{\overline{\rho}_{g,M}}}. \tag{56}$$

For larger pressure differences the compressibility of the gas has to be taken into account. In practice, simple nozzles with no divergence after the minimal cross section are normally used, and thus the velocity of the motive gas can be calculated by the following equations:

In the final cross section of the nozzle the gas velocity is the Laval velocity

$$a_{Lav} = \sqrt{\frac{2\kappa}{\kappa + 1} RT}. \tag{57}$$

The subsequent expansion from $p_{Lav} = 0.53 p_T$ to the system pressure p_{Sys} leads to a acceleration in the free jet region within a distance of 0.5–1.5D_T by

$$\Delta v = \frac{p_{Lav} - p_{Sys}}{\rho_{Lav} a_{Lav}} \tag{58}$$

with $\rho_{Lav} = 0.63 \rho_{g,T}$. Thus, the effective velocity of the motive gas is

$$v_T = a_{Lav} + \Delta v. \tag{59}$$

For the design of the injector the velocity v_F in the pneumatic conveyor is given. A guiding value for the average gas velocity v_M in the mixing chamber is

$$v_M = \sqrt{v_T v_F}. \tag{60}$$

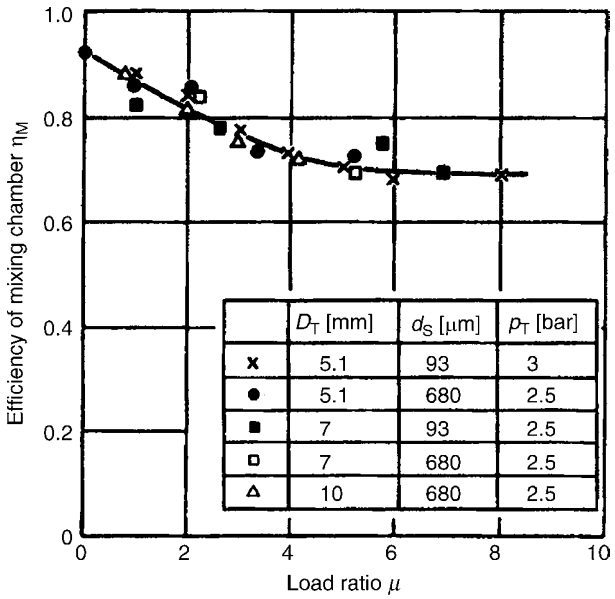
The real velocity can deviate from this value by ±30%. In the first step estimated mean density ρ_M in the mixing chamber the diameter of the mixing chamber is

$$D_M = \sqrt{\frac{M_T}{\frac{\pi}{4} v_M \rho_M}}. \tag{61}$$

A guiding value for the length of the mixing chamber is $L_M = 4D_M$. If the solids velocity is known, the pressure buildup can be calculated by taking into account momentum exchange and the pressure loss $\Delta p_{M,R}$ due to friction of the gas–solids flow in the mixing chamber:

$$\Delta p_M = \frac{M_T (v_T - v_M) - M_S \Delta c_M}{A_M} \eta_M + \Delta p_{M,R}. \tag{62}$$

The efficiency of the mixing in the mixing chamber has usually values between η_M = 0.7 and η_M = 0.9, reflecting that the momentum conversion of the gas and the solids can only be performed incompletely. Figure 22 shows the dependence of the mixing efficiency on the solids load μ.



L3.3. Fig. 22. Measured efficiency η_M of the mixing chamber as a function of the load ratio μ [10].

The pressure loss due to friction $\Delta p_{M,R}$ is calculated according to Sects. 2.3.1 and 2.3.2:

$$\Delta p_{M,R} = \Delta p_g + \Delta p_S = -\left(\lambda_g + \lambda_S \mu\right) \frac{L_M}{D_M} \frac{\overline{\rho}_{L,M}}{2} v_M^2. \tag{63}$$

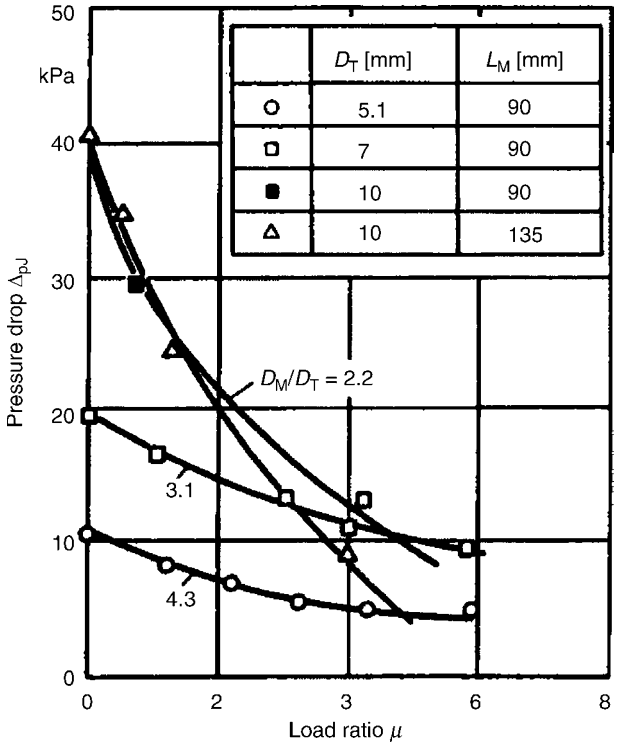
The pressure increase in the diffuser is calculated according to

$$\Delta p_{Diff} = \frac{\rho_{g,Diff}}{2} \left(v_M^2 - v_F^2\right) \eta_{Diff} - \mu \rho_{g,Diff} \sqrt{v_M v_R}\, \Delta c_{Diff}, \tag{64}$$

where the first part calculates the pressure buildup due to deceleration of the gas velocity and the second part calculates the pressure change due to the change of kinetic energy of the particles. Those diffusers have angles of aperture between 7° and 10° and efficiencies η_{Diff} between 0.85 and 0.9. The velocity change Δc_{Diff} of the solids is in most cases not very large. Therefore the second term in Eq. (64) can be neglected in the first estimations.

If at the end of the mixing chamber $c_M > v_F$, then for straight pipes sections of length $L_F > (5 \ldots 10)\, L_M$ behind the injector a small pressure buildup can be realized

$$\Delta p_F = -\mu \rho_{g,M} v_F \Delta c \tag{65}$$



L3.3. Fig. 23. Measured characteristics of an injector for solid feeding as a function of the ratio D_M/D_T of the diameters of nozzle and mixing section and nozzle [10]; P_T = 2.5 bar; d_{50} = 93 µm; ρ_S = 2,650 kg/m^3; D_M = 22 mm.

with

$$\Delta c = c_M - c_F. \tag{66}$$

The terminate velocity c_F is obtained from Fig. 9a–c. The total pressure buildup of the injector for solids feeding is

$$\Delta p_J = \Delta p_M + \Delta p_{Diff} + \Delta p_F. \tag{67}$$

The given equations are valid for a neutral operation of the injector. If in addition the injector sucks off air, the pressure buildup diminishes by up to 15%. If a part of the motive gas is blown out of the solids feeding opening, then the attainable pressure increases by up to 15%.

4.2 Particle Velocity

The exact calculation is described in [10]. In a first approximation the maximal gas velocity between nozzle and mixing chamber is calculated as

$$v_{max} = 0.6 \cdot (v_T - v_M) + v_M \tag{68}$$

and the average gas velocity during the whole sequence of acceleration as

$$\bar{v} = \sqrt{v_{max} v_M}. \tag{69}$$

For the air drag of the particle cloud Eq. (8) is valid and for the particle acceleration

$$b = \bar{c}\frac{\Delta c}{\Delta l} = \mathrm{sgn}\,(v - c) \cdot g \left(\frac{|v - c|}{w_S} \right)^{2-k}. \tag{70}$$

The average particle velocity in the mixing chamber is

$$\bar{c}_M \approx \frac{2}{3}\Delta c_M. \tag{71}$$

Thus, it follows for the velocity change in the mixing chamber

$$\Delta c_M = \sqrt{\frac{\Delta l}{2/3} g \left(\frac{\sqrt{v_{max} v_M} - \bar{c}_M}{w_S} \right)^{2-k}}. \tag{72}$$

For the settling velocity w_S at the solids load μ Eq. (19) is valid. The result can be quickly obtained by iteration. The given equations allow for an estimation of the solids velocity at the end of the mixing chamber with an accuracy of 20%.

4.3 Characteristic Curve of an Injector for Solid Feeding

The characteristic curve of an injector for solid feeding i.e., the pressure buildup as a function of the solids load can be determined by Eqs. (55–72). At first one calculates the pressure buildup of the motive gas jet for $\mu = 0$, then for a medium and for a high solids load. As a rule the characteristics of the curve is fixed by these three points.

Figure 23 shows the measured characteristics of an injector for solids feeding as a function of the diameter ratio D_M/D_T.

For $D_M/D_T < 2$, a high pressure builds up at low solids loadings. However, only small solid loadings can be conveyed. For $D_M/D_T > 3$, the maximum possible pressure buildup is reduced by more than 50%, the maximum possible solids loading increases, however, considerably.

Example 3 (Injector for solids feeding)
In a pipe with diameter D_F = 90 mm, solid material with particle size d_S = 200 µm and particle density ρ_S = 2,650 kg/m^3 should be conveyed at a gas velocity of v_F = 20 m/s. The gas density in the pipe is 1.44 kg/m^3. The temperature of the gas is 293 K. The feeding of the solid material should be realized by an injector.

The mixing chamber of the injector is designed with L_M/D_M = 4.

$$M_T = \frac{\pi}{4} D_F^2 \rho_F v_F = \frac{\pi}{4} 0.09^2 \cdot 1.44 \cdot 20 = 0.183\,\mathrm{kg/s}.$$

It results in the Laval velocity

$$a_{Lav} = \sqrt{\frac{2\kappa}{\kappa + 1} RT} = \sqrt{\frac{2 \cdot 1.4}{1.4 + 1} \cdot 287 \cdot 293} = 313\,\mathrm{m/s}$$

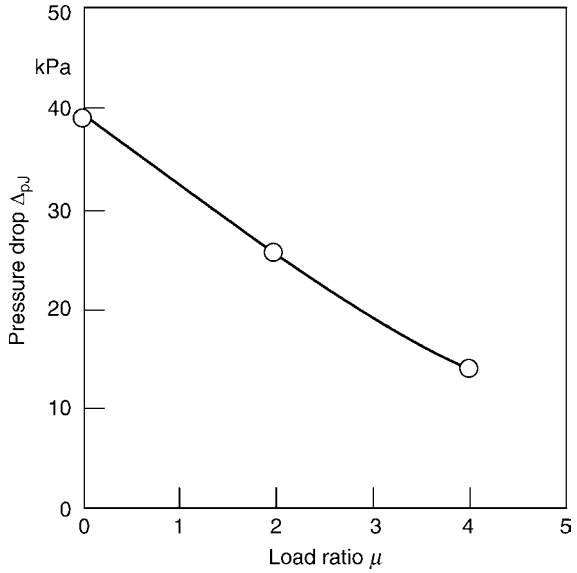
and the Laval density

$$\rho_{Lav} = 0.63\, \rho_{g,T} = 0.63\, \frac{p_T}{R\,T} = 0.63 \cdot \frac{2.5 \cdot 10^5}{287 \cdot 293} = 1.87\ \mathrm{kg/m^3}$$

and a diameter of the nozzle of

$$D_T = \sqrt{\frac{\dot{M}_T}{\frac{\pi}{4} \rho_{Lav} a_{Lav}}} = \sqrt{\frac{0.183}{\frac{\pi}{4} \cdot 1.87 \cdot 313}} = 0.02\,\mathrm{m}.$$

Thus, the points of the characteristics according to Eqs. (57–59): v_T = 368 m/s.



L3.3. Fig. 24. Calculated characteristics of the solids feeding injector in example 3.

Calculation for $\mu = 0$

According to Eq. (60): $v_M = \sqrt{v_T v_F} = \sqrt{368 \cdot 20} = 85\,\text{m/s}$, estimated pressure buildup until the end of the mixing chamber = 35,000 Pa.

Thus

$$\rho_M = \frac{p_M}{RT} = \frac{1.35 \cdot 10^5}{287 \cdot 293} = 1.6\,\text{kg/m}^3,$$

according to Eq. (61):

$$D_M = \sqrt{\frac{\dot{M}_T}{\frac{\pi}{4} v_M \rho_{L,M}}} = \sqrt{\frac{0.183}{\frac{\pi}{4} \cdot 85 \cdot 1.6}} = 0.041\,\text{m/s},$$

$$\mu = 0 \rightarrow M_S = 0; \quad \text{according to Fig. 22:} \quad \eta_M = 0.9,$$

and according to Eq. (62):

$$\Delta p_M = \frac{\dot{M}_T (v_T - v_M) - M_S \Delta c_M}{A_M} \eta_M + \Delta p_{M,R} = \frac{0.183(368 - 85) - 0}{\frac{\pi}{4} \cdot 0.041^2} 0.9 - 578 = 34{,}725\ \text{Pa},$$

Equation (64):

$$\Delta p_{Diff} = \frac{\rho_L}{2} (v_M^2 - v_F^2) \eta_{Diff} = \frac{1.6}{2} (85^2 - 20^2)\, 0.85 = 4{,}641\ \text{Pa},$$

Equation (67):

$$\Delta p_J = \Delta p_M + \Delta p_{Diff} = 34{,}725 + 4{,}641 = 39{,}366\ \text{Pa}.$$

Calculation for $\mu = 2$

Estimated pressure buildup until the end of the mixing section: 20,000 Pa. Accordingly, it is:

Density	$p_{L,M}$ = 1.4 kg/m^3
According to Eq. (60)	v_M = 99 m/s
According to Fig. 22	η_M = 0.83
Equation (68)	v_{max} = 0.6 (368−99) + 99 = 260 m/s
Equation (69)	$\bar{v} = \sqrt{v_{max} v_M} = \sqrt{260 \cdot 99} = 160\,\text{m/s}$

Estimated Re number according to Eq. (10):

$$\text{Re} = (160 - 50)\ \text{m/s} \cdot 200 \cdot 10^{-6} / 15 \cdot 10^{-16} = 1{,}466.$$

Thus, the Re number is in the Newton regime, therefore $k = 0$.

Equation (18)	w_{S0} = 3.14 m/s
Equation (19)	w_S = 5.00 m/s
Equation (72)	Δc = 40 m/s

Equation (62):

$$\Delta p_M = \frac{0.183(368 - 85) - 0.366 \cdot 40}{\frac{\pi}{4} \cdot 0.041^2} 0.83 - 1{,}125 = 20{,}618\ \text{Pa},$$

Equation (64):

$$\Delta p_{Diff} = \frac{\rho_L}{2} (v_M^2 - v_F^2)\ \eta_{Diff} = \frac{1.6}{2} (99^2 - 20^2)\ 0.85 = 5{,}594\ \text{Pa},$$

Equation (65):

$$\Delta p_F = -\mu \rho_L\, v_F \Delta c = -2 \cdot 1.4 \cdot 20 \cdot 20 = 1{,}120\,\text{Pa},$$

Equation (67):

$$\Delta p_J = \Delta p_M + \Delta p_{Diff} + \Delta p_F = 27{,}332\,\text{Pa}.$$

Calculation for $\mu = 4$: Δp_J = 14,500 Pa

Thus, it follows the characteristics for the solid feeding injector according to Fig. 24.

5 Symbols

A	cross-sectional area
a	spacing between particles
B	gravity parameter
Ba	Barth number
Ba*	modified Barth number
c	average particle velocity
Δc	particle velocity difference
c_w	drag coefficient for flow around a body
C	velocity ratio
d	particle size
d'	characteristic particle size of RRSB distribution
d_{50}	mean particle size of feed
D	pipe diameter
E	modulus of elasticity
f	coefficient of gliding friction
F	force
Fr	Froude number
g	acceleration due to gravity
h	height
K	elongation factor; parameter for calculating drag
k	exponent for calculating drag
L	dimensionless length
l, Δl	length, section length
M	mass
$\dot{M}$	mass flow
N	hydraulic power
n	exponent in RRSB particle size distribution
p	static pressure
Δp	pressure drop
R	size fraction retained on screen

dR	force due to wall friction of solids strand with length dl
Re	Reynolds number
s	wall thickness
S	impact coefficient; specific surface
T	temperature
$\dot{V}$	volume flow rate
V	volume
u_0	superficial velocity of gas in packed bed
v_0	average axial superficial velocity of gas
v	average axial velocity of gas
Δv	gas velocity difference
$v^\star$	shear stress velocity
v^*_{Ba}	air velocity close to the wall
w_{S}	settling velocity
W	air drag
$y^\star$	distance to wall
α	angle of inclination against the horizontal
β	coefficient for resistance caused by weight of product
ε	angle through which air stream is diverted; void fraction
η	dynamic viscosity; efficiency
λ_{g}	coefficient for pressure drop of pure gas flow
λ_{S}	coefficient for pressure drop of gas flow conveying solids
λ^*_{S}	coefficient for resistance due to collisions against wall
κ	adiabatic exponent
μ	load ratio
ρ	density
$\Delta\rho$	density difference between solids and gas
τ	shear stress at wall
φ	shape factor
ξ	pressure drop coefficient

Subscripts

B	acceleration
D	pipe

L3.4 Cyclones for the Precipitation of Solid Particles

Ulrich Muschelknautz
MK Engineering, Innsbruck, Austria

1 Flow Pattern

The pressure drop and the separation efficiency depend mainly on the tangential velocities in the cyclone. The tangential velocity u_a at the outer radius r_a depends on the inlet velocity v_e and on the design of the cyclone (cf. Fig. 1a–c).

1.1 Slotted Inlet

If the gas enters the cyclone through a tangential slot, the radial pressure field will force the gas stream against the wall. As a result, the jet is contracted and is thus accelerated. The effect is described by the contraction coefficient α (cf. Fig. 2), which primarily depends on the geometric ratio $\beta = b/r_a$ between the slot width b and the outer radius r_a. According to [1] α depends also on the load ratio of the particles in the inlet stream μ_e (Fig. 2):

$$\alpha = \frac{1 - \sqrt{1 + 4\left[\left(\frac{\beta}{2}\right)^2 - \left(\frac{\beta}{2}\right)\right]\sqrt{1 - \frac{1-\beta^2}{1+\mu_e}(2\beta - \beta^2)}}}{\beta}. \quad (1)$$

The outer tangential velocity is obtained from the momentum of the inlet jet expressed in terms of the outer radius, i.e.,

$$u_a = \frac{v_e r_e / r_a}{\alpha}. \quad (2)$$

The inlet velocity is given by

$$v_e = \frac{\dot{V}}{b h_e}. \quad (3)$$

It is referred to the central streamline of the entering flow (Figs. 2 and 3)

$$r_e = r_a - \frac{b}{2}. \quad (4)$$

1.2 Spiral Inlet

In the spiral inlet (Fig. 1b) the gas flow is decelerated due to wall friction. There is no contraction of the flow as in the case of a slotted inlet. The tangential outer velocity follows from the momentum balance with the force of friction

$$u_a = \frac{v_e \cdot r_e / r_a}{1 + \frac{\lambda_s}{2} \cdot \frac{A_{R,sp}}{\dot{V}} \cdot v_e \cdot \sqrt{r_e / r_a}}, \quad (5)$$

where λ_s is the coefficient of friction at the spiral wall according to [1] and $A_{R,sp}$ is the area in the spiral over which resistance is offered to friction

$$A_{R,sp} = \varepsilon\left[\frac{b + 2r_a}{2}(b + h_e)\right]. \quad (6)$$

The wall friction coefficient λ_0 for pure gas flowing within the spiral is approximately the double of that in the separation chamber, due to the small ratio between the area and volume in the spiral [1]. The wall friction coefficient for the gas carrying solids is higher and depends on the load ratio (cf. Sect. 1.2) according to

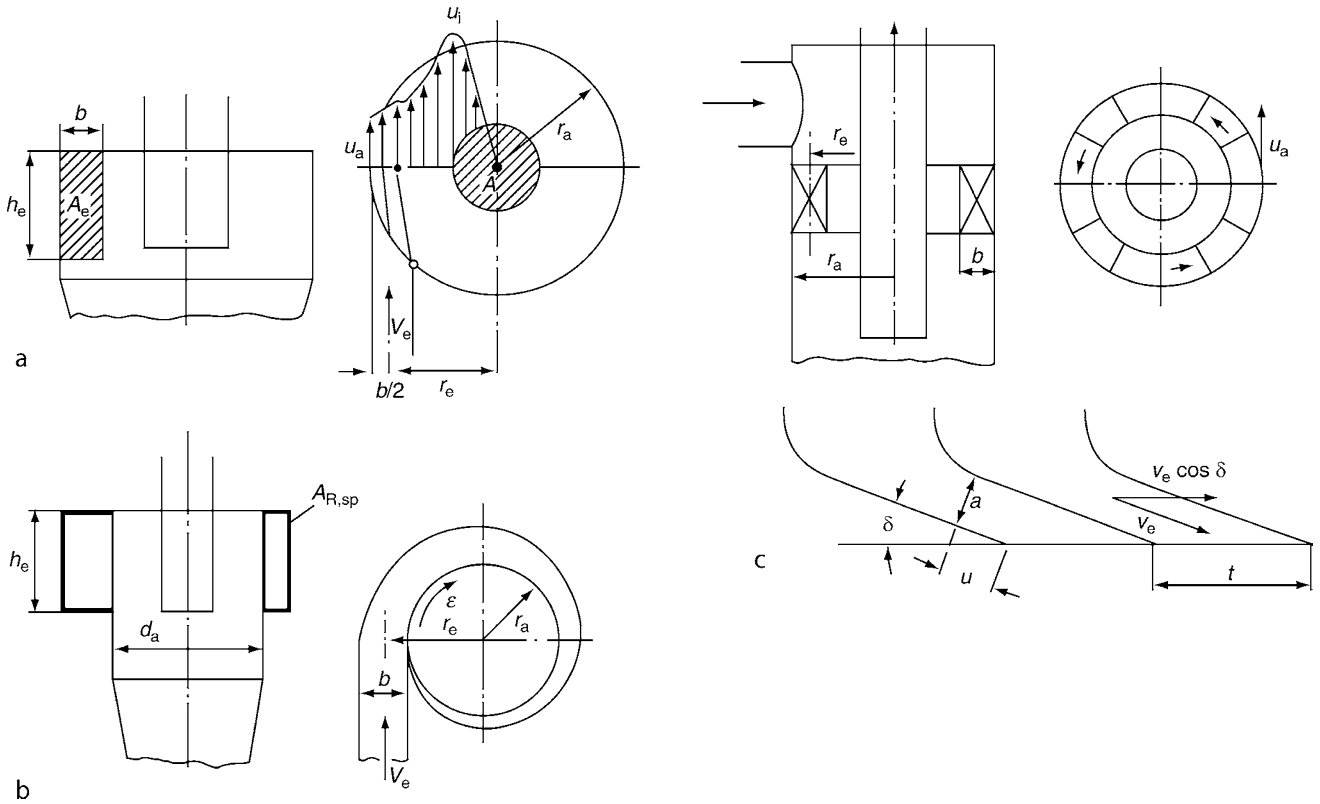
$$\lambda_s = \lambda_0\left(1 + 2\sqrt{\mu_e}\right). \quad (7)$$

1.3 Axial Guide Vanes

Axial guide vanes are mainly inserted in multicyclones at load ratios of $\mu_e < 0.1$. In most cases, simple plane vanes separated by a distance t with an overlap $ü$ of 25% (Fig. 1c) show sufficient performance. The guide vane angle δ is mostly between 15° and 30°.

The outer tangential velocity can be derived from this geometry (cf. Fig. 1c)

$$u_a = \frac{v_e \cos(\delta) r_e / r_a}{\alpha}, \quad (8)$$



L3.4. Fig. 1. (**a**) Tangential slotted inlet. (**b**) Spiral inlet (full spiral: $\varepsilon = 2\pi$, half spiral: $\varepsilon = \pi$). (**c**) Guide vanes (axial inlet): elevation, plan, and development of the vane rig.

where the contraction coefficient has a value of $\alpha = 0.85$ for simple straight vanes, $\alpha = 0.95$ for bent vanes, and $\alpha = 1.05$ for bent and twisted vanes [1, 2].

1.4 Inner Tangential Velocity

The inner tangential velocity u_i at the radius r_i (Fig. 3) of the gas outlet pipe is calculated from the coefficient of friction λ_s and the total inner area A_R of the cyclone including the cover and the outer wall of the vortex tube [3–5], i.e.,

$$u_i = \frac{u_a \cdot r_a / r_i}{1 + \frac{\lambda_s}{2} \cdot \frac{A_R}{V} \cdot u_a \cdot \sqrt{r_a / r_i}}. \tag{9}$$

If the lower cone diameter is smaller than the vortex tube diameter, then the cone area, enclosed in A_R, is calculated down to the height, where the inner vortex touches the cone wall at the diameter $2r_i$.

The second term in the denominator of Eq. (9) may assume a value between 0.25 and 0.75 if the load ratio μ_e is small, and values up to 2, if the load ratio is high.

Depending on the load ratio, the coefficient of friction at the wall for the gas flow loaded with solids, λ_s, can be much higher than the coefficient of wall friction λ_0 for pure gas. In this case, the friction caused by the dust strands ($\mu_e = 0.01 \ldots 1.0$) or by a carpet ($\mu_e > 1.0$) is superimposed on the friction brought about by the roughness of the walls k_s/r_a [2]:

$$\lambda_s = \lambda_0 + 0.25\sqrt{\eta_g \mu_e \mathrm{Fr}_i \frac{\rho_g}{\rho_s(1-\varepsilon_{Str})}}\left(\frac{r_a}{r_i}\right)^{-5/8}. \tag{10}$$

The Froude number

$$\mathrm{Fr}_i = \frac{v_i}{\sqrt{2gr_i}} \tag{11}$$

allows for the cyclone dimensions. The void fraction ε_{Str} of the solid strands is roughly twice that of the loose particles [6].

Equation (10) has been confirmed by measurements [1] for conical and cylindrical cyclone models of 800 mm diameter and load ratios of 0.001 to 10. For cyclones of this size Eq. (10) is usually shortened as follows:

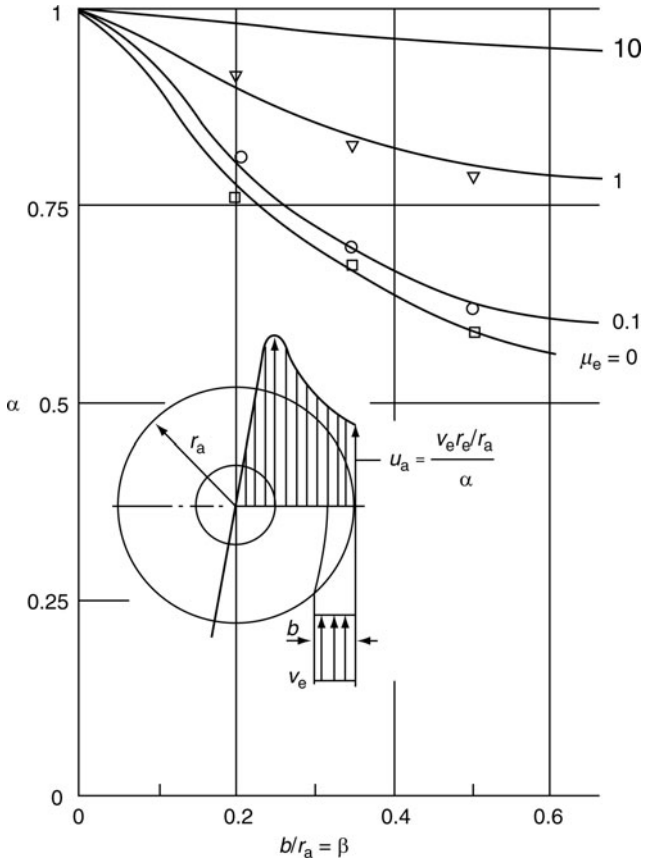
$$\lambda_s = \lambda_0\left(1 + 2\sqrt{\mu_e}\right). \tag{12}$$

In analogy to the flow through a pipe, the wall friction coefficient λ_0 for the unladen gas depends on the roughness parameter k_s/r_a and on the Reynolds number for the flow through the cyclone (Fig. 4)

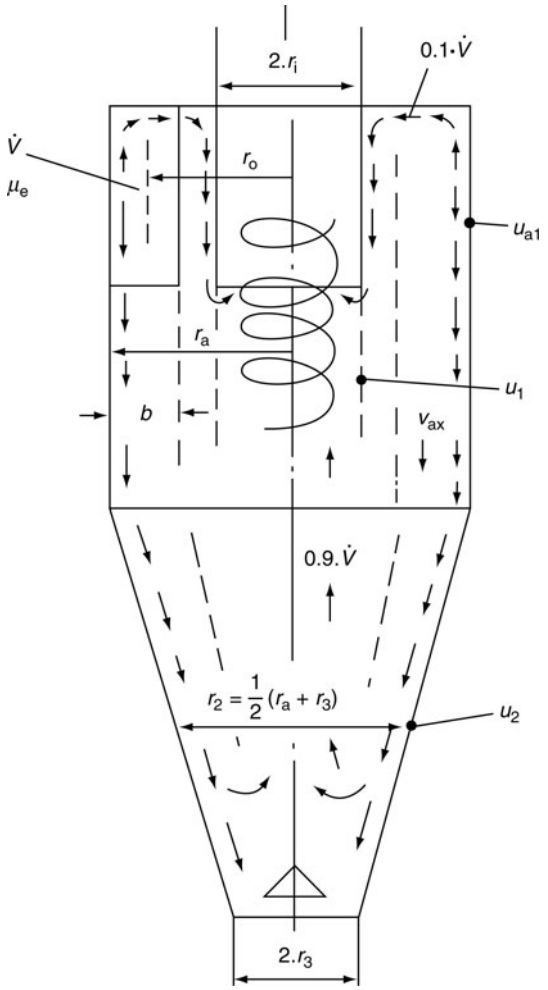
$$\mathrm{Re}_R = \frac{2r_e v_{ax}/\nu_g}{2\frac{h}{r_m}\left(1 + \left(\frac{v_{ax}}{u_m}\right)^2\right)} \tag{13}$$

with

$$v_{ax} = \frac{0.9 \cdot \dot{V}}{\pi\left(r_a^2 - r_m^2\right)} \tag{14}$$



L3.4. Fig. 2. Coefficient of contraction α for tangential slotted inlet as a function of $\beta = b/r_a$, with the load ratio of particles at the inlet μ_e as a parameter.



L3.4. Fig. 3. Flow pattern in a cyclone: About 90% of the entering gas flow streams as main flow along the cyclone wall downward and then as an inner vortex upward into the gas exit. About 10% of the entering gas streams as secondary flow along the top of the cyclone and then around the vortex tube into the gas exit.

and

$$r_m = \sqrt{r_a r_i}. \tag{15}$$

The wall friction coefficient is a function of temperature and pressure due to its dependency on the kinematic gas viscosity ν_g. If the temperature increases, then the kinematic viscosity ν_L increases as well and therefore, according to Eq. (13) and Fig. 4, also the wall friction coefficient rises. Thus, the inner tangential velocity (Eq. (9)) and the separation in the inner vortex (cf. Sect. 3.2) decrease when the temperature augments. This dependency has to be taken into account when the separation efficiency and the pressure drop of a cyclone are calculated. Hence, the model allows also for calculating the performance data of a cyclone at *high temperatures and/or high pressures* [8–10].

An alternative cyclone model for high temperatures and high pressures has been developed by [9–11]. Based on the approach of [12] this model divides the cyclone into four separation zones and calculates with particle flux balances. The tangential velocities of the main flow are calculated according to [13]. The wall friction coefficient is calculated as a function of the wall roughness and a Reynolds number, which is determined by the thickness and the tangential velocity of the boundary layer. Re-entrainment of particles, which are already separated from the gas stream, as well as the influence of the secondary flow on the cyclone separation efficiency are also taken into account.

The model allows also to calculate the separation effect, i.e., the width of the classification efficiency curve, cf. Sect. 3.2. Measurements in low loaded cyclones at temperatures up to 1,600°C and pressures up to 8 bar confirm the theory very well. All equations of the model are given in [9, 10].

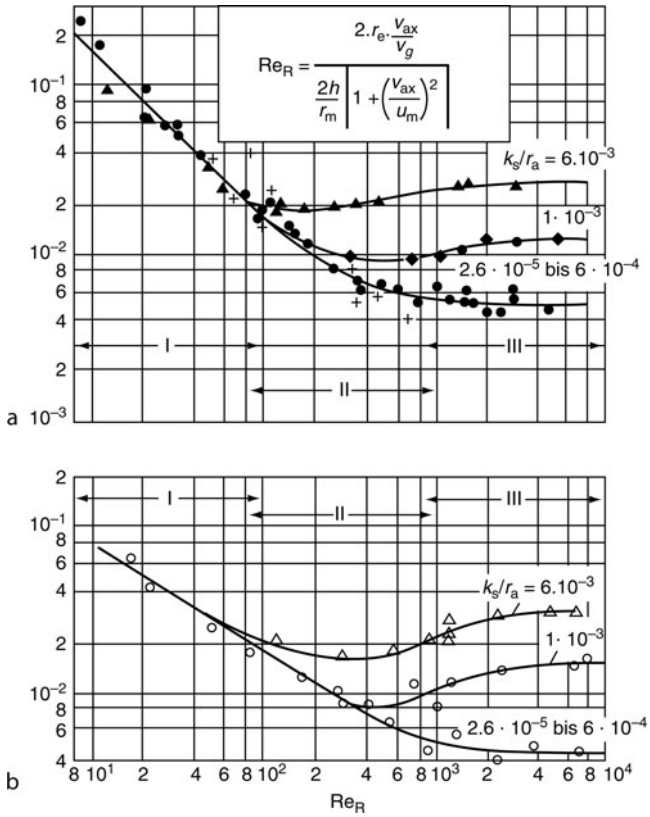
2 Pressure Drop and Pressure Drop Reduction

The total pressure drop can be divided into three parts [4]:

$$\Delta p_{tot} = \Delta p_{inlet} + \Delta p_e + \Delta p_i. \tag{16}$$

Here the single pressure drops are calculated as differences of *total* pressures $p_{stat} + v^2\rho_g/2$ and $p_{stat} + u^2\rho_g/2$, since the main parts Δp_e and Δp_i are determined mainly by the tangential velocities in the cyclone.

At low and medium load ratios the pressure loss Δp_{inlet} in the inlet duct is much smaller than in the other parts p_e and p_i. It is [3]



L3.4. Fig. 4. Coefficient of wall friction for pure gas as a function of the cyclone Reynolds number Re_R, Eq. (13), in a pure cylindrical (**a**) and a conical cyclone (**b**) [7].

$$\Delta p_{inlet} = 0 \text{ for slotted inlet}$$
$$\Delta p_{inlet} = -\frac{\pi \cdot r_i^2}{b \cdot h_e} \cdot \left(1 + \frac{\pi}{4}\left(\frac{r_i}{r_a}\right)^2\left(1 - \frac{1}{\alpha^2}\right)\right) \cdot \frac{\rho_g}{2} v_i^2 \quad \text{for spiral inlet,} \tag{17}$$
$$\Delta p_{inlet} = -(0.2 \ldots 0.5) \cdot \frac{\rho_g}{2} v_i^2 \text{ for axial inlet.}$$

In the equation for the pressure drop in a spiral inlet it is $\alpha = 1 + \frac{\lambda_s}{2}\frac{A_{R,sp}}{\dot{V}} v_e \sqrt{\frac{r_e}{r_a}}$ (cf. Eq. (5)).

The pressure drop Δp_e in the separation compartment depends on the outer tangential velocity, the area of the wall A_R, and the effective wall friction coefficient λ_s [14]:

$$\Delta p_e = -\lambda_s \frac{A_R}{0.9\dot{V}} \frac{\rho_g}{2} (u_a u_i)^{3/2}. \tag{18}$$

Allowance is thus made for the fact that the total gas flow rate $\dot{V}$ is split into a main flow of approximately $0.9\dot{V}$ and a secondary flow of approximately $0.1\dot{V}$ [15]. The main flow streams along the cyclone wall as an outer vortex downward and then, after reversing its axial direction, as an inner vortex upward into the gas outlet tube. The secondary flow streams in a short circuit through the boundary layer at the cover and at the outer wall of the gas outlet tube directly into the gas exit opening (Fig. 3).

The pressure drop in the gas outlet tube is for low and medium load ratios μ_e usually five to ten times larger than both other parts of the pressure drop in Eq. (16) together. At high load ratios the pressure drops in the separation compartment and in the gas outlet tube are of the same order.

The pressure drop in the gas outlet tube depends crucially on the ratio between the inner tangential velocity u_i and the mean axial velocity v_i in the gas outlet tube

$$v_i = \frac{\dot{V}}{\pi r_i^2} \tag{19}$$

i.e., [2]:

$$\Delta p_i = -\left[2 + 3\left(\frac{u_i}{v_i}\right)^{4/3} + \left(\frac{u_i}{v_i}\right)^2\right] \frac{\rho_g}{2} v_i^2. \tag{20}$$

The pressure drop, described by Eq. (20), arises between the imaginary cylinder area of the gas outlet pipe with radius r_i and a point in the gas outlet pipe far beyond the cyclone, where practically no more swirl exists in the gas flow. Thus, the calculated value allows also for the pressure drop, which emerges from the dissipation of the rotational energy due to wall friction in the pure gas pipe. In the model this additional pressure drop is counted along with the total cyclone pressure drop.

Often the pressure drop of a cyclone is measured between the cyclone inlet and a point in the pure gas pipe, which is very close to the cyclone cover. The pressure drop, resulting from this measurement, will be much lower than the value predicted by the theory.

Equation (20) yields the cyclone pressure drop in good agreement with measurements for those cases where the pure gas is blown into the atmosphere or where the pressure after the cyclone is measured at a point and where practically no swirl exists anymore (cf. [16]).

The pressure drop Δp_i in the gas outlet pipe can be reduced in a simple way by inserting a pressure plate, which acts as a radial diffusor. There the fast annular flow in the gas outlet pipe is guided in a small annular gap of height s between the cyclone cover and the pressure plate. The deflection of the flow is carried out with the deflection radius r_u. On its way outward the flow is decelerated, leading to an increase of the static pressure. The outlet spiral serves only as a collector. If the pressure plate is designed with the correct radius r_D, i.e., $r_D/r_i \geq 2$, $s/r_i = 0.2$, and $r_u/r_i \geq 0.1$, pressure recoveries between 40 and 50% can be achieved for swirl ratios u_i/v_i between 1.75 and 2.45, respectively. By inserting a simple outlet spiral without pressure plate the pressure recovery will be only about 15%, since in this case the spiral is not completely filled with the annular flow exiting the gas outlet pipe and thus, the flow is not sufficiently decelerated.

Pressure can be recovered more efficiently by installing swirl vane inserts in the gas outlet pipe. The device consists of a central, mostly cylindrical core with 6–12 curved guide vanes fixed on it. They deflect the annular flow with only small losses of kinetic energy into a pure axial flow and therefore, transform dynamical pressure into static pressure. Thus, the rotational energy stored in the annular flow is transformed into pressure instead of losing it due to dissipation, which would be the case, if no such measure is applied. At low to medium load ratios the

pressure drop can be reduced by 40–60%, depending on the swirl strength. For details see [14].

Cyclone with higher load ratios and short entrance ducts, where the solids feed has a low velocity at the beginning of the duct, exhibits a considerable pressure drop in the entrance duct and shows – compared to low loaded cyclones – modified influx conditions at the cyclone entrance [17, 18].

The differential pressure loss in a segment of such a cyclone entrance duct is the sum of the losses which result from gas and solids acceleration [19]

$$dp = dp_{gas} + dp_s = -\rho_g \cdot v \cdot dv - \mu_e \cdot \rho_g \cdot v \cdot dc. \qquad (21)$$

The total pressure drop in the entrance duct results from integrating Eq. (21) along the way through the duct. For high load ratios this pressure drop is of the same order as the pressure drops in the separation compartment and in the gas outlet pipe.

For high load ratios the mean solid velocity c_e at the end of the duct averaged over the duct cross section is often considerably smaller than the gas velocity v_e at that point. Then, in the succeeding entrance zone of the cyclone a rapid momentum exchange between solids and gas takes place. As is shown in [19] the solids velocity increases in this zone by the amount Δc and the gas velocity decreases by the amount

$$\Delta v = -\mu_e \cdot \Delta c. \qquad (22)$$

The velocities of solids and gas after the momentum exchange

$$c_{in} = v_{in} \qquad (23)$$

are generally considerably smaller than the gas velocity at the cyclone entrance v_e. In this case the cyclone calculation has to be performed by applying v_{in} instead of v_e as input quantity.

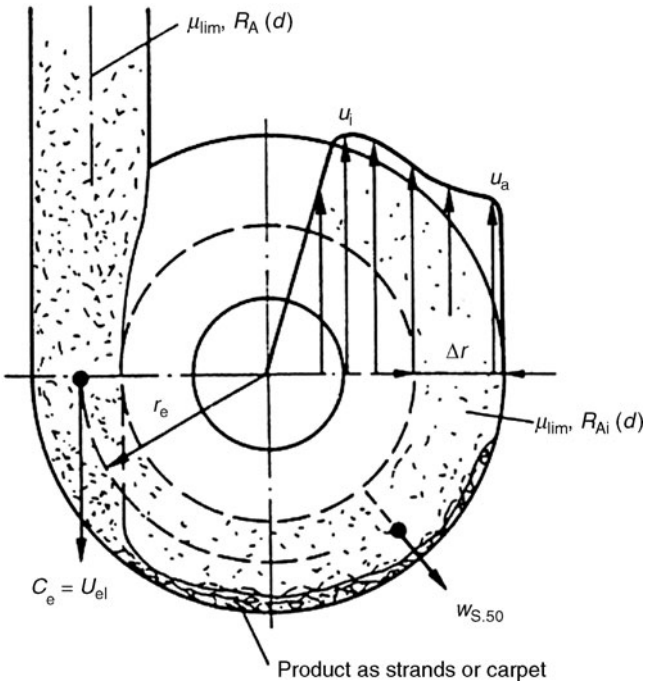
A more exact calculation allows for measured gas and solids flux pattern, whereupon with increasing height above the bottom of the duct the load ratio μ_e and the mean particle size d_{50} decrease and the gas and solids velocities v and c increase. For details see [20, 37].

3 Separation Efficiency

A factor to be taken into account in calculating the separation efficiency is that the restricted turbulence in the cyclone entails that only a certain solids fraction can be carried in the swirling flow [21]. If the load ratio in the inlet μ_e exceeds the limit μ_{lim} [2, 5], the excess mass fraction will be removed immediately after the gas jet enters the cyclone (Fig. 5), and only a small fraction that is restricted by the limit μ_{lim} will undergo the centrifugal separation process in the inner vortex of the cyclone. Accordingly, two separation mechanisms are distinguished:

- Separation due to exceeding the limiting load ratio, which is also called the wall separation
- Separation in the inner vortex

For load ratios in the inlet $\mu_e < \mu_{lim}$ only the second separation mechanism is active, and for load ratios $\mu_e \geq \mu_{lim}$, which is by far the more common case, both separation mechanisms are effective.



L3.4. Fig. 5. Separation due to exceeding the limited load ratio immediately after the cyclone entrance, cf. Eq. (33).

3.1 Separation at the Wall

If the load ratio in the inlet exceeds the limited load ratio, the excess mass is removed immediately after the cyclone inlet and forms strands or a continuous layer at the wall. Only a small fraction of finer particle size distribution remains in the gas flow and undergoes centrifugal separation in the vortex of the cyclone. This solids fraction is called the "inner feed." The wall separation thus leads to a classification of the solids feed [22]. The classification is characterized by the cut size for wall separation

$$d_e^* = \sqrt{w_{s,50} \frac{18\eta_g}{\Delta\rho \overline{z}_e}}, \qquad (24)$$

where $w_{s,50}$ is the settling velocity of a particle which is separated by 50% from the gas stream, while moving along the clarification area A_w in the zone of downward flow under the mean centrifugal acceleration $\overline{z}_e$ [23]. With a secondary flow of 10%, it is given as

$$w_{s,50} = \frac{0.5(0.9\dot{V})}{A_w}. \qquad (25)$$

The clarification area includes the cylindrical part of the cyclone and the upper part of the cone because of the reversing vortex, Fig. 3. For pure cylindrical cyclones A_w is the area of the total cylindrical wall.

Particles with the diameter d_e^* are separated by 50% from the gas stream moving along the clarification area A_w. Particles of sizes much larger than the cut size deposit immediately at the cyclone wall, whereas finer particles find their way into the inner area of the cyclone.

The mean centrifugal acceleration $\overline{z}_e$ along the streamline from the entrance of the radius $\overline{r}_e$ down to the lower end of the clarification area A_w of the radius r_2 (Fig. 3) is

$$\overline{z}_e = \frac{u_e u_2}{\overline{r}_z} \tag{26}$$

with the tangential velocities

$$u_e = \frac{u_a r_a/\overline{r}_e}{1 + \frac{\lambda_s}{2}\frac{A_{e1}}{0.9\dot{V}} u_a \sqrt{r_a/\overline{r}_e}} \tag{27}$$

of the radius $\overline{r}_e$ and

$$u_2 = \frac{u_a r_a/r_2}{1 + \frac{\lambda_s}{2}\frac{A_w}{0.9\dot{V}} u_a \sqrt{r_a/r_2}} \tag{28}$$

of the radius r_2. The area A_{e1}, over which the gas stream flows during its first turn, is approximately

$$A_{e1} = (2\pi r_a h_e)/2. \tag{29}$$

Allowing for contraction of the entering gas flow in the entrance zone (Fig. 5) the reference radius $\overline{r}_z$ is given by

$$\overline{r}_z = \sqrt{\overline{r}_e \cdot r_2} = \sqrt{\left(r_a - \frac{1}{2}\alpha b\right) r_2}. \tag{30}$$

The limited loading ratio μ_{lim} depends on the mean centrifugal acceleration for the separation and on the particle size distribution of the feed with the median diameter $d_{50,A}$ and further on the load ratio of the feed μ_e [2, 14, 22]:

$$\mu_{lim} = K_{lim} \cdot \left(\frac{d_e^*}{d_{50,A}}\right) \cdot (10\mu_e)^k. \tag{31}$$

The constant K_{lim} varies between 0.02 and 0.03. The minimum value was found for fine particles with large slope angles, and the maximum value for coarser particles with small slope angles. For a large number of dusts, it is $K_{lim} = 0.025$.

The exponent k has the value 0.81 for inlet loadings $\mu_e < 2.2 \times 10^{-5}$, is constant 0.15 for inlet loadings $\mu_e > 0.1$, and follows the curve

$$k = 0.15 + 0.66 \cdot \exp\left[-\left(\frac{\mu_e}{0.015}\right)^{0.6}\right] \tag{32}$$

in the region $2.2 \times 10^{-5} \le \mu_e \le 0.1$.

The efficiency for separation due to exceeding the limited load ratio is [2]

$$\eta_e = 1 - \frac{\mu_{lim}}{\mu_e}. \tag{33}$$

This separation mechanism takes place before the separation in the inner vortex and can, for feed loadings $\mu_e > 0.1$, easily exceed the latter (Fig. 9). With increasing feed loading μ_e the separation efficiency η_e rises, the separation efficiency of the inner vortex however, declines due to the decrease of the inner tangential velocity (Eqs. (9) and (10)).

The particle size distribution of the inner feed is determined by the characteristic particle size $d_{50,Ai}$ [22]. The complete residue curve of the inner feed may be approximated by an RRSB function as given in Eq. (34), i.e.,

$$R_{Ai}(d) = \exp\left[-\left(\frac{d}{d'_{Ai}}\right)^{n_{Ai}}\right] \tag{34}$$

with

$$d'_{Ai} = \frac{d_{50,Ai}}{0.7^{1/n_{Ai}}} \tag{35}$$

and

$$\begin{aligned} d_{50,Ai} &= d_{50,A} \quad \text{for } \mu_e < \mu_{lim} \\ d_{50,Ai} &= d_{50,A} - \left(d_{50,A} - d_e^*\right) \cdot \frac{(1 - \mu_{lim}/\mu_e)}{0.5} \\ &\text{for} \quad 0 \le \left(1 - \frac{\mu_{lim}}{\mu_e}\right) \le 0.5 \\ d_{50,Ai} &= d_e^* \quad \text{for } 0.5 < \left(1 - \frac{\mu_{lim}}{\mu_e}\right), \end{aligned} \tag{36}$$

where $d_{50,A}$ is the mean particle size of the feed.

The exponent n_{Ai} describes the width of the residue curve of the inner feed and depends on the loading of the feed according to

$$\begin{aligned} n_{Ai} &= \max(1.2; n_A) \quad \text{for } \mu_e \ge \mu_{lim}, \\ n_{Ai} &= n_A \quad \text{for } \mu_e < \mu_{lim}. \end{aligned} \tag{37}$$

Experiments have shown that for various particle size distributions of the feed and for various operating conditions the residue curve of the inner feed plotted over $d/d_{50,Ai}$ can be very well approximated by a single curve, which is shown in Fig. 6 [22].

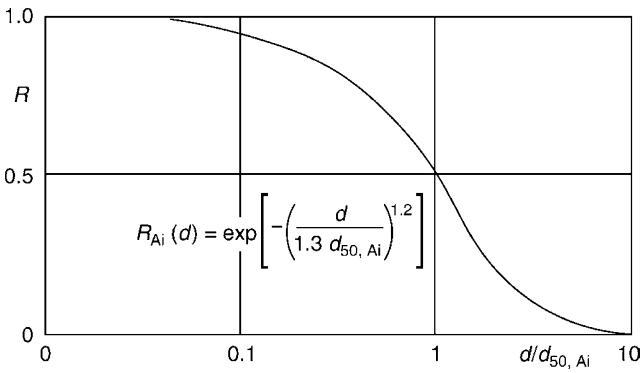
3.2 Separation in the Inner Vortex

The separation in the inner vortex is characterized by the cut size d^* of the main stream [4]. It is given by the balance of the centrifugal force acting on the particles with a diameter of d^* and its drag at the radius r_i of the vortex tube. Assuming a secondary flow of 10% the cut size can be calculated from [5]

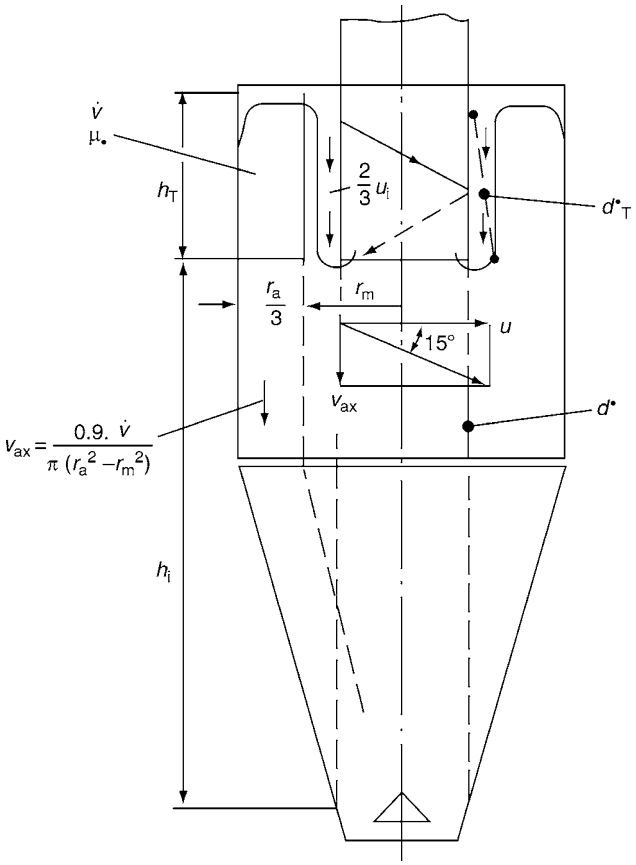
$$d^* = \sqrt{\frac{18\eta_g 0.9\dot{V}}{\Delta\rho u_i^2 2\pi h_i}}. \tag{38}$$

It depends mainly on the square of the inner tangential velocity and on the height h_i of the separation compartment (Fig. 7) below the vortex tube.

The cute size d^* characterizes the grade efficiency curve η_F for the separation in the inner vortex.



L3.4. Fig. 6. Residue curve of the inner feed for various feeds and operating conditions as a function of $d/d_{50,Ai}$, Eq. (34).



L3.4. Fig. 7. Calculation of the cut size d^* for the main gas stream, Eq. (38), and for the secondary gas stream (for details, see [15]).

Figure 8 shows experimental η_F- curves for various cyclone types [2]. The experimental value for the cut size is found to be the theoretical value multiplied by the factor ranging from 1.2 to 1.3, depending on the geometry and on the flow pattern in the cyclone. For the calculation the η_F- curve may be described in the region $D^{-1} \cdot d^* \le d \le D \cdot d^*$ by

$$\eta_F(d) = 0.5\left\{1 + \cos\left[\pi\left(1 - \frac{\log\left(\frac{d}{d^*}\right) + \log D}{2 \log D}\right)\right]\right\} \quad (39)$$

in the region $d < D^{-1} \cdot d^*$ by $\eta_F = 0$ and in the region $d > D \cdot d^*$ by $\eta_F = 1$; the shape of the curve is adapted to the cyclone type by the parameter [20]

$$D = \frac{d/d^*(\eta_F = 1)}{d/d^*(\eta_F = 0.5)}. \quad (40)$$

D may assume values between 2 and 4, and $D = 3$ for a typical cyclone.

The separation efficiency in the inner vortex is given by

$$\eta_i = \sum_{j=1}^{m} \eta_F(\bar{d}_j) \Delta R_{Ai}(\bar{d}_j). \quad (41)$$

In this equation, the residue curve of the inner feed is subdivided into m classes and it is calculated with the mean particle sizes in each particle size fraction. $\Delta R_{Ai}(d^*_j)$ is the mass fraction of the jth particle size fraction.

The grade efficiency in the inner vortex, $\eta_F(\bar{d}_j)$, is valid only if μ_e is less than μ_{lim}. A rough approximation of the grade efficiency can be obtained in one step from the cut size d^*, i.e.,

$$\eta_i \approx R_{Ai}(1.05 d^*). \quad (42)$$

3.3 Total Separation Efficiency

The total separation efficiency is the sum of two parts, according to the two separation mechanisms, i.e.,

$$\eta_{ges} = 1 - \frac{\mu_{lim}}{\mu_e} + \frac{\mu_{.lim}}{\mu_e} \cdot \eta_i. \quad (43)$$

The second part is calculated as in Sect. 3.2 by the grade efficiency curve $\eta_F(d)$, Eq. (39).

If the feed loading ratio is below the limited loading ratio, $\mu_e < \mu_{lim}$, only the separation in the inner vortex is valid and it is

$$\eta_{tot} = \eta_i. \quad (44)$$

The inner feed is, in this case, identical with the feed, i.e., $R_{Ai}(d) = R_A(d)$ (Fig. 9).

With increasing solids loading the inner tangential velocity decreases due to the increased wall friction. Therefore, the separation efficiency η_i in the inner vortex drops down, whereas the separation efficiency η_e at the wall increases and becomes dominant.

The amount of particle carryover is

$$S(\mathrm{kg/m^3}) = \left(1 - \eta_{ges}\right)\mu_e \rho_g \quad (45)$$

with η_{tot} calculated by Eqs. (43) and (44). The accuracy of S is approximately $\pm 20\%$ for a typical cyclone geometry.

The particle size distribution of the carryover, $R_F(d)$, can be determined in m size fractions by means of the total separation efficiency, the distribution of the inner feed, and the grade efficiency curve [22]:

$$\Delta R_F(d) = \frac{\mu_G}{\mu_e} \cdot \frac{(1 - \eta_{F,i}(d))}{1 - \eta_{ges}} \cdot \Delta R_{Ai}(d) \quad \text{for } \mu_e < \mu_G \quad (46)$$

$$\Delta R_F(d) = \frac{\mu_G}{\mu_e} \cdot \frac{(1 - \eta_{F,i}(d))}{1 - \eta_{ges}} \cdot \Delta R_A(d) \quad \text{for } \mu_e \ge \mu_G.$$

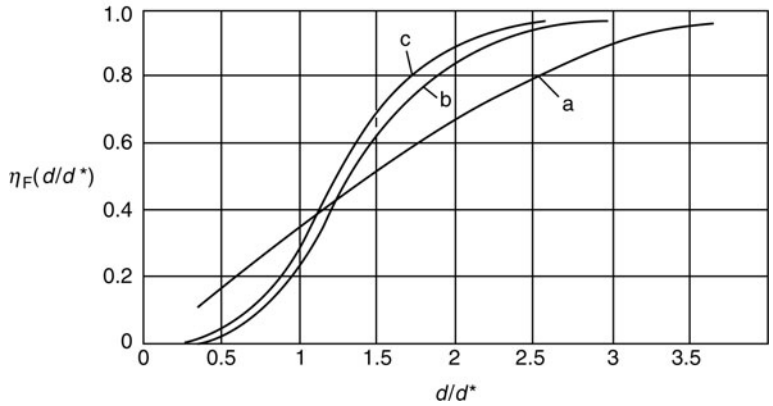
From Eq. (46) the total grade efficiency curve is obtained.

$$\eta_{F,tot}(\bar{d}) = 1 - \left(1 - \eta_{ges}\right)\frac{\Delta R_F(\bar{d})}{\Delta R_A(\bar{d})}. \quad (47)$$

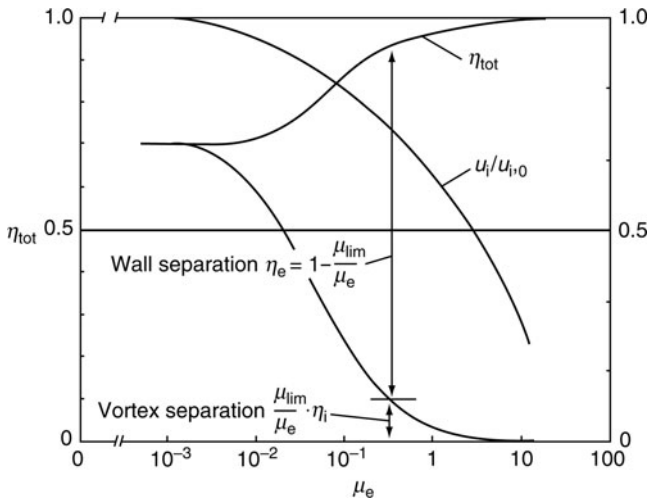
Figure 10 shows the influence of the feed loading ratio on the total grade efficiency curve. For $\mu_e > \mu_{lim}$ the curves no more drop down to zero but increase with decreasing particle size. The reason for the intensified separation of fine particles with increasing solids loading is that the fine particles are overwhelmed in the solids strands immediately after entering the cyclone.

For $\mu_e < \mu_{lim}$ the fine particles are no more overwhelmed in the strands. Therefore, the grade efficiency curve decreases to zero with decreasing particle size (Fig. 8).

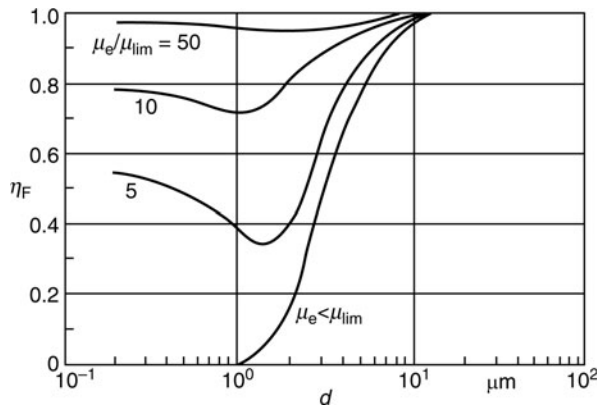
Curve	a	b	c
Design			
Inlet	Axial	Tangential	Tangential
h/r_i	15.0	13.0	10.0
h_i/r_i	10.0	10.0	7.5
r_a/r_i	2.0	3.0	4.0
A_e/A_i	2.70	0.90	0.44
b/r_a	0.40	0.27	0.19



L3.4. Fig. 8. Grade efficiency curves for separation in the inner vortex for three different cyclone geometries [2].



L3.4. Fig. 9. Separation efficiency and the inner tangential velocity u_i, related to the inner tangential velocity $u_{i,0}$ for pure gas, as a function of the feed loading ratio μ_e.



L3.4. Fig. 10. Influence of the load ratio of the feed μ_e on the total grade efficiency curve. For $\mu_e \leq \mu_{lim}$ only vortex separation is effective, for $\mu_e > \mu_{lim}$ wall separation also contributes to the separation.

An optimized calculation of the total separation efficiency, which takes also into account the secondary flow, is performed according to an approach of [22]:

$$\eta_{tot} = \left(1 - \frac{\dot{V}_{sec}}{\dot{V}}\right) \cdot \left[1 - \frac{\mu_{lim}}{\mu_e} + \frac{\mu_{lim}}{\mu_e} \cdot \eta_i\right] + \frac{\dot{V}_{sec}}{\dot{V}} \cdot \left[1 - \frac{\mu_D}{\mu_e} + \frac{\mu_D}{\mu_e} \cdot \eta_T\right]. \quad (48)$$

The first term describes the separation in the main flow and is calculated by means of Eqs. (24–44). The second term contains the separation in the secondary flow. The value of 10% for the fraction of the secondary flow, assumed in Eq. (38), is a mean value. The exact value depends essentially on the feed solids loading and is normally between 5% and 15%. According to [22] it is given by

$$\frac{\dot{V}_{sec}}{\dot{V}} = 0.0497 + 0.0684n + 0.0949n^2, \quad (49)$$

$$n = \frac{\ln(u_i/u_a)}{\ln(r_a/r_i)}. \quad (50)$$

An alternative approach for calculating $\dot{V}_{sec}$ is described in [24]. Both calculation methods are compared in [22].

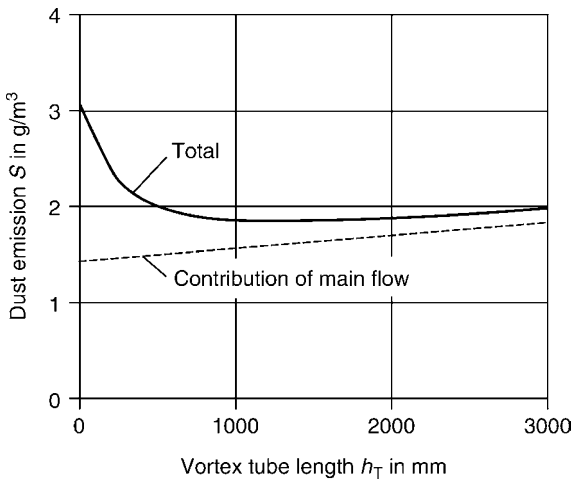
The secondary flow can carry more solids than the main flow, due to its lower tangential velocity and therefore, reduced attenuation of the turbulence. Measurements [1, 22] have shown that the limited loading ratio in the boundary layer at the covering μ_D is much larger than the limited loading ratio μ_{lim} of the main flow. According to [22] μ_D is given by $\frac{\mu_D}{\mu_{lim}} = 6$ for $\mu_e \geq 6\mu_{lim}$ and $\mu_D = \mu_e$ for $\mu_e < 6\mu_{lim}$.

Cyclones with a vortex tube force the secondary flow to move in spirals around the tube down to the opening. On its way around the tube, the secondary flow rotates much slower than the surrounding main flow. The particles carried in the secondary flow need some time to be captured by the surrounding faster main flow. It results, analogous to the main flow, in a cut size d_T^* for the separation out of the vortex tube boundary layer (details, see [15]). The separation efficiency η_T for the removal of particles from the vortex tube boundary layer increases with increasing vortex tube length. Measurements for different feed loadings lead to the relation

$$\eta_T(h_T) = 0.0105 \cdot \arctan(35 \cdot h_T/h) \quad (51)$$

with [arctan $(35h_T/h)$] = Degree.

On the other hand, an elongation of the vortex tube, at constant total height of the cyclone, reduces the height h_i of the separation compartment below the vortex tube and thus degrades the separation efficiency η_i in the main flow, Eqs. (38)–(41). Therefore, there exists an optimum length of the vortex tube, which results in a maximum total separation efficiency and a minimum carryover of particles (Fig. 11). If the vortex tube is too short, the secondary flow transports a considerable mass of dust into the pure gas. The optimum vortex tube length



L3.4. Fig. 11. Dust emission S of the cyclone in example 1 as a function of the vortex tube length: total emission (solid curve) and contribution of the main flow (dashed curve) to the total emission.

calculated according to Eqs. (48)–(51) agrees very well with the experiments [22, 25, 26] for various cyclones.

The grade efficiency curve η_T for the vortex tube separation mechanism, described earlier, is calculated by Eq. (51). This curve has been measured for one cyclone. For other cyclones Eq. (51) is a rough approximation. By means of an improved calculation method η_T can be obtained as a function of the vortex tube cut size d_T^* and therefore, as a function of the geometry and of the flow pattern in the cyclone. For more details see [22].

For small solids loadings the dust removal from the secondary flow contributes up to 15% to the total separation efficiency [22].

For higher loadings its contribution to the total separation efficiency is considerably lower, since over 95% of the entering particles are separated due to exceeding the limited loading ratio. Nevertheless, also in this case it can be very useful to achieve an optimum separation efficiency of the vortex tube, as has been shown for example in reactor systems with circulating fluidized bed, where only small changes of the length and of the position of the vortex tube (eccentrically shifted) had a large influence on the mass flow and on the particle size distribution of the circulating particles [20].

Also the geometry of the product outlet has an influence on the separation efficiency and the pressure drop of a cyclone. Its influence on the separation efficiency is of the same order as that of the secondary flow. Recommendations for an optimum geometry of the product outlet are given in [1, 2, 19, 27–30].

3.3.1 Particle Size Distributions for Agglomerating Fine Dusts

Fine dusts <40 µm can constitute, depending on the preliminary conditions to which they were subjected, agglomerates of 10–100 particles. In cyclones of diameters >1 m and outer tangential velocities u_a of 10–15 m/s, these agglomerates are not or only partially dissolved in the boundary layer of the wall.

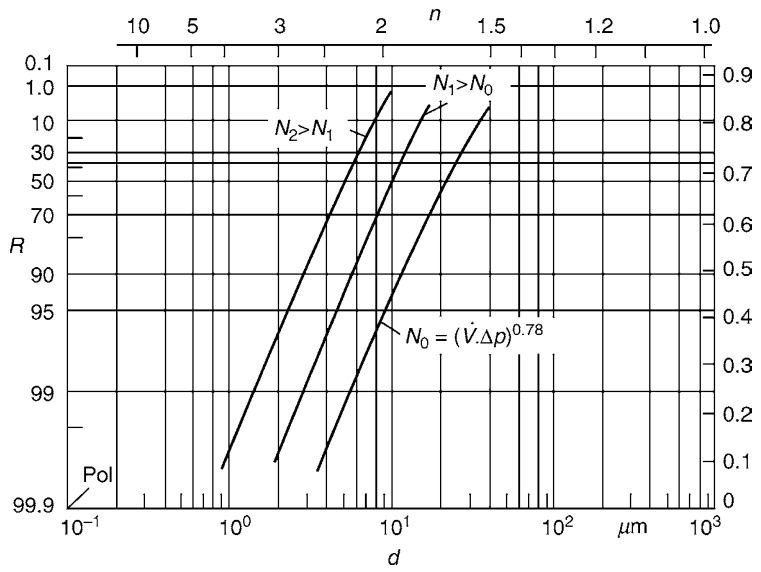
Figure 12 shows particle size distributions of cement dust collected in an electric precipitator. The curves 2 and 3 are shifted parallel with increasing exposure of the probe to a magnetic stirrer and ultrasound.

In cyclones it is for similar cases

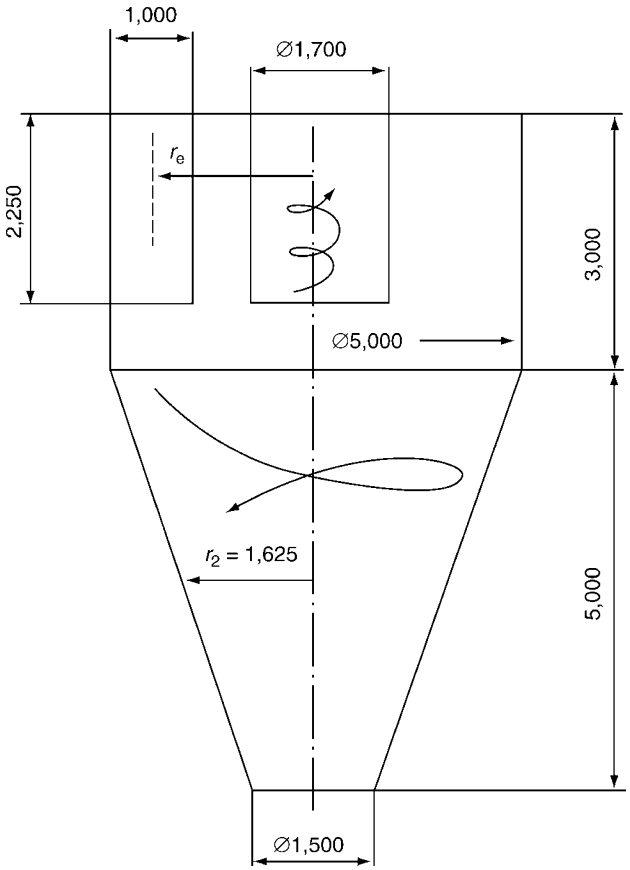
$$d' = d'_0 \cdot \left(\frac{\dot{V}_0 \cdot \Delta p_{e,0}}{\dot{V} \cdot \Delta p_e}\right)^{0.78}. \quad (52)$$

The agglomerates are stressed mainly in the boundary layer at the wall of the separation compartment, where the power of the stream $N_{Str} = \dot{V} \cdot \Delta p_e$ is transformed. The parameter for the width of the RRSB particle size distribution n remains constant for the three different powers N (Fig. 12), the characteristic particle size d′ is converted according to Eq. (52). Experiments were performed for volume flow rates of 60,000–80,000 m^3/h at a flue gas temperature of 350°C and a dust concentration of 50 mg/Sm^3.

Example 1 (High loaded hot gas cyclone):
For the high loaded hot gas cyclone (gas temperature 870°C) shown in Fig. 13 the separation efficiency and the pressure drop



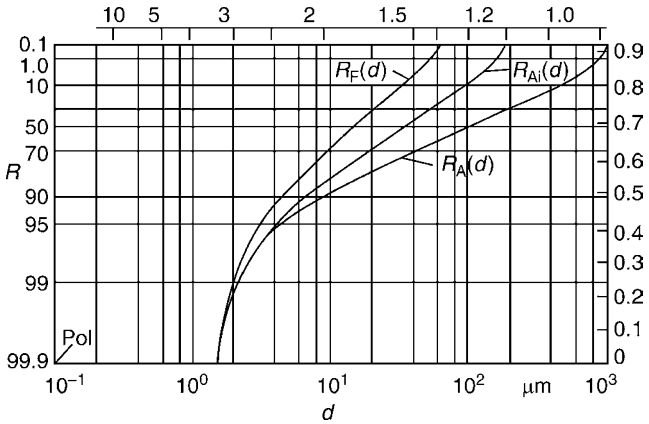
L3.4. Fig. 12. Residue curves of agglomerating dusts.



L3.4. Fig. 13. Geometry of the hot gas cyclone in Example 1.

are calculated. The feed has the particle size distribution $R_A(d)$ shown in Fig. 14.

The effective gas flow rate is 50 m^3/s, and the solids loading is μ_e = 5 kg/kg gas.



L3.4. Fig. 14. Residue curves of the feed $R_A(d)$, of the inner feed $R_{Ai}(d)$, and of the fines $R_F(d)$ for the Example 1, shown in an RRSB net.

Tangential velocities:

v_e = 22.2 m/s
β = b/r_a = 0.4 → α = 0.94 Eq. (1)
u_a = 18.9 m/s Eq. (2)

Operating data:

$\dot{V}$ = 50 m^3/s, T = 870°C
ρ_g = 0.305 kg/m^3, ρ_s = 2,000 kg/m^3
$\eta_g = 45 \cdot 10^{-6}$ Pa s, A_w = 81 m^2, A_R = 129 m^2

Coefficient of friction and tangential velocities:

λ_s = 0.0274 Eq. (12)
u_2 = 18.5 m/s Eq. (28)
u_i = 25.9 m/s Eq. (9)

Cut size and separation efficiency

d^*	= 29 μm	Eq. (38)
$w_{s,\,50}$	= 0.278 m/s	Eq. (25)
u_{e1}	= 20.2 m/s	Eq. (27)
$\overline{z}_e$	= 206 m/s^2	Eq. (26)
d_e^*	= 24 µm	Eq. (24)
μ_{lim}	= 0.0107	Eq. (31)
$\dot{V}_{sek}/\dot{V}$	= 0.078	Eqs. (49) and (50)
η_T	= 0.8841	Eq. (51)

Hence, the total separation efficiency including the separation at the vortex tube is

$$\eta_{tot} = (1 - 0.078) \cdot \left[1 - \frac{0.0107}{5} + \frac{0.0107}{5} \cdot 0.4256\right] + 0.078 \cdot \left[1 - \frac{0.0642}{5} + \frac{0.0642}{5} \cdot 0.8841\right] = 0.9987 \qquad \text{Eq. (48)}$$

and the emission is given by

$$S = \left(1 - \eta_{ges}\right) \cdot \mu_e \cdot \rho_g = 1,907\,\text{g/m}^3 \qquad \text{Eq. (45)}$$

The curve for the emission as a function of the vortex tube length has a broad minimum. Only for vortex tube lengths below 1,000 mm the emission increases considerably (see also measurements of [22, 25, 26]).

Pressure drops:

Δp_e = 127 Pa	Eq. (18)
Δp_i = 525 Pa	Eq. (20)

In Fig. 14 the particle size distributions of the feed $R_A(d)$, of the inner feed $R_{Ai}(d)$, and of the fines $R_F(d)$ are shown. Accordingly the dust, which arrives at the region of the inner vortex (R_{Ai}), is considerably finer than the feed. Each particle collective has a maximum particle size and a minimum particle size, d_{max} and d_{min}, respectively (see Subchap. L3.3). The parameter n_A for the width of the particle size distribution of the feed is readable at the upper scale.

3.3.2 Simplified Cyclone Design

If it has to be estimated in a short time whether a cyclone is appropriate for a dust removal problem, a simplified design according to the following scheme can be performed.
Example 2 (Rough design of a low loaded cyclone):

A cyclone for dust removal from air at environmental conditions is designed:

Gas flow rate	$\dot{V}$= 1 m^3/s
Solids loading of the feed	$\mu_e < 0.1$
Mean particle size of the feed	$d_{50,A}$ = 10 µm
Particle density	ρ_s = 2,600 kg/m^3
Allowed pressure drop	Δp_{tot} = 2,000 Pa

For a typical low loaded cyclone

It is approximately	$\Delta p_i \approx 0.9 \Delta p_{tot}$
Ratio of velocities	$u_i/v_i \approx 2$
Ratio of radii	$r_a/r_i \approx 3$
Ratio between height and radius	$h_i/r_a \approx 4$
Pressure drop coefficient of the vortex tube	$\xi_i \approx 15$

The pressure drop of the vortex tube is calculated approximately as that in a pipe flow:

$$\Delta p_i = \xi_i \cdot (\rho_g/2) \cdot v_i^2,$$
$$1,800 = 15 \cdot (1.189/2) \cdot v_i^2$$

Hence, it follows a mean axial velocity in the vortex tube of v_i = 14.2 m/s and an inner tangential velocity of $u_i = 2 \times 14.2 = 28.4$ m/s.

From v_i and the gas flow rate $\dot{V}$ the vortex tube radius is obtained:

$$n = \frac{\ln(u_i/u_a)}{\ln(r_a/r_i)} = 0.63.$$

The average axial velocity in the vortex tube and the gas flow rate determine the radius of the vortex tube

$$r_i = \sqrt{\frac{\dot{V}}{\pi \cdot v_i}} = 150\,\text{mm}.$$

With $r_a/r_i = 3$ it follows the cyclone radius r_a = 450 mm and with $h_i/r_a = 4$ the height of the separation compartment h_i = 1,800 mm.

From $h \approx h_i + 0.25 h_i$ (cf. [15]) the total height of the cyclone is obtained:

h = 2,250 mm.

Then the cut size d^* can be calculated according to Eq. (38) to d^* = 3.7 µm.

If for the feed an RRSB particle size distribution of medium width is assumed, i.e., n_A = 1, and further a sharp separation at the cut size d^* is assumed (cf. Eq. (42)), then a total separation efficiency of about 96% can be predicted. This estimation has for the given geometrical ratios and for low solids loadings an accuracy of a few percentages. However, for higher loadings the proper calculation procedure is recommended. Reviews [3, 19, 31–35] and short articles [21, 24, 36] about cyclones for the precipitation of solid particles are given in the literature.

4 Symbols

A_e	cross-sectional area of inlet (m^2)
A_i	cross-sectional area of gas outlet pipe (m^2)
A_R	area offering resistance to friction in cyclone (m^2)
$A_{R,Sp}$	area offering resistance to friction in spiral inlet (m^2)
A_W	area of cyclone wall (m^2)
b	width of inlet (m)

$\mathrm{Ba}(d)$	Barth number (–)
c_e	particle velocity at cyclone entrance (m/s)
c_{in}	particle velocity in entrance zone inside cyclone (m/s)
d	particle diameter (m)
d^*	cut size for separation in the cyclone vortex (m)
d_e^*	cut size for separation at wall (m)
d_T^*	cut size for separation in boundary layer around vortex tube (m)
$d_{50,A}$	median particle size of feed (m)
$d_{50,Ai}$	median particle size of inner feed (m)
d'	characteristic particle diameter of RRSB distribution (m)
D	parameter in η_F curve for separation in inner vortex (–)
$\mathrm{Fr_i}$	Froude number of cyclone flow (–)
h	total height of cyclone (m)
h_e	height of inlet (m)
h_i	height of separation compartment (m)
h_T	length of vortex tube (m)
k	exponent for calculating limited load ratio (–)
k_s/r_a	roughness parameter (–)
K_{lim}	constant for calculating limited load ratio (–)
m	number of size fractions (–)
$\dot{M}_{feed}$	mass flow of feed (kg/s)
$\dot{M}_{coarse}$	mass flow of collected coarse fraction (kg/s)
n	exponent for calculating tangential velocity (–)
n_A	slope parameter for residue curve of feed (–)
n_{Ai}	slope parameter for residue curve of inner feed (–)
Δp_{tot}	total pressure drop (Pa)
Δp_e	pressure drop in separation compartment (Pa)
Δp_{inlet}	pressure drop in inlet (Pa)
Δp_i	pressure drop in gas outlet pipe (Pa)
r_a	outer radius cyclone (m)
r_D	radius of pressure plate (m)
r_e	inlet radius (m)
r_i	radius of gas outlet pipe (m)
$r_m = \sqrt{r_a r_i}$	average radius (m)
r_u	radius of deflection at pressure plate (m)
r_2	average radius of cone (m)
r_3	radius of lower cone opening (m)
$\overline{r}_z$	reference radius for centrifugal acceleration (m)
$R(d)$	fraction retained on screen with mesh size d (Residue) (–)
$\Delta R(d)$	fraction retained in size interval around d (–)
$R_A(d)$	residue of feed (–)
$R_{Ai}(d)$	residue of inner feed (–)
$R_F(d)$	residue of fines (–)
$\mathrm{Re_R}$	Reynolds number of cyclone (–)
$\mathrm{Re_S}$	Reynolds number for flow around particles (–)
s	distance between pressure plate and cyclone cover (m)
S	particle emission (kg/m^3)
t	guide vane spacing (m)
$ü$	overlap guide vanes (m)
u	tangential velocity (m/s)
u_a	tangential velocity at radius r_a (m/s)
u_e	tangential velocity at radius r_e (m/s)
u_i	tangential velocity at radius r_i (m/s)
u_2	tangential velocity a t radius r_2 (m/s)
$u_m = \sqrt{u_a \cdot u_i}$	average tangential velocity (m/s)
v	axial velocity (m/s)
v_{ax}	average axial velocity in cyclone (m/s)
v_e	gas velocity at cyclone entrance (m/s)
v_i	average axial velocity in vortex tube (m/s)
v_{in}	gas velocity in entrance zone of cyclone (m/s)
$\dot{V}$	gas flow rate (m^3/s)
$\dot{V}_{sec}$	gas flow rate of secondary flow (m^3/s)
$w_{S,50}$	settling velocity of particles with size d_e^* (m/s)
$\overline{z}_e$	mean centrifugal acceleration at reference radius $\overline{r}_z$ (m/s^2)
α	coefficient of contraction (–)
$\beta = b/r_a$	relative width of inlet (–)
δ	guide vane angle (°)
ε	helix angle (°)
ε_{Str}	void fraction of strands (–)
η_g	dynamic viscosity of gas (Pa s)
η_{tot}	total separation efficiency (–)
η_e	separation efficiency at wall (–)
η_i	separation efficiency in cyclone vortex (–)
$\eta_F(d)$	grade efficiency (–)
λ_0	coefficient of friction for unladen gas (–)
λ_s	coefficient of friction for gas carrying solids (–)
μ_e	load ratio at inlet (–)
μ_{lim}	limited load ratio (–)
ν_g	kinematic viscosity of gas (m^2/s)
ρ_g	gas density (kg/m^3)
ρ_s	particle density (kg/m^3)
$\Delta\rho = \rho_s - \rho_g$	difference in density (kg/m^3)

L4.1 Formation and Movement of Bubbles and Drops

Norbert Räbiger[1] · *Michael Schlüter*[2]
[1]Universität Bremen, Bremen, Germany
[2]Technische Universität Hamburg-Harburg, Hamburg, Germany

1 Introduction

The heat and mass transfer between two immiscible fluid phases with different density is essential for many processes. Thereby usually one phase is dispersed into the other continuous phase to achieve preferably large interfacial areas and long contact times. Some examples are the distillation and rectification in petrochemical industry, the extraction out of fermentation brothes in biotechnology or the absorption of oxygen out of air in biological waste water treatment. The calculation of size and terminal velocity of fluid particles is the basis for the design and optimization of reactors and processes.

2 Formation and Movement of Bubbles and Drops at Orifices

The calculation of the particle size in multiphase flows is based on the equilibrium of forces acting on the particle surface. These forces are dominated by the hydrodynamic conditions above the dispersing system like orifices, nozzles, perforated plates, ceramics, or membranes. Due to the hydrodynamic conditions at the dispersing system a zone close and in more distance to the formation point has to be distinguished for the formation of drops and bubbles. For coalescing systems and/or under turbulent conditions, the particle size is dominated by coalescence and re-dispersion and therefore dependent on the local energy dissipation. For practical application the average particle size decisive for the calculation of the specific interfacial surface area a is often characterized by the Sauter-Diameter d_{32}

$$d_{32} = \frac{\sum n_i \cdot d_{Pi}^3}{\sum n_i \cdot d_{Pi}^2}. \quad (1)$$

In non-coalescing systems or low turbulence the particle diameter obtained by the dispersing system keeps almost constant.

At low flow rates the particle diameter is dominated by the force equilibrium at the dispersing system (primary diameter) and for higher throughput by the fragmentation above the dispersing system (secondary diameter). Whereas, the formation of bubbles and drops is very similar for low fluid throughput a significant difference in dispersion processes occurs for higher gas/liquid velocities (dynamic formation, Fig. 1).

The reason for the different behavior of bubbles and drops at high throughput is the different inertia and incompressibility. At low throughput the formation frequency is small enough to enable an undisturbed detachment of the particles and launch in almost the quiescent liquid. This range with periodically detaching of single particles is usually called "bubbly regime" or "periodic drop formation". At dynamic formation of fluid particles different formation mechanisms for drops and bubbles occur: Despite of high formation frequencies bubbles still detach as single particles but disintegrate into several secondary bubbles due to the dynamic of detachment [1, 2]. The slower formation of drops causes a deformation and aggregation to a liquid jet above a critical approaching velocity. The deformation energy and force of reaction (surface tension) causes a wavy shape of the jet and a disintegration at the tip (jet disintegration). The residual secondary droplets show similar to secondary bubbles a much smaller diameter with a wide size distribution [3].

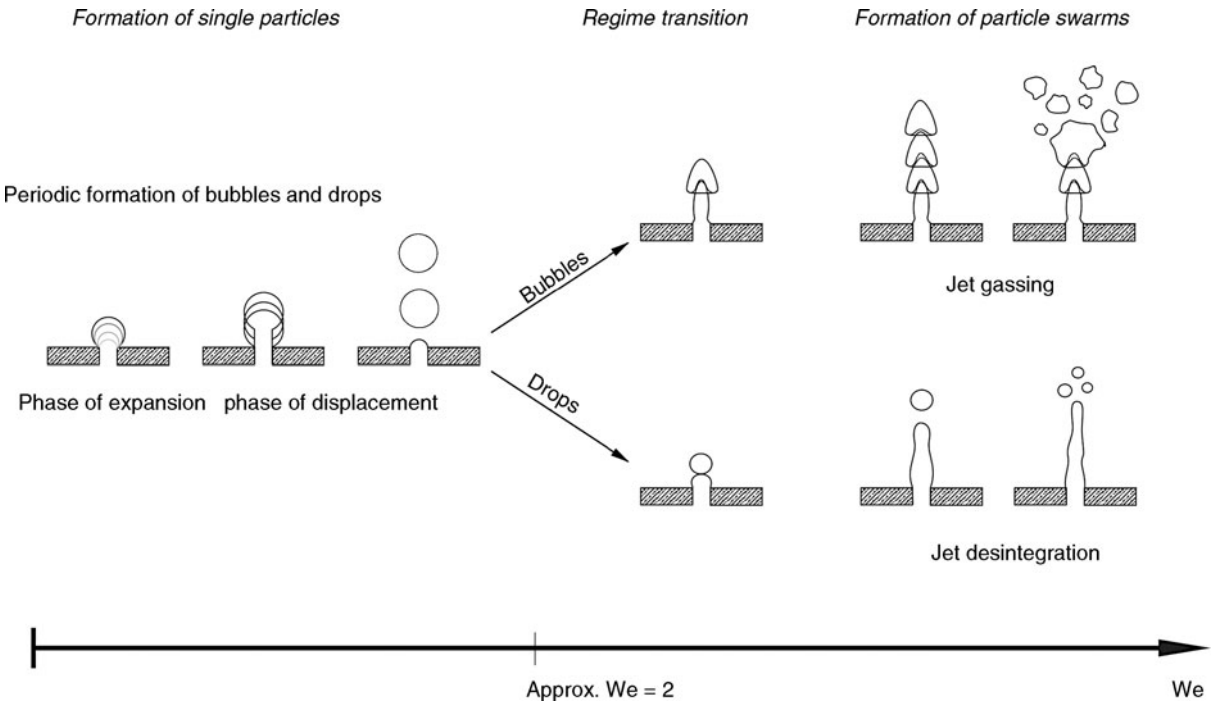
This makes clear that the equilibrium of forces will also be affected significantly by the formation process of neighboring particles. Therefore, the distance between the orifices as well as the prechamber volume is of great importance for widely-used perforated plates and membranes in industry.

The following recommendations for the calculation of particle formation diameters at orifices are classified into the above mentioned sections of **periodical formation of primary particle** and **formation of secondary particle**.

2.1 Periodical Formation of Primary Particles

The distinction between periodical formation of primary particles and secondary dispersion by jet gassing or jet disintegration is of great practical importance. A small particle size

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_49,



L4.1. Fig. 1. Schematic drawing of the particle formation at an orifice in dependency of the Weber number.

distribution can be reached in the regime of periodic particle formation whereas the Sauter-Diameter d_{32} increases with increasing throughput. The diameter of the generated particles is determined by the equilibrium of forces between buoyancy, surface tension, drag and inertia. Due to the balance of forces different models have to be taken into account (see Fig. 2).

For a very slow quasistatic formation process the formation of bubbles and drops follows the same mechanisms calculable with the analytical solution of the force balance by neglecting inertia. An overview is given by Chhabra [2], Räbiger [1], Blass [3], Tsuge [4] and Stölting [5].

For the periodic formation of fluid particles at nozzles and capillaries Voit [6] recommends a one step model that is applicable to Newtonian and to some extend also non-Newtonian liquids. Therefore, Voit simplifies the force balance by assuming a quasistatic equilibrium between buoyancy force

$$F_A = \frac{\pi}{6}\Delta\rho\, g\, d_p^3 \tag{2}$$

viscous force

$$F_\eta = 15\,\eta_K \frac{V_D}{d_P} \tag{3}$$

inertia force

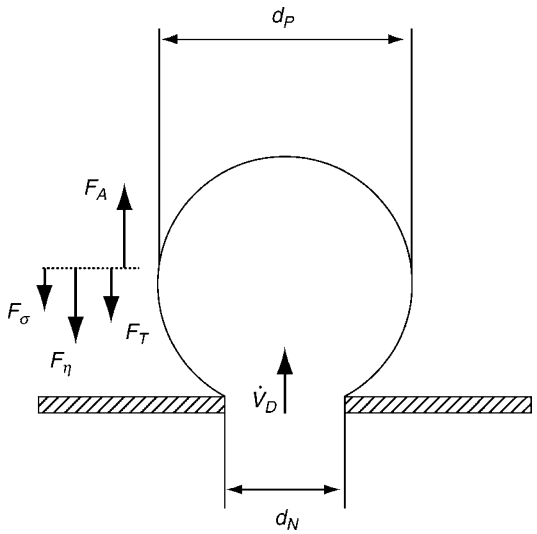
$$F_T = 1.3\,\rho_K \left(\frac{V_D}{d_P}\right)^2 \tag{4}$$

and the force by surface tension

$$F_\sigma = \pi\, d_N\, \sigma \tag{5}$$

due to

$$d_P = \left[\left(\frac{F_\eta + F_T + F_\sigma}{\Delta\rho\, g}\right)\frac{6}{\pi}\right]^{1/3}. \tag{6}$$



L4.1. Fig. 2. Equilibrium of forces for quasistatic formation of a particle.

For non-Newtonian liquids the effective viscosity is calculable by

$$\eta_{eff} = K^{\frac{1}{n}}\left[\frac{1}{6}\Delta\rho\, g\, d_P\right]^{\frac{n-1}{n}} \tag{7}$$

with the consistence factor K and the Ostwald de Waele index n for non-Newtonian behavior. K and n can be calculated by fitting the flow curve measured with a drag-torque viscometer to the power law

$$\eta_{eff} = K \cdot \dot{\gamma}^{n-1} \tag{8}$$

valid for most polysaccharide solutions, activated sludge, and fermentation brothes [7–10]. This method is applicable

for periodical formation of bubbles in Newtonian and non-Newtonian liquids and has been validated by Voit [6] for Carboxymethylcellulose (CMC: $K \leq 32$ mPas, $n \geq 0.4$), Polyacrylamid (PAA: $K \leq 7.1$ mPas, $n \geq 0.3$), Xanthan Gum (E 415: $K \leq 6.3$ mPas, $n \geq 0.2$), and water-based glucose solutions ($\eta_K \leq 5$ *Pas*) with a surface tension of $0.05\,\mathrm{N/m} \leq \sigma \leq 0.07\,\mathrm{N/m}$ a liquid density of $\rho_K = 1000\,\mathrm{kg/m^3}$, and a gas density of $\rho_D = 1.2\,\mathrm{kg/m^3}$. The orifice diameter was varied between $0.3\,\mathrm{mm} \leq d_N \leq 2.4\,\mathrm{mm}$. In accordance with Voit the deviation between calculated and measured diameter of primary bubbles is less than 10% and therefore in the order of measuring accuracy. The applicability of the model for periodical formation of droplets is due to Voit and also possible with an accuracy between experimental and calculated data in the range of the measuring accuracy [6].

Whereas the calculation of particle diameter according to equation 6 is quite complex due to the necessary iteration; the graphical solution given by Mersmann (1977) [11] gives a convenient possibility to estimate the primary particle diameter. Mersmann uses a normalized diagram with the simplified equilibrium of forces between viscous and buoyancy force ($d_{P\eta}$ according to eq. 6) as well as inertia and buoyancy force (d_{PT} according to eq. 6)

$$d_{P\eta} = C \cdot \left[\frac{K}{\Delta\rho g}\dot{V}_D^n\right]^{\frac{1}{3n+1}} \tag{9}$$

and

$$d_{PT} = 1.2 \cdot \left[\frac{\rho_K}{\Delta\rho}\frac{\dot{V}_D^2}{g}\right]^{0.2} \tag{10}$$

related to the smallest possible particle size, calculable with the force balance of surface tension and buoyancy according to

$$d_{P\sigma} = \sqrt[3]{\frac{6 d_N \sigma}{\Delta\rho g}}. \tag{11}$$

The constant C depends on the flowindex n calculabe by

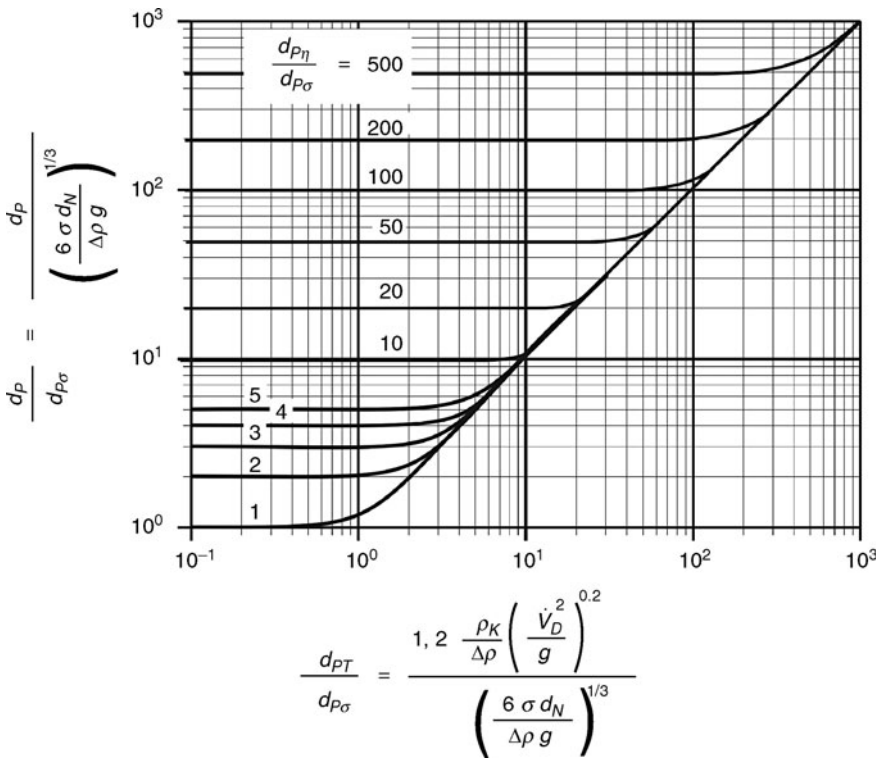
$$C = 2.32^{\frac{4n}{3n+1}} \cdot \left(\frac{1}{6}\right)^{\frac{n-1}{3n+1}} \tag{12}$$

in accordance to Voit [8]. For the graphical analysis of the particle size the log–log scale diagram given by Mersmann [11] has been established (Fig. 3).

According to Mersmann [12] the diagrams is also valid for extreme conditions like bubbles and drops in highly viscous liquids ($\eta_K = 3$ Pas) and liquid metals ($\sigma = 0.5\,\mathrm{Nm^{-1}}$) as well as drops of liquid metals in vacuum or supercritical gases. As restriction the dynamic viscosity of the dispersed phase is limited to $\eta_D < 50$ mPas.

2.2 Formation of Secondary Bubbles and Drops by Jet Bubbling and Jet Breakup at Single Orifices and Perforated Plates

For industrial application it is necessary to reach high throughputs of the dispersed phase and small particle sizes to get huge specific interfacial areas (jet bubbling, jet breakup). In this case, the inertia forces a secondary fragmentation of the primary particles above the orifice. The range of secondary particle formation is often characterized by the dimensionless Weber- or Froude



L4.1. Fig. 3. Normalized diagram to determine the primary particle diameter in Newton and Shear-Thinning liquids [11].

number. For small diameters of the orifice the buoyancy forces are neglectable and the surface tension dominates and vice versa for large orifices. Depending on the orifice diameter the dimensionless Weber- and modified Froude number

$$We_N = \frac{{w_N}^2 \cdot d_N \cdot \rho_D}{\sigma} \geq 2 \text{ for } d_N \sqrt{\frac{\rho_D \cdot g}{\sigma}} \left(\frac{\Delta\rho}{\rho_D}\right)^{5/8} \leq 2.32 \tag{13}$$

and

$$Fr_{N,\Delta\rho} = \frac{{w_N}^2}{d_N \cdot g} \left(\frac{\rho_D}{\Delta\rho}\right)^{5/4} \geq 0.37 \text{ for } d_N \sqrt{\frac{\rho_D \cdot g}{\sigma}} \left(\frac{\Delta\rho}{\rho_D}\right)^{5/8} > 2.32 \tag{14}$$

can be used as criteria for the formation of secondary particles [1, 13]. In this case the influences of an overlaid fluid flow w_K, the viscosity η_K, and the contact angle γ has been neglected. An overlaid fluid flow as well as an increased viscosity leads to an increased critical Weber number [1, 14, 15]. The contact angle γ depends on surface tension, wettability, and the geometry of the orifice [16, 17]. The critical Weber- and Froude numbers are important characteristic numbers for the performance of perforated plates, because if the throughput falls below this critical value a nonuniform fluid distribution occurs for gas as well as for liquid dispersion with the unwanted effect of a "raining" through the plate. For providing an uniform fluid distribution for every single orifice the critical Weber number $We_N \geq 2$ and Froude number $Fr_{N,\Delta\rho} \geq 0.37$ have to be reached. Although the upper limit for secondary particle formation can be described for bubbles and drops with the same laws the mechanism of secondary particle formation is totally different due to the deviation in density differences. This will be explained in the following section.

Bubble Formation in the Jet Bubbling Regime

At high gas throughput the particles are formed at the orifice that rapidly, that they follow each other directly and apparently forming a "gas jet". With high speed imaging Räbiger [18] was first able to show that single primary bubbles were created at the orifice even at very high gas throughputs. The diameter of this primary bubbles increases with increasing throughput (see Fig. 4, [1]). For higher critical Weber- and Froude numbers (see eq. 13 and eq. 14) the momentum of the liquid accelerated by the breaking bubble-tail leads to a fragmentation of primary bubbles above the orifice into multiple smaller secondary bubbles (see Fig. 4, [2]).

The primary as well as secondary bubble diameter increases with increasing gas throughput whereas the equation for calculating the primary bubble size (eq. 2.1) are still valid. In jet bubbling regimes the secondary bubble diameter at single orifices is calculable according to Brauer [19] by

$$d_{B,Sek} = d_N \cdot 0.72 \cdot {Fr_N}^{1/6}; \qquad \left(\frac{{We_{N,K}}^2}{Fr_N}\right)_{crit} \geq 675 \tag{15}$$

where Brauer distinguishes the transition between bubbling regime and jet bubbling regime with the critical relation between Weber number $We_{N,K}$ and Froude number Fr_N due to

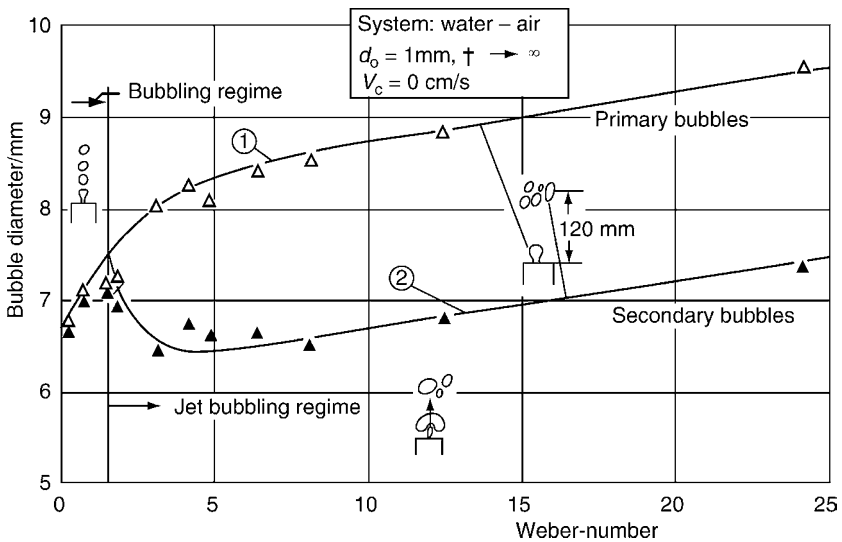
$$\left(\frac{{We_{N,K}}^2}{Fr_N}\right)_{crit} = 675. \tag{16}$$

The Weber number

$$We_{N,K} = \frac{{w_N}^2 \cdot d_N \cdot \rho_K}{\sigma} \tag{17}$$

is calculated with the density ρ_K of the continuous phase.

When perforated plates are used for technical application the interactive forces between bubbles formed side-by-side induces a strong shear field above the plate. For approximately $We_N > 6$ this shear stress leads to a secondary bubble size that is independent of the Weber number but depends on the hole pitch t [14]. According to Klug, the liquid displaced by the rising bubbles flows back between the bubble chains and induces an increasing shear stress with decreasing distance between the chains. Therefore, the secondary bubble size of air bubbles formed in water decreases with decreasing hole pitch t. For higher viscosities the smaller hole pitch promotes coalescence



L4.1. Fig. 4. Diameter of primary and secondary bubbles at a single orifice [14].

and larger secondary bubble sizes [14]. Under the assumption of force balance between surface tension and shear stress

$$\frac{12}{c_{w,K}}\frac{\sigma}{\rho_K \cdot {w_R}^2 \cdot d_B} = \frac{12}{c_{W,K}}\frac{\tau_W}{\rho_K \cdot {w_r}^2} + 1 \qquad (18)$$

Klug is able to calculate the secondary bubble size for perforated plates. As Klug investigated also the influence of an overlaid liquid velocity, he used the relative velocity w_r between gas- and liquid phase $w_r = w_G - w_F$ as the reference parameter. For the determination of the shear stress Klug assumes that the bubble chains are raising in separated virtual channels with the distance of the hole pitch. Assuming wall attachment of the liquid at the channel walls the shear stress is calculable due to

$$\tau = C_{W,R} \cdot \rho_K \cdot \frac{{w_r}^2}{8} \qquad (19)$$

with the drag coefficient $C_{W,R}$ the laminar flow regime

$$C_{W,R} = \frac{64}{Re_R} \qquad (20)$$

as well as the turbulent flow regime

$$C_{W,R} = \frac{0.3164}{{Re_R}^{0}.25} \qquad (21)$$

is predictable. The Reynolds number inside the virtual channels is given by

$$Re_R = \frac{w_r \cdot d_h \cdot \rho_K}{\eta_K} \qquad (22)$$

with the hydraulic diameter of the virtual channels due to

$$d_h = \frac{\sqrt[3]{3} \cdot t^2 - \frac{\pi}{2} \cdot {d_B}^2}{3 \cdot (t - d_B) + \frac{\pi}{2} \cdot d_B}. \qquad (23)$$

For the drag coefficient of a sphere the equation according to Brauer [19]

$$C_{W,K} = \frac{24}{Re_D} + \frac{4}{{Re_D}^{0.5}} + 0.4 \qquad (24)$$

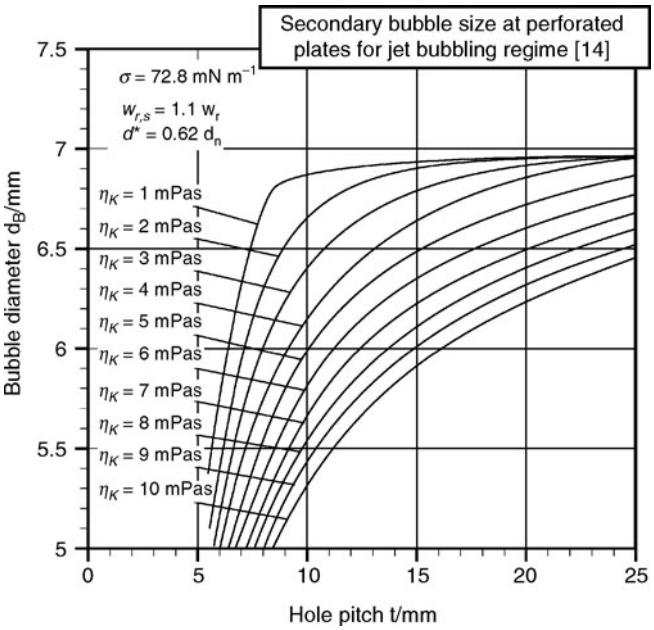
is applicable. Because the calculation of equation 18 is only possible by iteration, Fig. 5 and Fig. 6 gives a more convenient possibility to estimate the bubble diameter graphically.

The criteria for the flow regime is given by the coalescence of the primary bubbles directly above the orifice. According to Mersmann heterogeneous flow at perforated plates occurs if the hole pitch t becomes

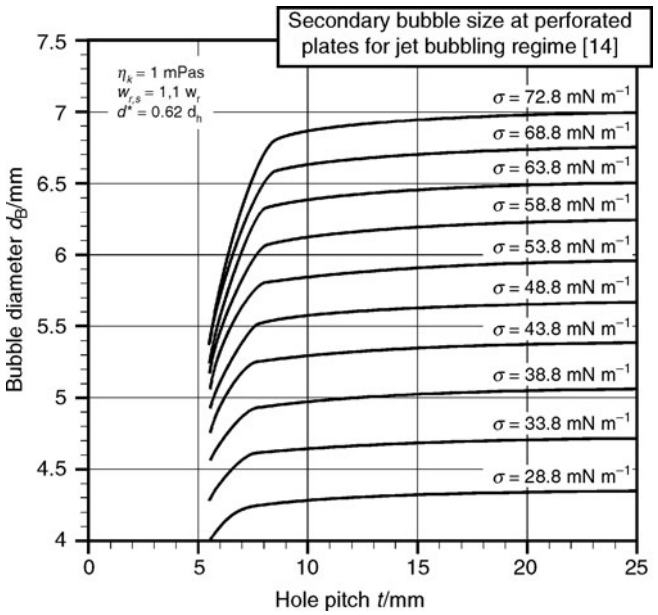
$$t \leq 2.7 \cdot d_N \left(\frac{{w_N}^2}{g\, d_N}\right)^{1/6}. \qquad (25)$$

Additional to the hole pitch t the volume of the prechamber is important because at low gas throughput the pressure inside the prechamber is constant and defines the bubble size [7]. Whereas, for small gas throughput the particle size increases with increasing prechamber volume, particulary Tadaki and Maeda had shown with several experimental results that at a critical dimensionless gas throughput of $We_{N,K} \cdot {Fr_N}^{0.5} \geq 10$ the bubble size is independent of the prechamber volume [20].

Due to the wide distribution of particle diameters in the jet bubbling regime very different relative velocities occur that



L4.1. Fig. 5. Size of secondary bubbles for perforated plates at high gas throughput ($We > 5$) for liquids with different viscosity.



L4.1. Fig. 6. Size of secondary bubbles for perforated plates at high gastroughtput ($We > 5$) for liquids with different surface tension.

causes strong interactions of the particles. For coalescing systems this causes coalescence and redispersion during the rising of the bubbles with a wide bubble size distribution above the perforated plate. The diameter of a gas bubble that is just still stable without breakup is given by the force balance between buoyancy and surface tension according to Mersmann [11]

$$d_{P,max} = 3\sqrt{\frac{\sigma}{\Delta\rho \cdot g}}. \qquad (26)$$

For liquids with low viscosity up to $\eta_K = 3$ mPas the Sauter-diameter can be estimated roughly by

$$d_{S32} = 0.6 \cdot d_{P,max}. \tag{27}$$

For a more precise description of an apparatus operating in jet bubbling regime population balances have been developed that uses different classes of bubble sizes taking coalescence, redispersion, and convection into account. For a more detailed description of population balances the readers are referred to the work of Lehr [21].

Drop Formation by Jet Desintegration

Because drops detach slower from orifices than bubbles due to the smaller density deviation at higher throughputs, multiple drops merge to a single liquid jet. Thereby the periodically changing force balance during the particle formation process leads to a dynamic fluctuation of the jet shape and an instability at the tip of the jet where the jet disintegrates. The length of the jet increases with increasing throughput to a maximum until it decreases again due to the increasing forces of inertia. Whereas, for a liquid throughput too low for the maximum jet length all droplets show an uniform size for higher throughput with decreasing jet length the drop size distribution gets wider [22]. The drop size decreases with increasing length of the jet until the jet reaches its maximum length. This interesting case for industrial application with maximum specific surface area occurs for a liquid throughput of the perforated plate that is twice the critical liquid velocity w_{crit} according to equation 13 and 14

$$w_N = 2 \cdot w_{crit} = 2 \cdot \sqrt{\frac{2 \cdot \sigma}{\rho_D \cdot d_N}} \tag{28}$$

The minimum drop size for that velocity is given by Ruff [13] due to

$$d_{P,min} = d_N \left(2.3 - 0.73 \sqrt{\frac{\Delta\rho\, g\, {d_N}^2}{\sigma}} \right) \quad \text{for} \quad \sqrt{\frac{\Delta\rho\, g\, {d_N}^2}{\sigma}} < 2.2 \tag{29}$$

respectively.

$$d_{P,min} = d_N \left(\frac{2.3}{1 + \sqrt{\frac{\Delta\rho\, g\, {d_N}^2}{\sigma}}} \right) \quad \text{for} \quad \sqrt{\frac{\Delta\rho\, g\, {d_N}^2}{\sigma}} \geq 2.2. \tag{30}$$

For any liquid velocity w_N the Sauter-diameter d_{S32} is calculable by Ruff [13] with the empirical correlation

$$d_{S32} = d_{P,min} \cdot \left(2.319 - 1.669 \cdot \frac{w_N}{w_{crit}} + 0.709 \cdot \left(\frac{w_N}{w_{crit}} \right)^2 - 0.114 \cdot \left(\frac{w_N}{w_{crit}} \right)^3 + 0.00629 \cdot \left(\frac{w_N}{w_{crit}} \right)^4 \right) \tag{31}$$

whereas $d_{P,min}$ is given by the minimal particle diameter according to equation 29 and 30.

In technical processes usually the dispersion of liquids takes place with perforated plates in the jet disintegration regime, where the coalescence and redispersion should be calculable according to Mersmann with the Sauter-diameter d_{S32} due to equation 27. A higher reliability is only reachable by calculating a representative particle diameter for the apparatus with population models.

Example 1:

As solvent for the extraction of penicillin butyl acetate has to be fed into the fermentation broth via 50 glass capillaries with an inner diameter of $d_N = 2$ *mm* each. Therefore, a high throughput is necessary but the shear stress should be as low as possible to prevent any damage to the microorganism. What is the maximum throughput and what average drop diameter occurs?

Thermophysical Properties:

Fermentation broth (Penicillium chrysogenum) [7]: $\rho_K = 1000\ \mathrm{kgm^{-3}}$; $n = 0.29$; $K = 1.85$ Pas Solvent (Butylacetat) [22]: $\rho_D = 880\ \mathrm{kgm^3}$; $\eta_D = 0.74$ mPas; $\sigma = 0.0135\ \mathrm{Nm^{-1}}$

Answer:

To assure a defined but low shear stress the dispersion should take place in the regime of periodic drop formation. From the limiting load at the beginning jet decomposition $We_N = 2$ the maximum throughput of a single capillary is calculable by

$$v_{crit} = \sqrt{\frac{2 \cdot \sigma}{d_N \cdot \rho_D}} = 0.124\,\mathrm{ms^{-1}}. \tag{32}$$

The volumetric flow rate is given by the orifice diameter of a capillary due to

$$\dot{V}_{D,EK} = 3.89 \cdot 10^{-7}\mathrm{m^3 s^{-1}} \tag{33}$$

and the maximum acceptable volumetric flow rate inside the column is given by

$$\dot{V}_D = 70\ \mathrm{Lh^{-1}}. \tag{34}$$

The particle diameter at periodical drop formation is calculable according to Mersmann by eq. 6. The parameter for the graphical solution is given by eq. 9–11 due to

$$c = 3.33, \tag{35}$$

$$\frac{d_{P\eta}}{d_{P\sigma}} = 2.07 \quad \text{and} \tag{36}$$

$$\frac{d_{PT}}{d_{P\sigma}} = 0.61. \tag{37}$$

With this data the dimensionless diameter of

$$\frac{d_P}{d_{p\sigma}} \approx 2 \tag{38}$$

is metering from Fig. 3 which gives an particle diameter of

$$d_P = 10.32\ \mathrm{mm}. \tag{39}$$

The iterative calculation of the force balance due to eq. 6 gives a particle diameter of $d_P = 10.86$ mm.

Example 2:

For the biological treatment of process water an activated sludge tank is aerated through a static disperser (perforated plate with 1000 orifices, diameter of orifice $d_N = 0.7$ mm, hole pitch $t = 8$ mm) with pressurized air. The viscosity of the broth is rising with cell growth up to total solids $TS = 5g/L$. The coalescence of

bubbles in process water is inhibited. How does the bubble diameter change for a constant gas flow rate of $\dot{V}_D = 32\,\mathrm{m/h}$ if the static pressure is negligible? How does the secondary bubble size in process water without biomass change, if the surface tension is changing due to surface active agents from $\sigma = 72.8\,\mathrm{mN/m}$ to $\sigma = 40\,\mathrm{mN/m}$?

Thermophysical Properties:

Process water without biomass [9]:

$$\eta_{C1} = 1\,\mathrm{mPas}; \rho_{C1} = 998\,\mathrm{kg/m^3};$$
$$\rho_{D1} = 1\,\mathrm{kg/m^3}; \sigma_1 = 0.0728\,\mathrm{N/m}$$

Process water with biomass:

$$\eta_{C2} = 2\,\mathrm{mPas}; \rho_{C2} = 1003\,\mathrm{kg/m^3};$$
$$\rho_{D2} = 1\,\mathrm{kg/m^3}; \sigma_2 = 0.0728\,\mathrm{N/m}$$

Answer:

Because the velocity in each orifice is $w_N = 23\,\mathrm{m/s}$ and

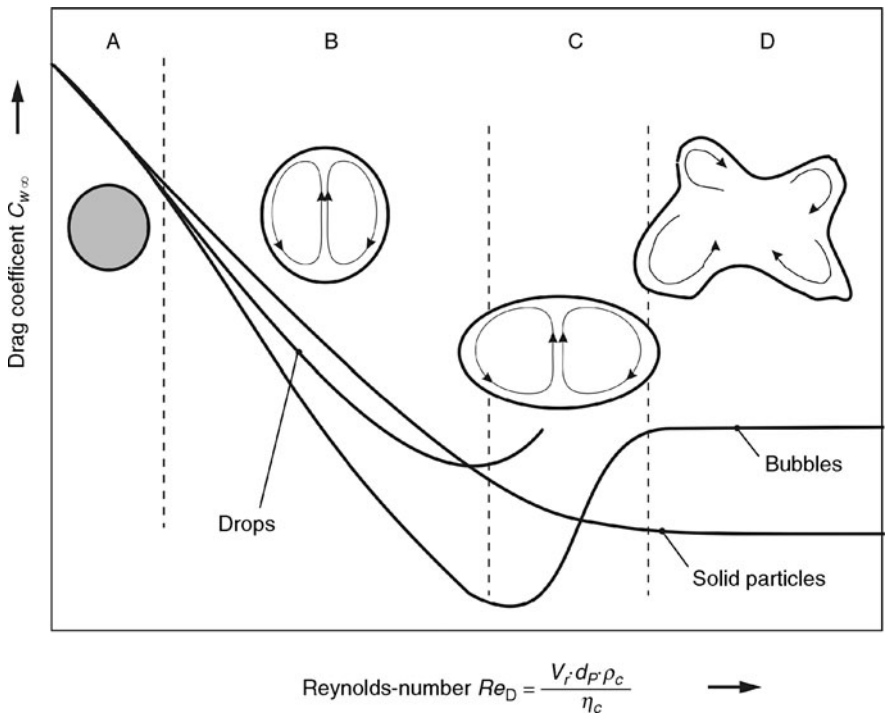
$$d_N \sqrt{\frac{\rho_D \cdot g}{\sigma}} \left(\frac{\Delta\rho}{\rho_D}\right)^{5/8} = 0.61 \leq 2.32 \quad \text{and} \quad We_N = 5.1 \quad (40)$$

the perforated plate is operating in jet bubbling regime. According to Klug [14], the secondary bubble diameter in process water without biomass for a hole pitch of $t = 8$ mm can be estimated from Fig. 5 to $d_B \approx 6.7$ mm. Because of cell growth and increasing viscosity the bubble diameter is decreasing down to $d_B = 6.3$ mm. Figure 6 shows that a reduced surface tension causes for the hole pitch of $t = 8$ mm and $\sigma = 40$ mN/m a secondary bubble size of approximately $d_B = 5.1$ mm in comparison to $d_B = 6.7$ mm in process water without surface active agents added.

3 Movement of Bubbles and Drops

After the formation process of single particle at orifices the buoyancy or weight force leads to an acceleration of each particle until force balance between all forces acting on the particle is reached. Whereas the equations for calculating the force balance acting on solid particles are also applicable for fluid particles, the flexible, deformable surface induces some additional effects that have to be taken into account for moving particles. Because of the complex interaction between flow field and particle form, due to compressibility and density difference of the dispersed phase the drag coefficient is not predictable with a general law. In dependency of the particle diameter the terminal velocity of particles and drops may be either monotonic increasing or increasing with a distinct maximum.

This diversity of the dependency between drag coefficient and Reynolds number for single particles is shown in Fig. 7. Because the dependence is influenced by the ratio of viscosities and densities of both phases as well as the mobility of the interface, usually the calculation of the drag coefficient is carried out with empirical correlation for separated intervals of the Reynolds number. Whereas fluid particles behave like solid particles within the first Reynolds number interval (see Fig. 7, A), for particles with moving interface the internal circulation leads to a lower drag coefficient (Fig. 7, B). The viscosity of the dispersed phase determines the momentum transfer inside the particle and causes the difference between drops and bubbles. In this Reynolds number interval, the mobility of the interface is strongly effected by surface active agents as well as interfacial mass fluxes (due to Marangoni convection)



L4.1. Fig. 7. Schematic drawing of the drag coefficient in dependency of the Reynolds number for solid particles, drops and bubbles according to [23].

which may cause the same behavior for bubbles than that for drops and rigid spheres. The third interval (Fig. 7, C) is dominated by deformation and oscillation of drops and bubbles that causes a higher drag coefficient than for rigid spheres. This is caused mainly by the higher pressure drop of nonspherical shapes visible by the characteristic vortices in particle wakes. Dependening on the Reynolds number ring-vortices or periodically forming and detaching vortices occur that force the particles on zigzag, helical or irregular rising pathes. The change in the moving direction causes a reduction of the perpendicular part of the rising velocity, which leads to an increasing drag coefficient. Recent publication shows that the wake shedding is not only eminent for the ascending trajectory [24, 26], but also for mass transfer performance and selectivity of chemical reactions due to the influence of bubble wakes on the mixing efficiency [25–27]. Whereas drops in the Reynolds-interval (C) above a critical diameter disintegrate into several fragments, bubbles change first into an irregular shape and with further increase in the Reynolds number into a Taylor-Bubble shape (Fig. 7, C). In this regime the drag coefficient keeps almost constant at $C_D = 2.61$. Mersmann developed an overall description for a rough estimation of the terminal velocity of single bubbles and drops independent of the Reynolds-interval and applicable for Newtonian and partly for non-Newtonian liquids (Fig. 8).

The notation of the ordinate with the dimensionless velocity

$$v_r^* = v_r \cdot \sqrt[3]{\frac{\rho_c^2}{\eta_c \cdot g \cdot \Delta\rho}} = \sqrt[3]{Re_D \cdot Fr} = \sqrt[3]{Lj} \qquad (41)$$

in dependency of the dimensionless particle diameter

$$d_P^* = d_P \cdot \sqrt[3]{\frac{\rho_c \cdot g \cdot \Delta\rho}{\eta_c^2}} = \sqrt[3]{Ar} \qquad (42)$$

with the logarithm of the modified liquid-number (reciprocal to Morton-number)

$$log\left(K_{F,\Delta\rho}\right) = log\left(\frac{\rho_c \cdot \sigma^3}{g \cdot \eta_c^4}\right)\frac{\rho_c}{\Delta\rho} \qquad (43)$$

allows the convenient estimation of the terminal velocity of single drops and bubbles and is easily transferable to other usual forms of diagrams (compare for e.g., [28]). For a more detailed estimation it has to be emphasized that the transition regimes e.g., between drop oscillation and bubble deformation are depicted only very roughly in Fig. 8. Furthermore, there is no possibility to take into account separately the different influences of e.g., surface active agents on the particle movement in the different regimes. Because the consideration of the local phenomena acting on single particles becomes more important concerning the precise calculation and design in process engineering, the calculation of the terminal velocity for drops and particles will be discussed separately in more detail in the following Sect. 3.1.

3.1 Movement of Single Drops

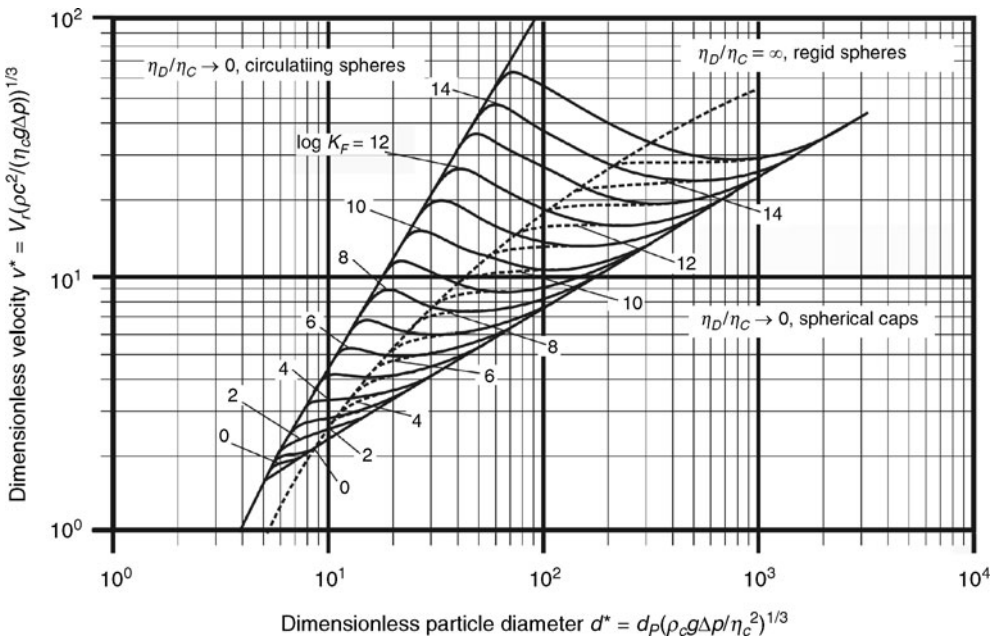
Due to the above mentioned phenomenology of particle behavior at free ascending drops it is reasonable to describe the drop movement in the three regimes

- rigid interface
- internal circulation
- oscillation

more precisely. As useful dimensional number to describe this circumstances the Archimedes number

$$Ar = \frac{d_P^3 \cdot g \cdot \rho_c \cdot \Delta\rho}{\eta_c^2} \qquad (44)$$

has been established.



L4.1. Fig. 8. Dimensionless local relative velocity of bubbles and drops in dependency of the dimensionless particle diameter [8, 11].

Section A: $Ar \leq 1.83 \cdot K_{F,\Delta\rho}^{0.275}$

In this regime, valid for very small droplets, the interface of the particles is assumed to be rigid. Therefore, the laws for rigid spheres are applicable with the drag coefficient $C_{w\infty} = 24/Re_P$ to

$$Re_P = \frac{1}{18} \cdot Ar. \tag{45}$$

Section B: $1.83 \cdot K_{F,\Delta\rho}^{0.275} < Ar \leq 372.9 \cdot K_{F,\Delta\rho}^{0.275}$

Above a distinct drop size and therefore drop velocity, the increasing shear stress at the drop interface induces an internal circulation of the drop. Within this regime dominated by the friction force, the drag coefficient decreases in comparison to the rigid sphere down to $C_{w\infty} = 16/Re_P$ and is calculable with the Reynolds number due to the empirical correlation

$$Re_P = K_{F,\Delta\rho}^{0.15}\left(Ar^{0.523} \cdot K_{F,\Delta\rho}^{-0.1435} - 0.75\right). \tag{46}$$

according to Blass [29].

Section C: $Ar > 372.9 \cdot K_{F,\Delta\rho}^{0.275}$

With further increasing drop diameter, the flow around the drops forces a deformation and oscillation that leads to an increased drag coefficient. The relative velocity and Reynolds number increase slightly in this regime with increasing drop diameter until they decrease. As empirical correlation, Blass recommends the equation

$$Re_P = K_{F,\Delta\rho}^{0.15}\left(4.18 \cdot Ar^{0.281} \cdot K_{F,\Delta\rho}^{-0.0733} - 0.75\right). \tag{47}$$

for the calculation of the Reynolds number [29].

The upper limit in this regime of drop movement is determined by the stability of the particles, because from a distinct particle diameter the forces acting on the droplet causes the defragmentation into small droplets. According to Mersmann the probability for a sufficient stability of fluid particles decreases if

$$\frac{We_D}{Fr}\frac{\Delta\rho}{\rho_D} > 9. \tag{48}$$

As the drag coefficient shows a minimum at the beginning of drop oscillation, the calculation of the optimum particle diameter is eminent concerning the design of apparatus, reactors, and plants (e.g. for the calculation of the flooding point of a liquid–liquid column). This particle diameter with a maximum relative velocity is calculable with the intersection between the curves of equation 46 and 47 to

$$d_{P(v_{max})} = 7.186 \cdot \left(\frac{\eta_c^2}{\rho_c \cdot \Delta\rho \cdot g}\right)^{1/3} \cdot K_{F,\Delta\rho}^{0.0917} \tag{49}$$

The above mentioned equations 46 to 49 have been developed by Blass [29] for the design of extraction columns and are applicable for a viscosity of the continuous phase of $\eta_c < 5 \cdot 10^{-3}$Pas [29, 30].

For liquids with viscosities of $\eta_c > 5 \cdot 10^{-3} Pas$ and/or non-Newtonian rheological properties the empirical equation of Mersmann [31]

$$v_r = \frac{v_{r,d_{P,max}}}{1 + 15 \cdot \frac{2/3 + \eta_D/\eta_c}{1 + \eta_D/\eta_c}} \cdot v_{r,d_{P,max}} \cdot \sqrt[3]{\frac{\rho_c^2}{\eta_c \cdot \Delta\rho \cdot g}}\left(\frac{1}{d_P^*}\right)^{1.75} \tag{50}$$

with the velocity of the largest stable droplet of

$$w_{r,d_{P,max}} = 1.55 \cdot \sqrt[4]{\frac{\sigma \cdot \Delta\rho \cdot g}{\rho_c^2}} \quad \text{and} \quad d_P^* \equiv d_P \cdot \sqrt[3]{\frac{\rho_c \cdot \Delta\rho \cdot g}{\eta_c^2}} \tag{51}$$

gives an adequate solution [8, 12].

The equation by Mersmann is in good agreement with experimental data [32] because the drop oscillation that would not be satisfactorily predictable with equation 51 is damped down anyway to $\eta_c > 7 \cdot 10^{-3}$Pas [18]. Further description of the particle behavior in higher viscous and non-Newtonian liquids is given in [2]. Basically, all empirical equations have been derived out of measurements with more or less pure systems. Therefore, the equations are not taking into account specific impurities of the continuous phase such as surface active agents that accumulate at the interface, prevent surface agitation, and increase the drag coefficient. Furthermore, the nonequilibrium of forces may induce interfacial convection that can reach an eruptive character (Marangoni convection), and therefore, influences the drag coefficient of drops strongly [33].

Example 1:

In a spray column pentachlorethane is used as extracting solvent in water and dispersed with a perforated plate (orifices diameter d_N = 1.5 mm). What drop diameter is necessary to reach a maximum relative velocity between drops and surrounding liquid and how large is the reachable relative velocity with this drop size? Thermophysical Properties for Pentachlorethane/Water:

$$\eta_c = 0.95 \text{ mPas}; \rho_c = 998 \text{ kg/m}^3; \eta_D = 2.03 \text{ mPas};$$
$$\rho_D = 1674 \text{ kg/m}^3; \sigma = 0.0424 \text{ N/m}$$

Answer:

The drag coefficient of a single drop reaches a minimum with onset of oscillation. The associated drop diameter is calculable with equation 49 to

$$d_{P(w_{max})} = 7.186 \cdot \left(\frac{\eta_c^2}{\rho_c \cdot \Delta\rho \cdot g}\right)^{1/3} \cdot K_{F,\Delta\rho}^{0.0917} \tag{52}$$

with

$$K_{F,\Delta\rho} = \frac{\rho_c \cdot \sigma_c^3}{g \cdot \eta_c^4}\frac{\rho_c}{\Delta\rho} \tag{53}$$

follows $K_{F,\Delta\rho} = 1.41 \cdot 10^{10}$ and thus $d_{P(max)} = 3.15$ mm. This value is in good agreement with experimental data [29]. For the determination of the relative velocity the graphical or calculable solution is applicable.

a) Graphical solution:

For a drop diameter of d_P = 3.15 mm the dimensionless drop diameter d_P^* is calculable by using equation 42 due to

$$d_P^* = d_P \cdot \sqrt[3]{\frac{\rho_c \cdot g \cdot \Delta\rho}{\eta_c^2}} = 61.2 \tag{54}$$

as well as equation 43

$$log\left(K_{F,\Delta\rho}\right) = log\left(\frac{\rho_c \cdot \sigma^3}{g \cdot \eta_c^4}\frac{\rho_c}{\Delta\rho}\right) = 10.1. \tag{55}$$

Figure 8 shows a dimensionless velocity of $v^* \approx 11$ that enables the calculation of the terminal velocity of a pentachlorethane drop with equation 41 to

$$v_r = v_r^* \left(\frac{\rho^2}{\eta_c \cdot g \cdot \Delta\rho} \right)^{-1/3} = 0.203 \; ms^{-1}. \tag{56}$$

b) Calculated solution:
With the Archimedes number

$$Ar = \frac{g \cdot \Delta\rho \cdot d_P^3 \cdot \rho_c}{\eta_c^2} = 2.29 \cdot 10^5 \tag{57}$$

and the assumption

$$1.83 \cdot K_{F,\Delta\rho}^{0.275} < 2.29 \cdot 10^5 < 372.9 \cdot K_{F,\Delta\rho}^{0.275} \tag{58}$$

it becomes clear that the drop of pentachlorethane with a diameter of $d_P = 3.15 \; mm$ is just rising with internal circulation and without oscillation. Therefore, equation 46 is applicable due to

$$Re_P = K_{F,\Delta\rho}^{0.15} \left(Ar^{0.523} \cdot K_{F,\Delta\rho}^{-0.1435} - 0.75 \right) = 715.3. \tag{59}$$

With $Re_P = 715.3$ the terminal velocity of $v_r = 21.6 \; cm/s$ is in good agreement with the graphical solution considering the reading accuracy. Furthermore, a very good agreement with experimental data of Blass can be achieved [29].

3.2 Movement of Single Bubbles

Analogous to the behavior of moving single drops the relative velocity of single bubbles is dominated by the shape, whereas the influence of impurities and surface active agents is usually more important due to the larger difference in density and negligible inertia of the gas phase. For the characterization of bubble shapes the differentiation according to Peebles and Garber has been established [34] with four different general shapes (Fig. 9).

The change in bubble shape and flow field around the bubble occurs relatively sudden if a critical characteristic Reynolds number is passed. This depends on the properties of the continuous phase. With the dimensionless liquid number K_F as well as the Reynolds number of the bubble Re_D due to

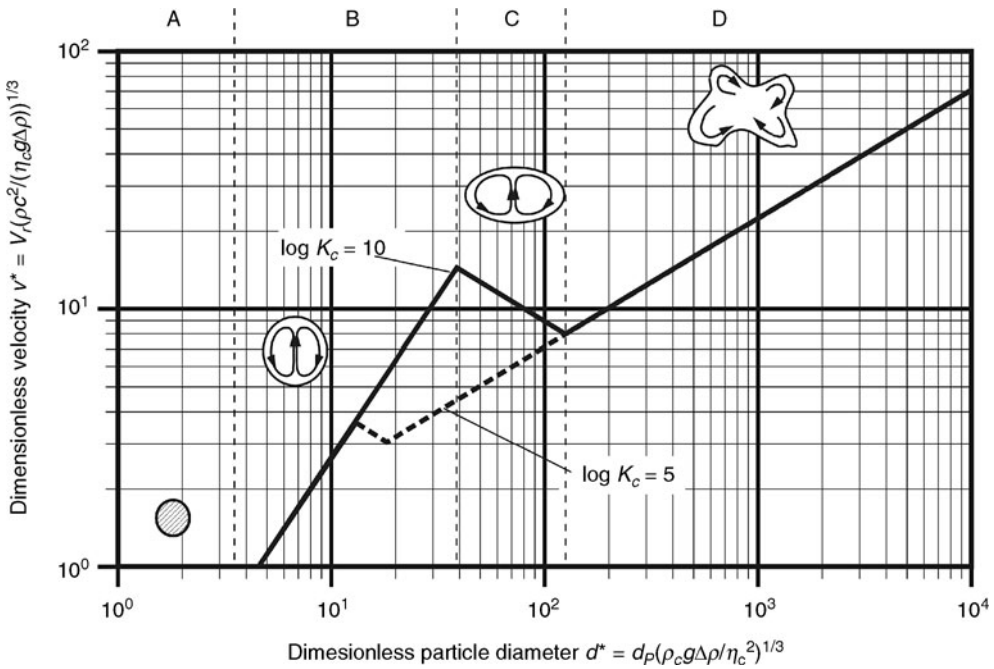
$$k_F = \frac{\rho_c . \sigma^3}{g . \eta_c^4} \quad \mathrm{Re}_D = \frac{v_r \cdot d_B \cdot \rho_c}{\eta_c} \tag{60}$$

the calculation of drag force and terminal velocity is possible for different gas/liquid systems classified into four characteristic regimes (Fig. 9). For the graphical presentation of the results the normalized plot according to Mersmann [11] with the dimensionless velocity (equation 41) depending on the dimensionless particle diameter (equation 42) allows a clearly arranged differentiation between different gas/liquid systems by means of the dimensionless liquid number 43. Furthermore, the scope of validity of individual equations can be metered directly at the abscissa by using the Archimedes number because

$$d_P^* = \sqrt[3]{Ar}. \tag{61}$$

Section A: $Ar \leq 7$, $Re \leq 0.2$

Gas bubbles with an Archimedes number of $Ar \leq 7$ and a low rising velocities ($Re \leq 0.2$) are dominated by surface tension and therefore almost spherical. They are rising without internal circulation rectilinear (Regime A, not depicted in Fig. 9). Analogous to the sedimentation velocity of solid particles, the terminal bubble rising velocity for this range of diameter



L4.1. Fig. 9. Dimensionless local relative velocity of gas bubbles in dependency of the dimensionless particle diameter [19, 34].

is calculable according to the drag law of Stokes with $C_{w\infty} = 24/Re_D$ due to

$$\sqrt[3]{Re_D \cdot Fr} = \frac{1}{18} \cdot Ar^{2/3} \tag{62}$$

[19].

Section A⁺: $Ar \leq 7.2$, $Re_D > 0.2$

For a distinct terminal rising velocity that strongly depends on impurities inside the gas/liquid system (e. g., $Re_D > 0.2$ [19]), the interface begins to move. Therefore, the drag coefficient decreases according to the correction factor of Hadamard–Rybczynski [35]

$$K_{HR} \equiv \frac{1 + \frac{\eta_D}{\eta_C}}{\frac{2}{3} + \frac{\eta_D}{\eta_C}} \tag{63}$$

for an air/water system and the ratio of $\frac{1}{K_{HR}} = \frac{1}{1.46}$ the corrected drag coefficient C_{W,A^+} is given by

$$C_{W,A^+} = \frac{24}{Re_D}\frac{1}{K_{HR}} \approx \frac{16}{Re_D} \tag{64}$$

respectively [36]. Therefore, the dimensionless terminal velocity of bubbles with moving interface is calculable by

$$\sqrt[3]{Re_D \cdot Fr} = \frac{1}{12} \cdot Ar^{2/3}. \tag{65}$$

For low Morton-numbers (e. g., for water) the minimum drag coefficient of a single bubble can be estimated to

$$C_{W,A,min} = 11.1 \cdot Re^{-0.71} \tag{66}$$

according to Maxworthy et al. [37].

Section B: $7.2 \leq Ar < 125 \cdot K_F^{0.25}$

With increasing Archimedes number, the forces of inertia become more dominant and the drag coefficient is calculable by the empirical equation

$$C_{W,B} = \frac{14.9}{Re_D^{0.078}} \tag{67}$$

due to [38] and [39] (see interval B in Fig. 9). The validity of this equation depends on the liquid properties and can be defined by the dimensionless liquid-number. The dimensionless terminal velocity is calculable by the empirical correlation

$$\sqrt[3]{Re_D \cdot Fr} = 0.136 \cdot Ar^{0.4266} \tag{68}$$

within this range of Archimedes numbers [19].

Section C: $125 \cdot K_F^{0.25} < Ar \leq K_F^{0.5}$

With further increasing Archimedes number (section C), the increasing forces induced by the flow around the particle cause a deformation of the bubble interface to a spheroid. This deformation depends strongly on the liquid properties. The increasing cross-section of the flattened bubble in the flow causes an increasing pressure drop that induces spacial and temporal fluctuating vortices at the rear side of the bubble (wake shedding). The vortex shedding causes a cyclic change in the orientation of the main bubble axis and induces a tumbling or helical rising trajectory. Because the terminal velocity is defined as the vertical part of the rising velocity vector, this tumbling or helical movement causes an decreasing terminal velocity with increasing tumbling or spiraling intensity despite the particle diameter increases. Peebles and Garber [34] used the empirical correlation

$$\sqrt[3]{Re_D \cdot Fr} = 1.91 \cdot K_F^{1/6} \cdot Ar^{-1/6} \tag{69}$$

for the description of their experimental results. The drag coefficient within this range is calculable by

$$C_{W,C} = \frac{1.332}{Fr} \tag{70}$$

Section D: $Ar > 22.6K_F^{0.5}$

For $Ar > 22.6K_F^{0.5}$ gas bubbles in water are rising with an irregular shape (Fig. 9, D) as "spherical cup bubbles" or "Taylor-Davis-Cup bubbles." The terminal velocity is calculable according to Brauer [19] with

$$\sqrt[3]{Re_D \cdot Fr} = 0.714 \cdot Ar^{1/6} \tag{71}$$

whereas, the drag coefficient within this range reaches the constant value of

$$C_{W,D} = 2.61. \tag{72}$$

For Newtonian liquids with low viscosity the helical rising trajectory leads to an decreasing terminal velocity, whereas, for increasing viscosities (approximately $\eta_C > 7$ *mPas*) the shape fluctuations are damped down and hence rectilineal trajectories occur [11, 18, 40, 41].

This dependency is considered with the dimensionless fluid number that decreases with increasing viscosity and diminishes the range of ellipsoidal bubbles. For dimensionless liquid numbers $K_F < 104$, the fluctuations of the bubble shape are fully damped by viscous forces [36].

Previous empirical correlations for a sectional calculation of the terminal velocity are well suitable to understand the physical interdependencies between bubble size, trajectory, and terminal velocity in pure systems. For the practical use their applicability is not convenient due to the dimensionless notation. Fan [42] published an empirical equation that uses a continuous function that is much more easy to use in process engineering. Fan connected the sections of different moving behavior in such a way, that for small bubble diameters Eq. 62 respectively Eq. 65 dominates, whereas for medium size and large bubbles the equation given by Mendelsohn [43]

$$v_r = \sqrt{\frac{2 \cdot \sigma}{\rho_C \cdot d_B} + \frac{g \cdot d_B}{2}} \tag{73}$$

gets an increasing influence [42].

Regarding the parameters k_1 which considers the dynamic surface tension, k_2 which takes into account impurities of the system, and k_3 which describes the mobility of the interface, Fan recommends the empirical equation

$$\sqrt[4]{We_C \cdot Fr} = \left[\left(\frac{K_C^{1/4}}{k_3}\frac{We_K}{Fr}\right)^{-k_2} + \left(\frac{2 \cdot k_1}{\sqrt{\frac{We_C}{Fr}}} + \frac{\sqrt{\frac{We_C}{Fr}}}{2}\right)^{-k_2/2}\right]^{-1/k_2}. \tag{74}$$

According to Fan the dynamic of the adsorption of surface active agents depends on whether it is used in a pure system ($k_1 = 1.2$) or a multicomponent system with impurities ($k_1 = 1.4$). Whereas, the parameter k_2 was experimental determined by Fan for several systems (table 1) the parameter k_3 is calculable due to

$$\text{for} \quad k_3 > 12 \quad k_3 = k_3^* \cdot K_F^{0.038} \tag{75}$$

$$\text{for} \quad k_3 \leq 12 \quad k_3 = 12 \tag{76}$$

with an acceptable reliability. The additional parameters are $k_3^* = 14.7$ for water and aqueous solutions and $k_3^* = 10.2$ for organic solvents. According to Fan, the scope of validity for the above mentioned equation is $10^{-5} < K_F < 10^{12}$ with an accuracy of −6% to +9% for 20 different Newtonian liquids. Despite the fact that Fan's equation is not able to fit the form transitions satisfactorily (section B → C, section C → D) its application is recommended especially for non pure systems, because the parameters have been adapted to a large variety of systems (Table 1).

For the detailed description of single bubbles rising in non-Newtonian liquids only a few investigations have been performed on shear thinning liquids like aqueous carboxylmethyl-cellulose (CMC-solutions) or viscous aqueous polyacrylamide (PAA-solutions) and aqueous glycerine solutions [18, 46, 47]. In highly concentrated CMC-solutions the terminal velocity increases with increasing bubble diameter due to a rectilinear trajectory, although strong fluctuations occur in the bubble shape. Therefore, highly concentrated CMC-solutions cause a more uniform movement of bubble swarms until no further coalescence occurs. Contrary to the uniform behavior of bubbles rising in CMC-solutions in viscoelastic PAA-solutions, an unsteady jump appears at a distinct bubble size [47, 48]. The reason for this sudden five to ten times increase in terminal velocity is mentioned by the higher mobility of the interface when surface active agents are sheared off or by the shear thinning effect of the PAA-solution. Furthermore, Starke has shown that the elastic properties of the liquid affect the bubble shape strongly and cause a significant reduction of the drag coefficient [47].

Hence, mainly the dimensionless plot of Mersmann is practically applicable for the calculation of the terminal velocity in non-Newtonian liquids (see Fig. 8).

[1] data from Kubota et al. [44]
[2] data from Kojima et al. [45]

L4.1. Table 2.

	η_C Pas	ρ_c kgm^{-3}	σ Nm^{-1}	K_F-	$lg(K_F)$	d_P^*	v^*	v_r ms^{-1}
dist. water/air	0.001	998	0.0727	$3.91 \cdot 10^{10}$	10.59	42.74	14.00	0.30
tap water/air	0.00098	998	0.0726	$4.22 \cdot 10^{10}$	10.63	43.32	14.00	0.30
aqueous glycerine/air	0.00915	1143	0.0699	$5.68 \cdot 10^{6}$	6.75	10.70	5.00	0.21

Example 4:
What is the terminal velocity of a gas bubble with a diameter of d_B = 2 mm in distilled water, tap water, and a 56% aqueous glycerine solution?
a) Graphical soluion:

The parameter for the graphical solution are given in (Table 2).

Due to the graphical solution it becomes clear that small differences in the viscosity and surface tension are difficult to read from the diagram. Therefore, similar values of the terminal velocity have to be used for distilled water and tap water despite of the fact that experimental data shows a significant difference between the terminal velocity of gas bubbles in distilled and tap water [42]. Furthermore, the terminal velocity in aqueous glycerine solutions is predicted much too high.
b) Calculated solution (in sections):

	Ar	$125 \cdot K_F^{0.25}$	$22.6 \cdot K_F^{0.5}$	$Re \cdot Fr$	v_r ms^{-1}
dist. water/air	$7.8 \cdot 10^4$	$5.6 \cdot 10^4$	$4.5 \cdot 10^6$	4932.39	0.36
tap water/air	$8.1 \cdot 10^4$	$5.7 \cdot 10^4$	$4.6 \cdot 10^6$	5022.67	0.36

The calculated solution considering the different sections of bubble movement shows a significant higher terminal velocity for distilled water and tap water. Furthermore, a distinction concerning the purity of the gas/liquid system is not possible. The terminal velocity of a single gas bubble rising in viscous liquids is calculable with a good accuracy.
c) Calculated solution (according to Fan):

	k_1	k_2	k_3	$We \cdot Fr^{-1}$	$(We \cdot Fr)^{0.25}$	v_r ms^{-1}
dist. water/air	1.2	1.6	37.14	0.54	1.75	0.287
tap water/air	1.2	0.8	37.25	0.54	1.28	0.210

Because the parameters for Eq. 74 have been adapted experimentally to a large variety of systems the consideration of surface active agents is possible with high accuracy. Therefore, the different terminal velocities in distilled water and tap water are well calculable. The comparison with experimental results shows a good agreement [42]. If the slope of the velocity curve in dependance of the particle diameter changes sharply like in the transition regimes (Fig. 9), the equation of Fan is less accurate. For higher viscous liquids in which the regimes for different moving behavior merge more smoothly the equation of Fan is a reliable approximation.

For the practical use of the above mentioned methods in process engineering it should always be considered whether surface active agents or higher viscosities are present. Whereas, for pure systems with low viscosity the calculation should be performed for each section of moving behavior, for contaminated systems and higher viscosities the method by Fan provides more accurate results.

4 Symbols

Phase

C	-	constant
$C_{W,K}$	–	drag coefficient of a single sphere
$C_{W,R}$	–	drag coefficient for an annular pipe flow
d_B	m	bubble diameter
d_h	m	hydraulic diameter
d_P	m	particle diameter
d_P^*	–	dimensionless diameter
$d_{P,min}$	m	minimal particle diameter
$d_{P,max}$	m	maximum particle diameter
d_N	m	diameter of nozzle/orifice
$d_{P\eta}$	m	bubble diameter with dominating viscous forces
d_{PT}	m	bubble diameter with dominating inertia forces
$d_{P\sigma}$	m	bubble diameter with dominating surface tension
d_{S32}	m	Sauter-diameter
F_A	N	buoyancy force
F_η	N	viscous force
F_T	N	force by inertia
F_σ	N	force by surface tension
g	ms^{-2}	gravitational force ($= 9.81\ ms^{-2}$)
K	$(Pas)^n$	consistency factor
n	–	exponent / flow-index
t	m	hole pitch
v_L	ms^{-1}	velocity of the liquid phase
v_G	ms^{-1}	velocity of the gaseous phase
v_{crit}	ms^{-1}	critical velocity before jet disintegration
v_N	ms^{-1}	velocity in the orifice
v_r	ms^{-1}	relative velocity
v_r^*	ms^{-1}	dimensionless relative velocity
$v_{r,dPma}$	ms^{-1}	relative velocity at maximum particle diameter
V_P	m^3	volume of particles
V_L	m^3	volume of liquid phase
$\dot{V}_D$	m^3s^{-1}	flow rate of the dispersed
$\dot{V}_{D,SC}$	m^3s^{-1}	flow rate of the dispersed phase through a single capillary
γ	^{o}	contact angle
$\dot{\gamma}$	s^{-1}	shear rate
ε_P		particle hold up
σ	Nm^{-1}	surface tension
$\Delta\rho$	kgm^{-3}	density difference ($\Delta\rho = \lvert\rho_C - \rho_D\rvert$)
ρ_C	kgm^{-3}	density of the continuous phase
ρ_D	kgm^{-3}	density of the dispersed phase

η_C	*Pass*	viscosity of the continuous phase
η_D	*Pass*	viscosity of the dispersed phase
η_{eff}	*Pass*	effective viscosity
τ_W	Nm^{-2}	shear stress inside the virtual channal

Dimensionless numbers:

Archimedes number

$$Ar = \frac{d_p^3 \cdot g \cdot \rho C \cdot \Delta\rho}{\eta_C^2} \tag{77}$$

Froude number

$$Fr = \frac{v_r^2}{dp \cdot g} \tag{78}$$

Froude number (particle formation)

$$Fr_N = \frac{v_N^2}{dN \cdot g} \tag{79}$$

Modified Froude number (particle formation)

$$Fr_{N,\Delta\rho} = \frac{v_r^2}{d_N \cdot g} \left(\frac{\rho_D}{\Delta\rho}\right)^{5/4} \tag{80}$$

Reynolds number of the dispersed phase

$$Re_D = \frac{v_r \cdot d \cdot \rho_C}{\eta_C} \tag{81}$$

Reynolds number in the virtual channel according to Klug [14]

$$Re_R = \frac{v_r \cdot d_h \cdot \rho_C}{\eta_C} \tag{82}$$

Dimensionless liquid number

$$K_L = \frac{\rho_C \cdot \sigma^3}{g \cdot \eta_C} \tag{83}$$

Modified dimensionless liquid number

$$K_{L,\Delta\rho} = \frac{\rho_C \cdot \sigma^3}{g \cdot \eta_C} \frac{\rho_C}{\Delta\rho} \tag{84}$$

Weber number of the dispersed phase

$$We_D = \frac{v_r^2 \cdot d_P \cdot \rho_D}{\sigma} \tag{85}$$

Weber number of the continuous phase

$$We_C = \frac{v_r^2 \cdot d_p \cdot \rho_C}{\sigma} \tag{86}$$

Weber number for particle formation

$$We_N = \frac{v_N^2 \cdot d_N \cdot \rho_D}{\sigma} \tag{87}$$

L4.2 Production and Mechanical Destruction of Foams

Alfons Mersmann
Technische Universität München, Munich, Germany

1 Introduction

Foams are produced when a gas is introduced or desorbed in a liquid which contains detergents. Pure liquids are non-foaming. The gas is dispersed into bubbles. A solution capable of foaming is a solvent – in most cases it is water with a high surface tension $\sigma = 72.4$ mJ/m^2 or 72.4 10^{-3} N/m at 25°C – with surface active agents which lead to a remarkable reduction of the surface tension. These detergents are more or less concentrated in the surface where an adsorption layer with the thickness of roughly one molecule diameter is formed.

The molar mass of strong surface active agents (detergents or tensides) is in the range of some hundreds of kilograms per kilomole (kg/kmol). The length of the hydrocarbon chain is between 1 and 5 nm with a hydrophilic functional group in the case of aqueous foams. When the molar mass of the detergent is too small, and the hydrophobic chain is too short, foams are not stable. However, if the molar mass assumes very high values with the consequence of low diffusivities of the surface active agents the detergent is only slowly enriched at the surface. This also leads to poor foam stabilities.

Gas can be introduced into the liquid by rotors (stirrers etc.) adjusted at the principal gas–liquid interface, falling drops, or spargers below the liquid surface. Bubbles can also be produced by depressurization and/or heating of a liquid which contains dissolved gas. The introduction of a gas leads to primary foams with bubbles in the diameter range of some millimeters. As a rule their liquid hold-up is small. Primary foams can be transformed to secondary foams by foam breakers. In secondary foams the liquid hold-up is high and the small bubbles are in the micrometer (μm) range. As a rule the objective of foam breaking is to form secondary foam with a high density and the ability of a certain flow in a gravitational field. This can be achieved if the mean bubble diameter is reduced to 50–100 μm by means of a power input. The specific energy in Joules per kilogram (J/kg) or square meters per square seconds (m^2/s^2) increases with the square w_u^2 of the tip speed w_u of a rotor. A minimum tip speed is necessary to start the mechanical destruction of primary foams. The density and the flow ability of secondary foams in a gravitational or centrifugal field increases with the tip speed of a rotor. The destruction of foams by the addition of chemicals (chemical destruction) is not considered here.

2 Detergents

According to [1] and [2] detergents can be

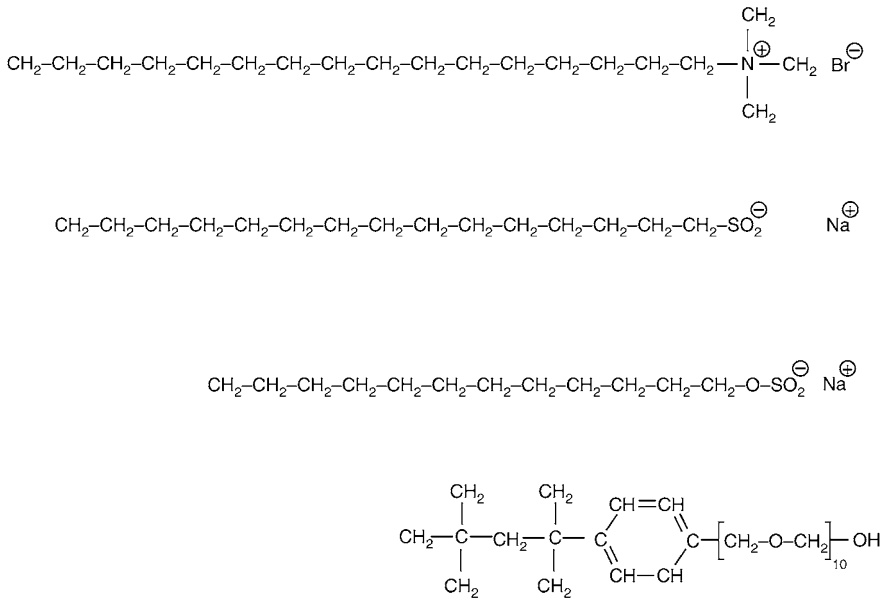
- Anionic
- Cationic
- Non-ionic and
- Amphoter

In Table 1 a survey of typical data and structures of the detergents CTAB, Mersolate, SDS, and Triton are given (see Table 1). These detergents have been investigated in research (see Fig. 1). All these substances can be characterized by their ability to reduce the surface tension of water in the concentration range between 10^{-4} and 10^{-3} mol/dm^3. In Fig. 2, the surface tension of aqueous solutions valid for 25°C is plotted against the concentration. Long-chained detergent molecules are adsorbed in a more flat structure (the chain is parallel to the surface) for low-concentrated solutions; however, with increasing concentration the hydrophilic groups are attracted by the water molecules at the surface whereas the hydrophobic tails form an adsoption layer.

In the case of a quick and strong stretching of this layer in combination with a remarkable reduction of the Gibbs surface concentration Γ according to

L4.2. Table 1. Properties and data of some tensides

Tenside	Type	molar mass kg/kmol	CMC kmol/m³	Surface concentration mol/m²	Area of a molecule nm²/molec
N-Cetyl-N, N, N-tnmethylammoniumbromide (CTAB)	cationic	346,46	$1 \cdot 10^{-3}$	$3.9 \cdot 10^{-6}$	0.4275
Pentadecan-sulfonacidsodium salt (Mersolat H 95)	anionic	314	$2 \cdot 10^{-3}$	$5.6 \cdot 10^{-6}$	0.2965
Dodecylsulfate (SDS)	anionic	288,38	$3 \cdot 10^{-3}$		
Octylphenolpolyglycolether (Triton X 100)	non-ionic	648,38	$4.4 \cdot 10^{-4}$	$4.4 \cdot 10^{-6}$	0.3773



L4.2. Fig. 1. Structure of some tensides (see Table 1).

$$\Gamma = -\frac{a}{\Re T}\frac{\mathrm{d}\sigma}{\mathrm{d}a} \approx -\frac{c}{\Re T}\frac{\mathrm{d}\sigma}{\mathrm{d}c}$$

a transport of tenside molecules, or a so-called Marangoni flow to spots with high surface tension is started. This leads to a healing process of the adsorption layer with the result of a remarkable elasticity and stability of foam lamellae. The surface concentration Γ is proportional to the negative slope of the surface tension with respect to the activity, and decreases with the absolute temperature T. In diluted solutions the activity is often approximately the same as the concentration; however, in general there can be great differences. Above the Critical Micell Concentration (CMC) micells or molecule clusters are formed.

3 Properties of Primary Foams

Primary foams can be characterised by their

- Density ρ_S
- Volume fraction Ψ_L of the liquid or $\Psi_G = (1–\Psi_L)$ of the gas
- Density ρ_L and viscosity η_L of the lamella liquid
- The mean layer thickness s between bubbles in a gas in liquid dispersion
- The lamella thickness δ and the radius r_P of a Plateau channel of a polyhedric foam
- The volumetric interfacial area a and
- The Sauter diameter $d_{B,32} = \Sigma\, n_i d_i^3 / \Sigma\, n_i d_i^2$

Based on the definition

$$a = \frac{6(1-\psi_L)}{d_{B,32}} = \frac{6\psi_G}{d_{B,32}}$$

of the volumetric area and the definition of the mean layer thickness s according to

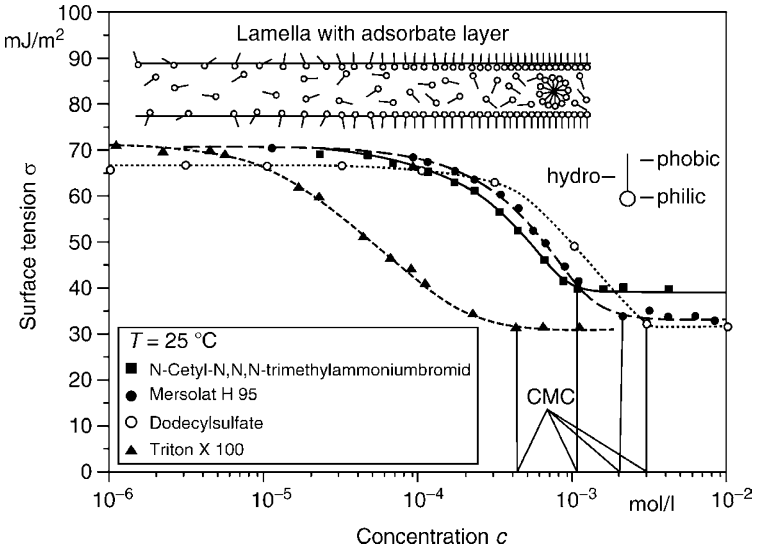
$$s = \frac{\psi_L}{a}$$

the relationship

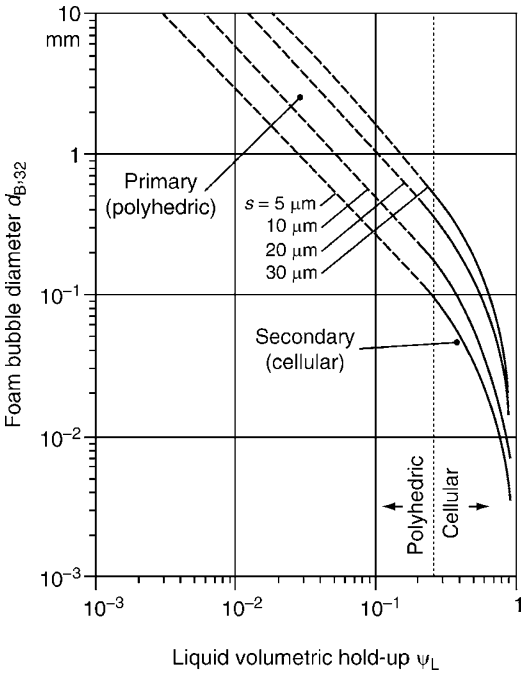
$$\frac{\psi_L}{1-\psi_L} \approx \frac{\rho_S/\rho_L}{1-\rho_S/\rho_L} = 6\frac{s}{d_{B,32}} \text{ or } \psi_L = \frac{6s}{d_{B,32}+6s}$$

is obtained valid for $\rho_G << \rho_L$.

In Fig. 3, the mean Sauter diameter $d_{B,32}$ of foam bubbles is plotted against the volume fraction Ψ_L with the mean thickness s of the liquid between two bubbles as parameter [3]. Many experimental results have shown that the mean thickness s of aqueous primary foams is in the range between 10 and 20 µm and usually below 30 µm. In the case of primary foams



L4.2. Fig. 2. Surface tension of aqueous solutions.



L4.2. Fig. 3. Mean bubble size $d_{B,32}$ against the liquid hold-up Ψ_L with the layer thickness s as parameter.

with large bubbles but a small liquid hold-up ($\Psi_L < 0.1$) and $6s << d_{B,32}$ one obtains $\psi_L d_{B,32} \approx 6s$. This means that the liquid hold-up increases approximately with a decreasing mean bubble diameter. Therefore, the objective of mechanical foam breaking is to reduce the bubble diameter to a higher degree or to release most of the gas into the bulk gas volume

The mean thickness s decreases with increasing foam age in a gravitational or centrifugal field because of the drainage of lamella liquid. In the beginning of drainage the bubble diameter remains constant; however, the foam density and the volumetric liquid hold-up are decreasing.

An apparatus is considered (e.g., a bubble column) with the cross section area f. Primary foam is continuously produced by a gas flow rate density $\dot{v}_G$ in $m^3/(m^2 s)$. The density of the foam decreases with the residence time τ of the foam in the apparatus:

$$\tau = \frac{V_S}{\dot{V}_S} = \frac{V_S(1-\psi_L)}{\dot{v}_G f}$$

In this equation V_S is the foam volume and $\dot{V}_S$ is the volumetric foam rate (see Fig. 4). With respect to the drainage effect the values of the foam density and of the hold-up increase from the top to the bottom of the foam in the column. A foam with a high liquid hold-up can be obtained when small bubbles are produced in the liquid. This can be done by means of a gas distributor with hole diameters below 0.5 mm and volumetric gas flow rates smaller than $\dot{v}_G = 0.05\ m^3/(m^2 s)$.

4 Structure of Primary Foams

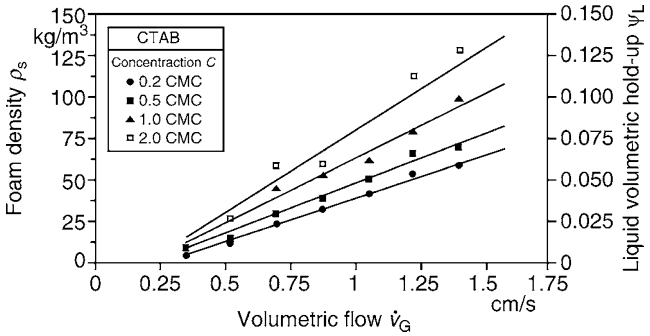
The structure of a gas in liquid dispersion in a bubble-foam column is dependent on the ratio of the volumetric gas flow rate based on the rising velocity w_B of a single bubble in an extended quiescent liquid with a low viscosity [4]:

$$w_B \approx 1.55 \sqrt[4]{\frac{\sigma(\rho_L - \rho_G)g}{\rho_L^2}}$$

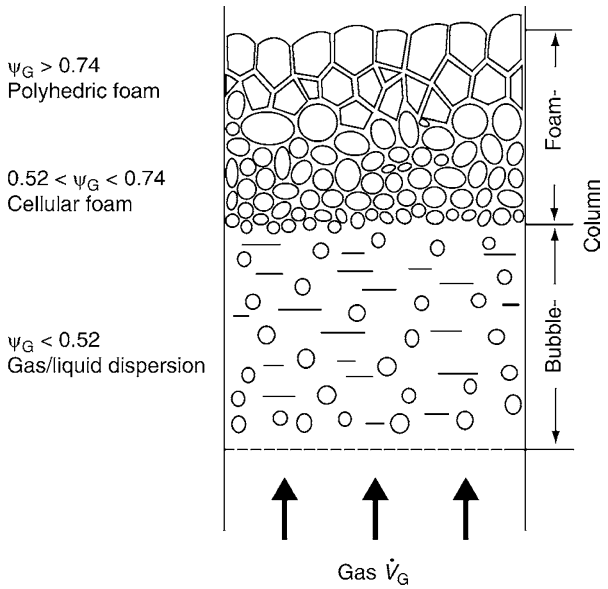
Here σ is the surface tension of the liquid and ρ_L its density. The structure can be predicted when a bubble/foam column is equipped with a perforated bottom plate with small holes (<0.5 mm) and the condition

$$\frac{\dot{v}_G}{w_B} < 0.2$$

is fullfilled. Above the distributor a gas/liquid dispersion is produced with the gas hold-up $\psi_G < 0.52$. Above this layer the hold-up of the gas is between 0.52 and 0.74 (cellular foam of bubbles with a maximum size $d_B^2(\rho_L - \rho_G)g/\sigma < 9$). At the top of the column polyhedric foam can be found with $\psi_G > 0.74$



L4.2. Fig. 4. Density ρ_S of primary foams against the volumetric flow density $\dot{v}_G$.



L4.2. Fig. 5. Structure of a gas in liquid dispersion (*below*) and of primary foam (*above*).

(see Fig. 5). The volumetric hold-up of the gas at the bottom of the column is approximately

$$\psi_G = \frac{\dot{v}_G/w_B}{1 + K\dot{v}_G/w_B}$$

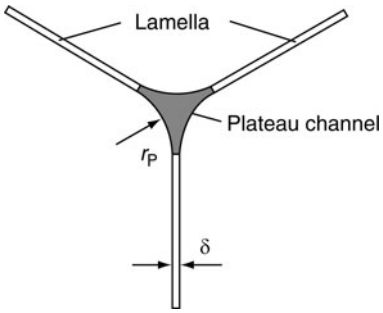
with K ≈ 1.3 for low viscous liquids and K ≈ 2 for viscous liquids. The cellular foam in the bottom layer is transformed to polyhedric foam at the top due to drainage. In polyhedric foams the gas within the foam bubbles is surrounded by thin lamellae with the thickness δ (approximately 50 µm) and the Plateau channels with thicknesses $> \delta$. The basis of always three lamellae with opening angles of 120° is the Plateau channel with the radius r_P (see Fig. 6). The cross section area A_P of a Plateau channel for $r_P >> \delta$ is

$$A_P = 0.161 r_p^2,$$

and the radius r_P is approximately

$$r_P \approx \sqrt{0.84\psi_L} \cdot d_B$$

Since the liquid hold-up gets smaller with increasing height as a result of drainage this is also true for the radius r_P and the



L4.2. Fig. 6. Cross section of a vertical Plateau channel.

area A_P. At the height h_K which is equal to the rising height in a capillary the radius r_P is

$$r_P = \frac{\sigma}{\rho_L g h_K}$$

and the radius in an arbitrary height h of a polyhedric foam layer with the total height h_{tot} and the mean liquid hold-up $\bar{\psi}_L$ is given by

$$r_P = \frac{\sigma}{\rho_L g\left(h - h_{tot}\bar{\psi}_L\right)}$$

As a rule the radius r_P is between 0.1 and 1 mm for aqueous foams.

Based on equations presented in the next section many authors have developed models for the prediction of drainage phenomena such as the reduction of the lamella thickness [7, 8], the liquid hold-up ψ_L [9] with increasing height, or the liquid overflow in the case of separations in foam columns. According to Hartland [7] the thickness of a lamella as a function of the height is given by

$$\delta = C_\delta \frac{(\eta_L \dot{v}_G)^{5/7} d_B^{9/7}}{(\rho_L g)^{1/7} (\sigma h)^{4/7}},$$

The number C_δ takes into account the flow condition at the surface of a lamella. $C_\delta = 0.71$ is valid for rigid surfaces which have an effect like solid walls; however, C_δ is smaller in the case of mobile surfaces. The lamella thickness δ is between 30 µm for "young" foams and 0.1 µm for foams after complete drainage. According to the last equation the thickness $\delta \to 0$ is expected for $h \to \infty$; however, in lamellae with thicknesses below 100 nm van der Waals forces as well as electrical and steric repulsion forces are important [13].

Besides the pressure difference Δp_{PL} between the Plateau channel and the lamella the pressure p_d according to

$$p_d = \frac{A_H}{6\pi\delta^3}$$

as a consequence of the van der Waals forces is effective for the thinning of a lamella. The Hamaker constant A_H is often in the range between 10^{-21} and 10^{-20} J for many liquids [14].

Contrary to these attracting forces electrical and steric repulsive forces are effective. If the lamella thickness is more than 1 nm and the electrical double layers are not interfering each

other the electrical repulsive force based on the unit area of a lamella is [15]

$$p_{el} = 64nkTe^{\kappa\delta}\left[\frac{e^{\frac{ze_0\psi_0}{2kT}} - 1}{e\left(\frac{ze_0\psi_0}{2kT} + 1\right)}\right]^2$$

with n as the number of ions per unit volume of the double layer, ψ_0 as the surface potential and $1/\kappa$ as the Debey-Hückel parameter according to

$$1/\kappa = (\varepsilon_r\varepsilon_0 kT/(\sum (ze_0)^2 n))^{1/2}.$$

In the case of large molecules the steric separation pressure is $p_{st} = p_{st}{}^0 \exp(-\delta/l_{st})$ with the reference pressure $p_{st}{}^0$ valid for $\delta = l_{st}$ as an empirical length which depends on the size and the structure of the detergent molecule under discussion.

The drainage of the lamella liquid into the Plateau channels is finished when the pressure in a lamella is the same as in the channel:

$$\Delta p_{PL} + p_d = p_{el} + p_{st}$$

Since the electrical and steric repulsion forces grow faster with the lamella thinning than the attracting forces (always based on the unit surface area) an equilibrium thickness δ^* will be obtained. This thickness is often in the range between 10 and 100 nm and is dependent on the kind and concentration of the detergent molecules. In the absence of any disturbance (evaporation, percussion, etc.) the lamella may stay stable for a very long time.

5 Drainage of Polyhedric Foams

A mechanical foam breaker can be applied in order to reduce the volume of primary foams to a higher degree; however, a complete separation into the two phases, gas and liquid, is nearly impossible. The decay of foams is started in a gravitational or centrifugal field by the drainage of the liquid present in the lamellae and in the Plateau channels. The drainage time $t_{Dr,L}$ of a lamella with the thickness δ_α at the beginning to the final thickness δ depends on the ratio of the surface force to the friction force within the liquid in the Plateau channels:

$$t_{Dr,L} = \frac{1}{c_L}\frac{r_P d_B^2 \eta_L}{2\sigma}\left(\frac{1}{\delta^2} - \frac{1}{\delta_\alpha^2}\right),$$

The quantity c_L depends on the kind of the detergent and is in the range $0.1 < c_L < 4$ [3]. After a certain drainage time the thickness δ is $\delta < 1/3\ \delta_\alpha$ with the result that the last equation can be simplified:

$$t_{Dr,L} \approx \frac{r_P \eta_L}{c_L 2\sigma}\left(\frac{d_B}{\delta}\right)^2.$$

Very thin lamellae are obtained after $t_{Dr,L} \to \infty$; however, evaporation and/or percussions may result in a breakage of a lamella. Contrary to the time $t_{Dr,L}$ of lamellae the drainage of Plateau channels is dependent on the ratio of gravitational or centrifugal forces and friction forces within the liquid. The flow velocity w_P of the liquid in a Plateau channel is given by

$$w_P = c_P \frac{r_P^2 \rho_L g}{\eta_L}.$$

The constant c_P is in the order of magnitude of 10^{-3} [3, 5]. Based on the very simple assumption that a Plateau channel with the length L_P is emptied by a liquid flow with the characteristic mean velocity w_P the order of magnitude of the drainage time of a Plateau channel is

$$t_{Dr,P} \approx \frac{L_P}{w_P} \approx \frac{L_P \eta_L}{c_P r_P^2 \rho_L g}$$

or with the equation derived for the liquid hold-up ψ_L

$$t_{Dr,P} \approx \frac{1.25 L_P \eta_L}{c_P \psi_L d_B^2 \rho_L g} \approx \frac{1.25}{c_P}\frac{L_P \eta_L}{6 s d_B \rho_L g}$$

In any case the qualitative result is: The higher the foam layer and the more viscous the liquid the longer is the decay time. This separation time can be reduced by the use of a centrifuge. In this case the gravitational acceleration must be replaced by the centrifugal acceleration $r\omega^2$ with ω as the angular speed and r as the effective radius of the foam layer in the centrifuge. This has been confirmed by experimental results [5].

6 Bubble Growth by Diffusion

Since the pressure in small bubbles is higher in comparison to adjacent large bubbles a diffusion of gas through the common liquid lamella takes place. As a result the diameter of small bubbles decreases with the tendency $d_B \to \infty$ for $t \to \infty$ and the size of large bubbles increases with time. This increase of large bubbles from the starting size $d_{B,\alpha}$ to the diameter d_B after the time t is given by [3]

$$d_B = \sqrt{d_{B,\alpha}^2 + c_B \frac{\sigma D_L}{\delta He_i} t}.$$

The quantity c_B depends of geometrical parameter (curvature, contacting area) of the bubbles and according to Gutwald [3] it is $c_B = 12$. D_L is the diffusion coefficient of the gas in the lamella liquid and the Henry coefficient He_i is defined by

$$He_i = \frac{p_i}{x_i}.$$

with the partial pressure p_i of the gas component i and x_i as its mole fraction. The diffusion time

$$t_{Dif} = \left(d_{B,\omega}^2 - d_{B,\alpha}^2\right)\frac{\delta He_i}{c_B \sigma D_L}$$

necessary to enlarge a bubble from the size $d_{B,\alpha}$ to the size $d_{B,\omega}$ is the time necessary in order to change a secondary foam into a coarse foam with the tendency of breakdown. This time is long for thick lamellae and high Henry coefficients and is reduced by strong diffusivities. Gas diffusion is decisive for the collapse of foams when the lamella thickness is below 1 µm. During diffusion a permanent breakdown of foam bubbles takes place, however, it is difficult to predict this breakage.

7 Bubble Size in Foams

It has been shown that the times necessary for the processes of drainage and diffusion are dependent on the bubble size and increase with the hold-up Ψ_L of the liquid. According to Fig. 3 the approximation $\Psi_L d_B \approx 6s$ is valid. In the following the

prediction of the mean bubble size is discussed. In the case of rising bubbles in a quiescent low-viscosity liquid in a gravitational field ($(\rho_L - \rho_G)\, g = \Delta\rho g$) the maximum stable bubble size is given by

$$\frac{d_{B,max}^2 \Delta\rho g}{\sigma} = C_B,$$

with $C_B \approx 9$ for the bubble Reynolds number [4]

$$\frac{w_B d_B \rho_C}{\eta_C} > 300.$$

The mean bubble size is $d_{B,50} \approx (0.5 \ldots 0.7)\, d_{B,max}$. In a turbulent flow field the bubble size decreases with increasing fluctuation velocities u',v', and w'. In the case of coalescing fluid particles (pure liquids, especially no detergents), the particle size depends of the local specific power input ε. With the macroscale of turbulence, Λ, this quantity is

$$\varepsilon = \frac{u'^3}{\Lambda}$$

valid for isotropic turbulence. The bubble size d_B is

$$d_B = C_\varepsilon \frac{\sigma^{0.6}}{\rho_c^{0.6} \varepsilon^{0.4}}$$

As a rule the mean specific power input ε is applied because the parameter Λ and C_δ are difficult to determine. In a system with a rotor with the diameter D (stirrer in a vessel, rotating foam breaker) in a cylindrical volume with the diameter T and the height H the mean specific power input is

$$\bar{\varepsilon} = \frac{4\mathrm{Ne}}{\pi^4} \left(\frac{D^3}{T^2 H}\right) \frac{w_u^3}{D}.$$

Ne is the Newton number ($0.5 < \mathrm{Ne} < 5$) and w_u is the tip speed $w_u = \pi$ and with n as the rate of rotation. The last equation can be transformed into

$$\frac{d_B}{D} = C_D \left(\frac{\sigma}{w_u^2 D \rho_L}\right)^{0.6} = \frac{C_D}{\pi^{1.2}} \left(\frac{\sigma}{n^2 D^3 \rho_L}\right)^{0.6} \text{ or}$$

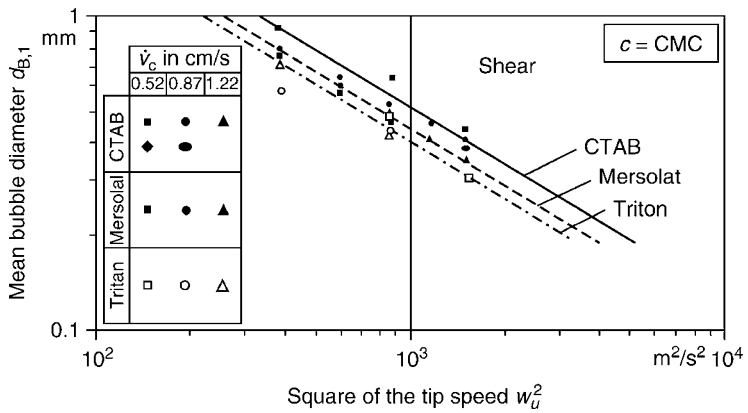
$$d_B = C_D' \left(\frac{\sigma}{\rho_L}\right)^{0.6} \left(\frac{D}{w_u^3}\right)^{0.4} = C_D' D^{0.4} \left(\frac{\sigma}{\rho_L}\right)^{0.6} \left(\frac{1}{w_u^2}\right)^{0.6}$$

The quantities C_D and C_D' depend on the ratio $\varepsilon/\bar{\varepsilon}$, which is dependent of the geometry but difficult to predict or to determine.

This means that the bubble size decreases with the exponent 0.6 of the specific energy w_u^2 in $m^2/s^2 = J/kg$. For a given system, for example, geometry (geometry of the rotor and its diameter) and a given gas in liquid dispersion such an interdependency has been often confirmed experimentally.

In Fig. 7, the mean bubble size $d_{B,1}$ is plotted against the square of the rotor tip speed for different foams after a first destruction process realized by shear [3]. The experimental results are valid for a certain rotor-stator system (D = 300 mm; T = 634 mm; stator plate with 48 mm holes drilled on a radius of 130 mm). The rotor speed in the figure refers to the radius 130 mm because here the shear process of the foam bubbles takes place. This shearing results in a size reduction of the bubbles from 1 to 0.3 mm valid for $w_u^2 = 1{,}500\ m^2/s^2$ and an increase of the liquid hold-up ψ_L (see Fig. 3). The partially broken foam is further destructed by an impingement effect, for example, the foam is crashed into the side wall of the chamber. The mean bubble size is reduced from $d_{B,1}$ to $d_{B,2}$ (see Fig. 8). Now the square w_u^2 is calculated with the rotor diameter D according to $w_u = \pi n D$. In all cases the reduction of the bubble size depends of the square w_u^2. However, Triton foams can be continuously destructed at 100 m^2/s^2 whereas the foams of the other detergents need approximately 2,000 m^2/s^2 for the same size reduction. (In the literature many diagrams can be found in which the size of fluid [22] or solid [23] particles is plotted against volumetric or specific energy in the range from 10^2 up to 10^6 J/kg.)

In the case of a continuous destruction of a foam mass flow $\dot{V}_S \rho_L \psi_L$ the specific energy must be continuously added as specific power which can be provided by a rotor. The mean bubble size based on the rotor diameter D decreases with the exponent –0.6 of the Weber number. This has been experimentally confirmed for CTAB and Mersolat foams [3]. In the Fig. 9, the ratio d_B/D is plotted against the Weber number for coalescing fluid particles [16]. In addition, the size of non-coalescing bubbles in foams after the passage of a foam breaker is shown with $d_{B,1}$ obtained after only shearing and $d_{B,2}$ after an additional impingement effect [3, 5]. The different behavior of foams with the long-chained detergents CTAB and Mersolate on the one hand and Triton foams on the other hand indicates



L4.2. Fig. 7. Mean bubble size $d_{B,1}$ after a shear process against the square of the tip speed.

that the property surface tension σ is not sufficient to describe the foam-breaking process.

8 Minimum Speed of Mechanical Defoamer

Many experiments carried out in industrial and scientific research have shown that the volume of primary foams can be remarkably reduced by rotors of different geometries. Sometimes the foam is passing channels in radial or radial/axial direction or contacting a rotor with blades. In all cases the foam is stressed by shear, stretch, and/or impingement forces (see Fig. 10). Blade stirrers applied in agitated vessels are easy to manufacture and can be very effective. The decisive mechanism of foam breaking is the repeated disruption or opening of gas bubbles with the result that a great deal of the gas is removed from the bubbles and transferred into the bulk gas without the formation of a new bubble. The shear, stretch, and/or impingement rate should be very high in order to avoid the healing effect of lamella holes by Marangoni flow. The spreading velocity w_L of a hole is

$$w_L = \sqrt{\frac{2\sigma}{\delta\rho_L}}$$

and increases inversely with the lamella thickness. The greater the difference $\Delta\sigma$ of a lamella spot with and without an adsorption layer the greater must be the tip speed in order to introduce the rupture of the lamella. According to these considerations the minimum tip speed $w_{u,min}$ can be derived [3]:

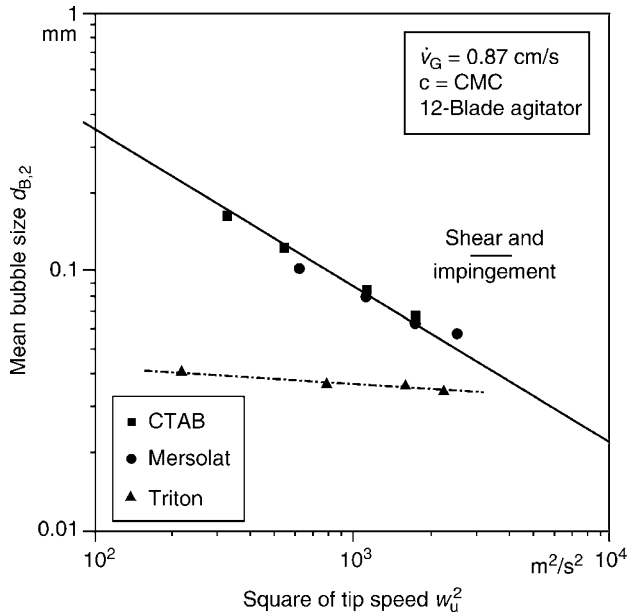
$$w_{u,min} = \sqrt{\frac{12K'\Delta\sigma(d_B - d_{B,X})}{d_B^2\psi_L\rho_L}}$$

with $K' = 1$ for non-ionic detergents and $K' = 2$ for ionic tensides. The diameter $d_{B,X}$ is the minimum size of a foam bubble deformed by shear, stretch, and/or impingement forces. The deformation degree $(d_B - d_{B,X})/d_B \approx 0.5$ has been experimentally determined.

With $K' = 2$ and $(d_B - d_{B,X})/d_B = 0.5$ the minimum tip speed is given by

$$w_{u,min} \approx 3.5\sqrt{\frac{\Delta\sigma}{d_B\psi_L\rho_L}}$$

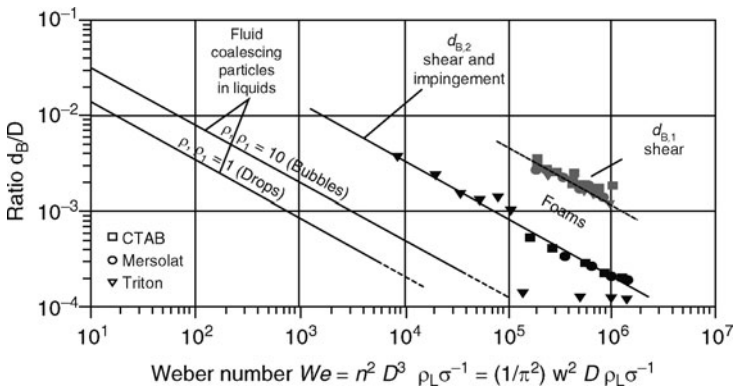
By this way the velocity $w_{u,min} = 15.7$ m/s can be calculated for the data $\Delta\sigma = 40$ mJ/m^2, $\rho_L = 1{,}000$ kg/m^3, $\psi_L = 0.001$, and $d_B = 2$ mm for a "dry" aqueous primary foam.



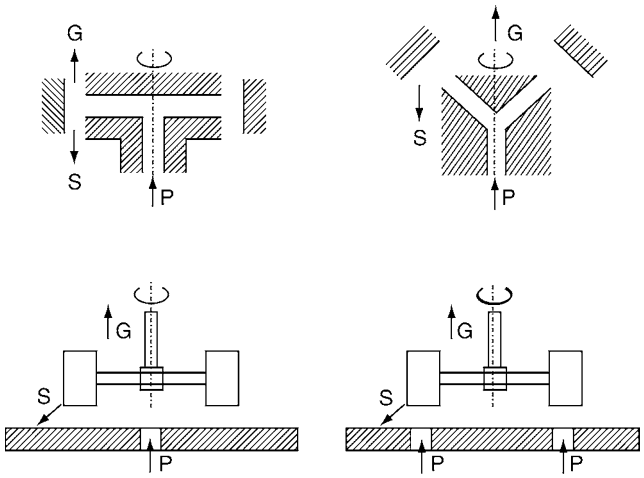
L4.2. Fig. 8. Mean bubble size $d_{B,2}$ after shear and impingement against the square of the tip speed.

9 Volume Reduction of Foams

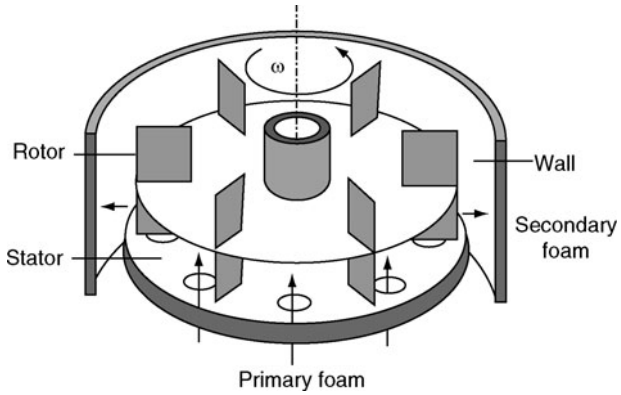
As a rule the objective of foam breaking is the effective volume reduction of primary foams to such a degree that the secondary foam is flowing in a gravitational field. This requires high foam densities or liquid hold-up and, consequently, small bubbles in



L4.2. Fig. 9. Ratio d_B/D against the Weber number for foams and coalescing fluid particles in liquids.



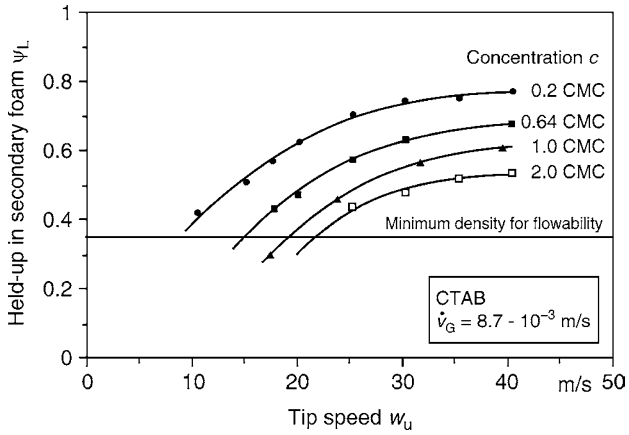
L4.2. Fig. 10. Rotating foam breakers; *P* Primary foam, *S* Secondary.



L4.2. Fig. 11. Mechanical foam breaker [3].

the secondary foam (see Fig. 3). This is the case when the size of the bubbles in low-viscous liquids is below 100 µm. In Fig. 11, a mechanical foam breaker with a triple effect is shown. At first the bubbles are stretched above the holes and then further deformed by the blades. This impingement effect is repeated on the chamber wall because the foam is accelerated in radial direction. By these effects the bubble size d_B of the entering primary foam is at first reduced to $d_{B,1}$ and then further to $d_{B,2}$. In the case of a tip speed of 40 m/s (34.7 m/s at the centers of the holes) and the properties $\rho_L = 1{,}000$ kg/m^3 and $\Delta\sigma = 40$ mJ/m^2 a liquid hold-up of $\Psi_L = 0.15$ and a bubble size of $d_{B,1} \approx 100$ µm has been obtained as a result of shear effects above the holes and stretching by the gas flow. Caused by the additional effect of impingement on the chamber wall a secondary foam with $\psi_L \approx 0.5$ and $d_{B,2} \approx 30$ µm has been produced. It is important to note that the thickness of the liquid film on the wall should be below 1 mm, otherwise drops can be introduced with the result that adhering gas penetrates into the secondary foam and its liquid hold-up is decreased.

In Fig. 12, the liquid hold-up ψ_L of secondary foams is plotted against the tip speed for CTAB foams of different detergent concentrations [3]. The lower the concentration of the lamella liquid (here as the manifold of the CMC) the higher is the density of the secondary foam. Above the tip speed of 30 up to 40 m/s it is difficult to reduce the bubble size and the liquid hold-up remains nearly constant. However, in the case of other detergents the hold-up can be quite different for the same geometry and operating parameter (see Fig. 13). The density of secondary Triton foams is much higher for the same tip speed and concentration because the stability of this foam is much lower than for the ionic long-chained detergents CTAB and Mersolate.



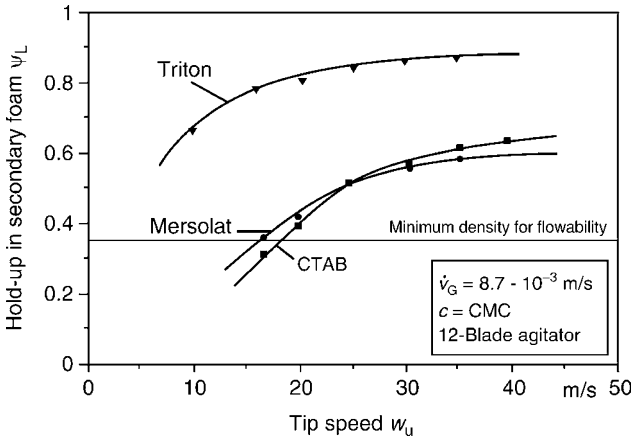
L4.2. Fig. 12. Liquid hold-up of secondary CTAB foams against the tip speed.

10 Collapse of Foams

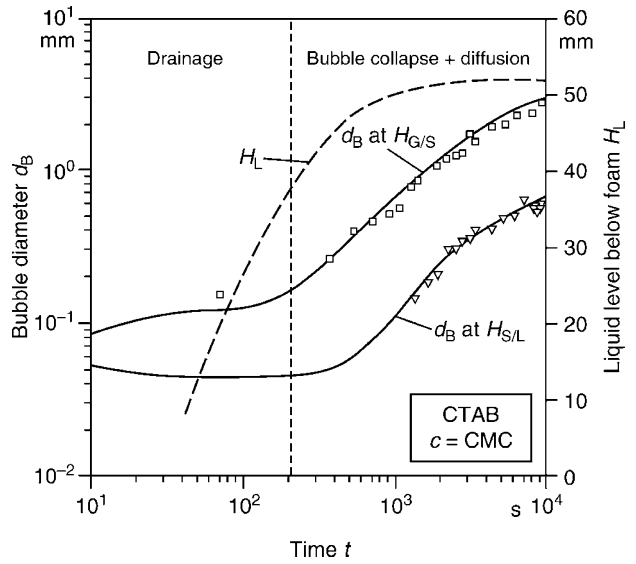
The drainage of lamellae followed by gas diffusion from the small bubbles to the bigger ones and finally the coalescence of bubbles leads to the collapse of a stagnant foam layer. In Fig. 14 the bubble diameter is plotted against the time for CTAB foams with c = CMC. After approximately 200 s the drainage with $d_B \approx$ constant is finished. Then the diffusion accompanied by bubble collapse lead to an enlargement of large bubbles at the expense of smaller ones which finally disappear. After 10^4 s the final size of $d_B \approx 3$ mm is obtained regardless of how the foam has been produced. The polydisperse gas in liquid system breaks down and is finally separated in the gas and in liquid phase.

11 Irrigation of Foams

Principally speaking foams can be destroyed by falling or sprayed solvent drops. (The addition of a component with a low surface tension can be very effective) [18, 19]. A breaking of foam can be obtained if the degree of stretching and deformation of the bubbles within the foam is sufficient. A doubling of the surface of an originally spherical or polyhedric bubble in combination with a velocity of 5 m/s can be effective for foam breaking. The final falling velocity of 5 mm drops with



L4.2. Fig. 13. Liquid hold-up of secondary foams against the tip speed.



L4.2. Fig. 14. Bubble size d_B against the time.

ρ_L = 1,000 kg/m^3 is approximately 5 m/s. However, it can happen that gas is entrained by the drops with the result that the foam is stabilized. Therefore, irrigation can be problematic. Sometimes the foam breaking is achieved by impingement of horizontally moving jets.

L4.3 Droplet Separation

Hans Detlef Dahl
Marl, Germany

1 Introduction

1.1 Mechanisms of Droplet Formation

Mists or spray may be generated by a number of processes, such as condensation, chemical reaction, entrainment from column internals (trays, packings), spray nozzles, or the flashing of superheated liquids. The size distribution of the spray depends on the mechanism of droplet formation. The physical properties of gas and liquid influence the droplet size distribution as well. Liquids with lower surface tension or viscosity tend to produce rather smaller droplets. Typical ranges are shown in Table 1.

1.2 Key Factors for Separator Selection and Design

Before starting to select or to design a droplet separator it is essential to be aware of the following key factors:

- The amount of liquid and the size of the droplets, which shall be removed
- The type of flow in the separator' inlet (see Subchap. L2.1)
- The allowable amount of liquid in the gas stream leaving the separator
- The allowable pressure drop
- The presence of solids or salts, which may lead to plugging
- Tendency of the liquid to foam
- Material of construction

There is a great variety of different droplet separators. The most commonly used types are gravitational separators, often in combination with wire mesh elements, wave plate separators, and cyclones.

A comprehensive description of all kinds of droplet separators can be found in the work of Bürkholz [1]. For additional practical advice on the selection of mist eliminators, the works of Fabian et al. and Ziebold can be referred to [2, 3].

2 Gravitational Separators, Flash Drums

The maximum allowable axial vapor velocity in vertical flash drums equipped with wire mesh demisters can be estimated by using the Souders–Brown equation [4, 5]:

$$w = k\left(\frac{\rho_L - \rho_G}{\rho_G}\right)^{0.5}, \tag{1}$$

where the coefficient k is in the range of 0.05–0.11 m/s. For higher pressures it is proposed to reduce k according to the percentages given in Table 2.

Equation (1) is purely empirical. The resulting limit droplet diameter is often in the range of 200 µm (and 50 µm for separators without wire mesh).

To avoid surprises, it should be checked which limit droplet size will result. This can be done by using Newton's law for the limit droplet size:

$$d^* = \frac{3\rho_G c_W w^2}{4(\rho_L - \rho_G)g}, \tag{2}$$

whereas $c_W = 0.5$ for spherical droplets, if the Reynolds number

$$\mathrm{Re} = \frac{\rho_G d^* w}{\eta_G} \tag{3}$$

of this limit droplet is bigger than 1,000. If this should not be the case, Eqs. (22) and (24) can be applied if the centrifugal acceleration z is substituted by the gravitational acceleration g.

The pressure loss of the wire mesh pad is normally in the range below 250 Pa, the wires having diameters between 100 µm and 300 µm. This is sufficient to separate droplets 3–10 µm with an efficiency nearly 100%.

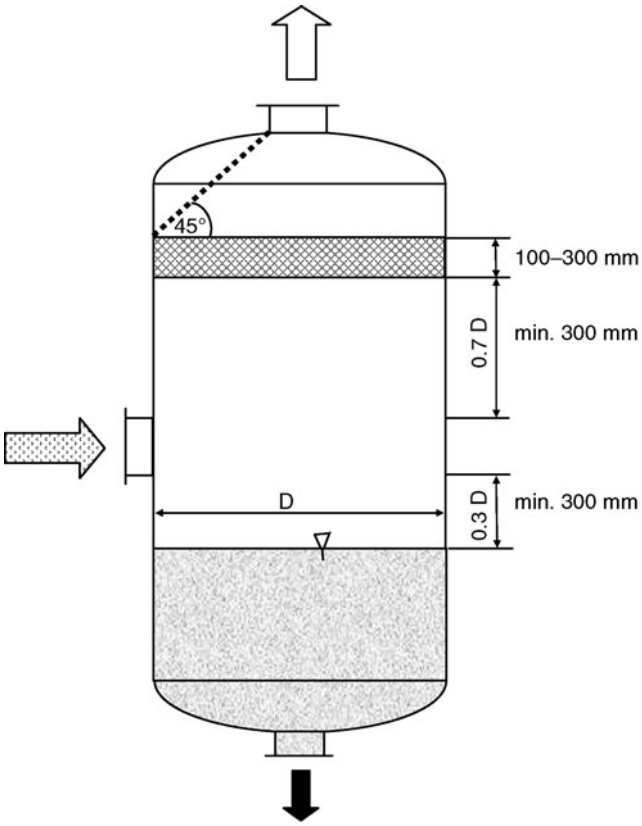
L4.3. Table 1. Typical ranges for droplet size distributions

Mechanism	Size (μm)
Condensation and chemical reaction	~0.1–25
Two-phase pneumatic nozzles	~1–200
Entrainment, flashing liquids, and single-phase pneumatic nozzles	~5–1,000

L4.3. Table 2. Adjustment of *k* [5]. Combine the single percentages in case more than one criterion applies, e.g., use 80% x 50% = 40% for a flash drum without wire mesh operating at 40 bar

		Adjustment of *k*, % of design value
Pressure	Atmospheric	100%
	10 bar	90%
	20 bar	85%
	40 bar	80%
	80 bar	75%
Glycol and amine solutions		60–80%
Separators without wire mesh demisters		50%
Compressor suction scrubbers		70–80%

If mists with droplet diameters lower than 3 μm are to be separated, fiber beds can be used. Their pressure loss ranges between 1,000 and 3,000 Pa (Fig. 1 shows a typical vertical separator).



L4.3. Fig. 1. Vertical separator with wire mesh pad of typical dimensions.

3 Cyclones

The calculation of cyclones for droplet separation is similar to the calculation of cyclones for the separation of solid particles, which is described in detail in Subchap. L3.4. Therefore, this chapter deals only with those topics in which liquid and solid separators differ.

3.1 General Description

Figure 2 shows a cyclone for droplet separation. The liquid loaded gas stream is sent to the cyclone via a tangential pipe inlet. A part of the liquid flows as a film along the pipe wall into the cyclone, whereas the other part is distributed as droplets in the core.

The centrifugal forces caused by the rotational flow within the cyclone act on the droplets and force them toward the wall. There the liquid flows in the form a film or single threads toward the bottom of the separator. A cone prevents the already separated liquid from getting sucked back in the core of the rotational flow, which may happen due to the underpressure prevailing there.

Near the cyclone's upper shell a boundary layer is formed. As in this boundary layer the circumferential velocity is low, the gas and liquid in this layer are not subject to the centrifugal forces of rotational flow and can flow directly to the dip pipe in the center, where the static pressure is lower than on the outer diameter. In order to prevent the thin liquid from creeping in thin threads toward and into the dip pipe, it makes sense to install a collar, which redistributes the liquid in the form of large droplets to the main flow within the cyclone [6].

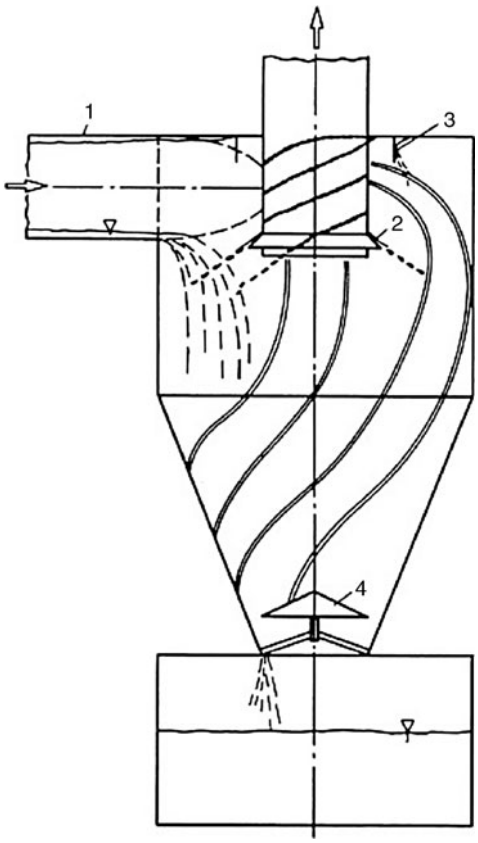
A very first check of the separation efficiency can be made using a simple empirical equation developed by Bürkholz [1] using experimental data obtained for cyclones with outer diameters of up to 100 mm:

$$d^*(\mu\mathrm{m}) = 1.7\left(\frac{r_\mathrm{i}(\mathrm{mm})}{\Delta p(\mathrm{mbar})}\right)^{1/3}. \qquad (4)$$

The results of this equation fit only for cyclones with $r_\mathrm{a}/h_\mathrm{i} < 0.25$ with the exact calculation. The influence of liquid load and its limit is not taken into account.

Applications of cyclones as liquid separators range from standardized units such as steam dryers to customized solutions such as separators in emergency relief systems [7].

Instead of the tangential inlet shown in Fig. 2 axial inlets can be applied as well. In this case the rotational flow is effected by means of guide vanes, which are arranged concentrically around the dip pipe.



L4.3. Fig. 2. Cyclone for droplet separation, schematic: 1 – tangential pipe inlet, 2 – collar for liquid redistribution, 3 – additional collar for high liquid loads, 4 – cone.

With highly efficient internals in the dip pipe, which regain the angular momentum of the gas flow, it is possible to reduce the cyclone's pressure loss by a factor of 4. This closes the gap to wave plate separators, which when compared to cyclones have a lower pressure loss.

Cyclones are insensitive even against highest liquid loads. As their wall is increasingly wetted and rinsed from the inlet toward the liquid outlet, they are also well suited if solids with up to 30 g/l are present in the liquid. According to Muschelknautz and Herold [8], the inlet can be designed with sloped boxes in a way that all parts of the wall are completely wetted. The upper shell and the dip pipe, which tend to stay dry, can be cleaned with a few spray nozzles and clean or lightly contaminated liquid. The secondary flow along the upper shell drives the liquid with increasing film thickness toward the center and the dip pipe.

3.2 Calculation of the Flow

The flow, which enters the cyclone via the tangential inlet, is pressed to the wall by the radial pressure gradient, contracts, and accelerates. This is described by means of a contraction coefficient

$$\alpha = (u_e r_e)/(u_a r_a) \tag{5}$$

L4.3. Table 3. Contraction coefficient α for inlets with circular cross section and a ratio $d_{inlet}/r_a = 0.64$ as a function of the liquid load in the entrance μ_e

μ_e	0	0.1	1
α	0.69	0.7	0.8

which depends on the quotient of the inlet diameter d_{inlet} to the outer radius r_a and on the liquid load

$$\mu_e = \frac{\dot{M}_L}{\dot{M}_G} \tag{6}$$

of the flow entering the cyclone. The entrance radius r_e is

$$r_e = r_a - d_{inlet}/2 \tag{7}$$

Table 3 shows experimentally obtained values for the contraction coefficient.

By means of a balance of angular momentum the circumferential velocity along the radius of the dip pipe is calculated as [9, 10]:

$$u_i = \frac{u_a \frac{r_a}{r_i}}{1 + \frac{\lambda_L}{2}\frac{A_R u_a}{V}\sqrt{\frac{r_a}{r_i}}}. \tag{8}$$

By means of experimental tests with a cyclone model of 900 mm diameter and liquid loads up to 1 kg/kg, the dependence of the wall friction coefficient λ_L on the liquid load was determined. Due to liquid trickling along the wall, the wall friction coefficient increases compared to the friction coefficient for pure gas λ_0, as given in Subchap. L3.4:

$$\lambda_L = \lambda_0\left(1 + 0.4\mu_e^{0.1}\right). \tag{9}$$

Normally, cyclones are designed in a way that the pressure loss is in the range between 500 and 2,500 Pa. The calculation is carried out according to Subchap. L3.4. With highly efficient internals in the dip pipe, which recover the angular momentum of the flow, the pressure loss can be reduced to by a factor of 4.

3.3 Separation Efficiency

The turbulence of the gas flow in the cyclone does not suffice to carry unlimited amounts of liquid. Directly after entering the cyclone the amount of liquid exceeding the load limit separates from the gas and flows down along the cyclone's wall. This is the reason why the total separation efficiency increases for higher liquid loads (Barth [11]).

As it was shown by own experiments, the load limit of liquid separators lies only in the range of 10–35% of comparable dust cyclones, the reason being that droplets cannot re-enter the gas flow once they are separated as solid particles can do. As a liquid film, which was already formed in the pipe feeding the separator, does not influence the load limit mechanism, and the calculation is based not on the total liquid load in the cyclone' feed pipe but instead on the liquid load in the core of the flow $\mu_{e,k}$, which is the quotient of the droplet mass flow to the mass

flow of the gas. According to the experiments with mean droplet diameters in the range of 60–190 µm in the gas feed and liquid loads in the flow' core in the range of 0.01–0.5, the load limit μ_G can be calculated by means of the following empirical equation:

$$\mu_G = 0.0087\left(\frac{d_e^*}{d_{50}}\right)(10\mu_{e,k})^k \qquad (10)$$

with

$$k = 0.07 - 0.16\ln\mu_{e,k}. \qquad (11)$$

The limit droplet diameter d_e^* is calculated according to Subchap. L3.4. The same applies for the fractional separation efficiency curve and for the size distribution of the droplets entering the cyclones core flow. For liquid loads above the load limit the total separation efficiency is calculated as

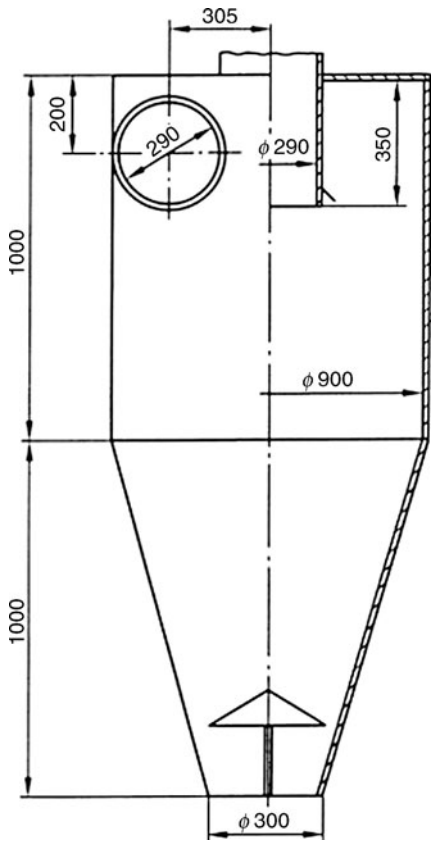
$$\eta_{total} = \left(1 - \frac{\mu_G}{\mu_e}\right) + \frac{\mu_G}{\mu_e}\sum_{l=1}^{m}\eta_F(\bar{d}_l)\Delta R_{Ai,I}. \qquad (12)$$

When designing droplet separators it should be kept in mind that the droplets may shrink by evaporation.

Example

Total separation efficiency and pressure loss of the cyclone shown in Fig. 3 have to be calculated.

Operational and physical data: $V_G = 0.7\ m^3/s$; $\rho_G = 1.2\ kg/m^3$; $\eta_G = 18 \times 10^{-6}$ Pa s; $\rho_L = 1{,}000\ kg/m^3$; $d_{50} = 60$ µm; $A_w = 3.32\ m^2$; $A_R = 5.69\ m^2$.



L4.3. Fig. 3. Example calculation: main dimensions of the droplet separation cyclone.

The feed' liquid load μ_e is 0.02, and the liquid load in the core of the flow is 0.01.

Angular velocities:

$$v_e = \frac{\dot{V}}{\pi/4 d_{inlet}^2} = 10.6\ m/s,$$

$\mu_e = 0.02$ and $d_{inlet}/r_a = 0.64 \rightarrow \alpha = 0.69$, Table 3

$u_a = 10.4$ m/s, Eq. (5)

$\lambda_L = \lambda_0(1 + 0.4\mu_e^{0.1}) = 0.0045(1 + 0.4 \cdot 0.02^{0.1})$ Eq. (9)
$= 0.0057$,

$u_i = 22.0$ m/s Eq. (8)

According to Subchap. L3.4:

$u_{e1} = 13.1$ m/s; $u_2 = 13.1$ m/s; $z_e = 530\ m/s^2$; $w_{s,50} = 0.095$ m/s, $d_c^* = 7.6$ µm; $d^* = 6.8$ µm,

$k = 0.81$, Eq. (11)

$\mu_G = 1.71 \times 10^{-4}$. Eq. (10)

Total separation efficiency

$$\eta_{total} = \left(1 - \frac{1.71 \times 10^{-4}}{0.02}\right) + \left(\frac{1.71 \times 10^{-4}}{0.02}0.57\right) = 0.9963 \quad \text{Eq. (12)}$$

The pressure loss according to Subchap. L3.4 is

$$\Delta p = \Delta p_i + \Delta p_e = 961\ Pa + 107\ Pa = 1{,}068\ Pa.$$

4 Wave Plate Separators

4.1 Working Principle and Comparison to Cyclones

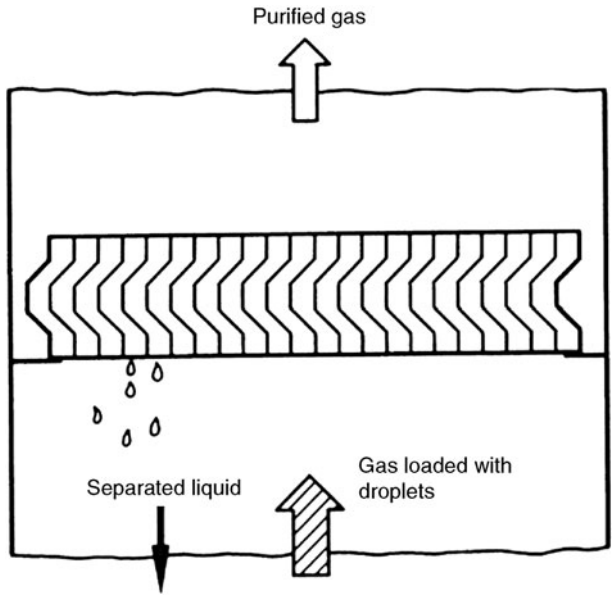
Wave plate separators are packings of profiled plates which are arranged parallel to each other. The gas flow is perpendicular to the waves. Due to centrifugal forces droplets drift in the curved gas flow toward the plates where they separate from the gas (Fig. 4).

In wave plate separators with horizontal flow the separated liquid flows crosswise in vertical flutings downward. They are considerably smaller than cyclones and have a lower pressure loss (Fig. 5).

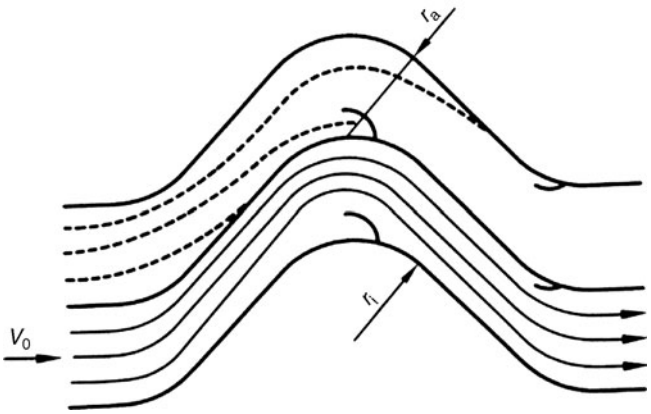
The plates at the inner side of the curve are more or less dry. In multistage packings the curve's outer side gets dry also toward the outlet. This causes, even with only lightly contaminated liquids, e.g., in the washing towers of desulphurization plants, crusting or fouling in the transition zone from the wet to the dry wall. Cleaning can be done periodically with the aid of high pressure spray nozzles.

4.2 Hydrodynamics

The already separated liquid can be forced back from the flutings into the gas flow by a combined overpressure/underpressure effect if the gas velocity is too high. For horizontal flow and vertical flutings the limit is at



L4.3. Fig. 4. Schematic drawing of a vertically arranged wave plate separator.



L4.3. Fig. 5. Path of droplets (- - -) and streamlines (—) in a wave plate separator.

$$\frac{\rho_G}{2} v_0^2 \approx 100 \text{ to } 150 \text{ Pa}. \tag{13}$$

With specially designed flutings in the lee, this limit moves up to 300 Pa (horizontal flow). Wave plates made out of thin metal sheets tend to vibrate crosswise to the flow.

For vertical flow in upward direction, as in washing towers of desulphurization units, the upper limit of the gas velocity is around 5–6 m/s (1 bar, $s = 20$ mm and $\rho_G = 1$ kg/m^3).

For other gas densities, the following formula may be used:

$$\left(\frac{\rho_G v_0^2}{\rho_L s g}\right)_{max} = 0.1 \text{ to } 0.15. \tag{14}$$

At larger velocities the entrainment of already separated liquid increases.

The gas flow constricts to 60% and 40% of the total cross section as its direction changes with angles 60° and 90°, respectively. This causes pressure loss.

As the width of the channels is much smaller than their length ($l/s >> 5$), it is not possible to recover pressure by decelerating the flow as in a diffusor. The pressure loss for every two direction changes or one packing element is roughly

$$\Delta\rho = (3 \text{ to } 6)\frac{\rho_G}{2} v_0^2 \tag{15}$$

for direction changes with $\alpha = 60°$–$90°$. For a number of packing elements n the pressure loss will increase roughly with a factor of $n^{1/4}$.

4.3 Separation Efficiency

Comparable to the cyclone, the separation limit is calculated approximately with the separation area:

$$A = 2\pi \frac{a}{360°} r_a l. \tag{16}$$

It is sufficient to take average contours according to Fig. 4. l is the height or length of the wave plate. The volume flow through one channel with the width s and the incoming gas velocity v_0 is

$$\dot{V} = l s v_0. \tag{17}$$

For a separation efficiency of 50%, the following equation applies for the settling velocity w_s^* of the limit droplet:

$$w_s^* = \frac{\dot{V}/2}{A}. \tag{18}$$

This droplet is subject to a mean centrifugal acceleration

$$\bar{z} = \frac{\bar{u}^2}{\bar{r}} \tag{19}$$

on its way with a radius of curvature

$$\bar{r} = \sqrt{r_a r_i}. \tag{20}$$

For direction changes of $\alpha = 45°$, $60°$, and $90°$ the flow constricts in average to 65%, 55%, and 45% of the channel width s, respectively. Therefore, the mean angular velocity

$$u = \frac{v_0}{0.65(0.55 \text{ or } 0.45 \text{ respectively})} \tag{21}$$

is much higher than the incoming velocity v_0.

The limit droplet diameter $d^* \sim d_e^*$ is calculated according to Stokes' law:

$$d_e^* = \sqrt{\frac{18\eta_G w_s^*}{\rho_L \bar{z}}}. \tag{22}$$

The Reynolds number of this limit droplet

$$\text{Re} = \frac{\rho_G w_s^* d_e^*}{\eta_G} \tag{23}$$

is normally in the range of 0.5 and 2. If this number is bigger than 10, which may be the case for a low viscosity or a high density of the gas, Stokes' law no longer applies. Then the following equation, which gives a good approximation for Reynolds numbers between 10 and 1,000, may be applied:

$$d_e^* = \frac{4.3(\rho_G \eta_G)^{1/3}}{(\rho_L \bar{z})^{2/3}} w_s^*. \tag{24}$$

The fractional separation efficiency curve is similar to that of the cyclone.

Normally, the liquid load of the gas entering the wave plate separator is 0.03 or below. However, if the separation efficiency of the first wave plate element is influenced by the limit load mechanism as in cyclones, it is possible to use cyclone theory for a rough estimate.

If the gas flow passes several packings subsequently, which are arranged with a larger distance between each other, the fractional efficiency for d_e^* is

$$\eta_F = 1 - 0.5e^{-0.7(i-1)} \tag{25}$$

whereas the total number of packings is i.

The number of 0.7 in the exponent of Eq. (25) is valid only for larger distances between the single packings and good mixing of the gas flow between these stages. In case of smaller distances and poor mixing, 0.7 has to be substituted by 0.25.

The modeling of wave plate separators with CFD simulation is described by Wang and Davies [12].

Example

Water droplets containing 2% lime shall separate in from a gas stream passing a wave plate separator in vertical direction. The gas stream has ambient pressure and a temperature of 75°C.

Physical data and dimensions:

$$\rho_G = 1\,\text{kg/m}^3;\ \eta_G = 21 \times 10^{-6}\,\text{Pa s};\ \rho_L = 1{,}025\,\text{kg/m}^3$$
$$r_i = s = 0.02\,\text{m};\ r_a = 2\,s = 0.04\,\text{m};\ \alpha = 90°;\ l = 0.5\,\text{m}.$$

Equation (14) shows in which flow range this separator can be operated:

$$v_0 = \sqrt{0.13 \cdot s \cdot g \cdot \frac{\rho_L}{\rho_G}} = 5.11\ \text{m/s} \approx 5\ \text{m/s},$$

$\dot{V} = 0.05\,\text{m}^3/\text{s}$,	Eq. (17)
$w_s^* = 0.8\,\text{m/s}$,	Eq. (18)
$r = 0.03\,\text{m}$,	Eq. (20)
$d_e^* = d^* = 8.5\,\mu\text{m}$,	Eq. (22)
$A = 0.031\,\text{m}^2$,	Eq. (16)
$\bar{u} = \frac{v_0}{0.45} = 11.1\,\text{m/s}$,	Eq. (21)
$\bar{z} = 4{,}100\,\text{m/s}^2$.	Eq. (19)

The calculation of the Reynolds number according Eq. (23) shows that Re = 0.32 < 1. Therefore, the application of Stokes' law has been correct.

The pressure loss according to Eq. (15) is

$$\Delta p = 6\frac{\rho_G}{2} v_0^2 = 75\,\text{Pa}.$$

5 Symbols

A	separation area (m^2)
A_R	friction area (m^2)
c_W	drag coefficient

Specific Heat Transfer Problems

M1 Heat Transfer to Finned Tubes

Klaus Gerhard Schmidt
Institut für Energie- und Umwelttechnik (IUTA) e.V., Duisburg, Germany

Heat release and absorption from surfaces can be enhanced by fins. The fins are to be placed on the side of poorer heat transfer. Fins will be effective all the more as the ratio of the heat transfer coefficient from the side of better heat transfer to that of poorer increases.

Basic requirement for the following approach is an ideal contact between the fin base and tube or surface. The shown method has to be regarded as a first approach. It will not fit for abnormal dimensions or extremely high Reynolds numbers. Indispensable for such cases is the examination of appropriate literature and far reaching modeling related to experimental data.

A mean heat transfer coefficient has to be found and evaluated on the base of geometrically determined consideration. Therefore, the model cannot differentiate local changes in heat flux due to different temperatures over the fin caused by convection.

It is assumed that the direction of fluid flow corresponds to the orientation of the fins. Heat transfer by thermal radiation will not be considered as well as the heat transfer on the fin's tip which normally contributes less to the total surface.

Design, shape dimensions, and abbreviations of finned surfaces are shown in Fig. 1.

1 Heat Transfer for Finned Tube

The heat flow from a finned tube is

$$\dot{Q} = kA\Delta\theta_{LM}. \tag{1}$$

Related to the total surface and the temperature gradient between both fluids the heat transfer coefficient k is given by

$$\frac{1}{k} = \frac{1}{\alpha_v} + \frac{A}{A_i}\left(\frac{1}{\alpha_i} + \frac{d_0 - d_i}{2\lambda_t}\right). \tag{2}$$

Equation (2) does not include additional heat transfer resistances caused by

Fouling processes on the fin surface
Poor contact between the tube and fin base

α_v is a virtual heat transfer coefficient. Assuming uniform heat transfer coefficient α_m for bare tube and fin surface α_v is derived from the fin efficiency η_f.

The heat flow then is

$$\dot{Q} = \alpha_m(A_t + \eta_f A_f)(\Theta_t - \Theta_a). \tag{3}$$

The driving temperature gradient for this case is the difference between surface temperature of the tube and fluid. α_m may be calculated as shown in Chap. G6. The characteristic length of the circular fin tube is [1–4]

$$l = \frac{\pi}{2}\sqrt{d_0^2 + h_f^2}$$

Values calculated in this way are greater than those to get with the following method.

Experimentally based values for α_m can be derived from Eqs. (15), (16), and (18) for corresponding applications. Characteristic length has to be always the same for the whole calculation procedure. The velocity w_s in the smallest cross section is calculated from die velocity in the free flow w_0, the ratio from inflow cross sectional area A_0, and smallest sectional area between fins A_s.

$$w_s = w_0\frac{A_0}{A_s}. \tag{4}$$

This value can be fitted furthermore for the velocity change due to changing density with temperature of the fluid.

The fin efficiency is the ratio of the mean temperatures between the respective base of fin or tube and fluid.

$$\eta_f = \frac{\Theta_f - \Theta_a}{\Theta_t - \Theta_a}. \tag{5}$$

Together with this the virtual heat transfer coefficient becomes

$$\alpha_v = \alpha_m\left[\frac{A_t}{A} + \eta_f\frac{A_f}{A}\right] = \alpha_m\left[1 - (1 - \eta_f)\frac{A_f}{A}\right]. \tag{6}$$

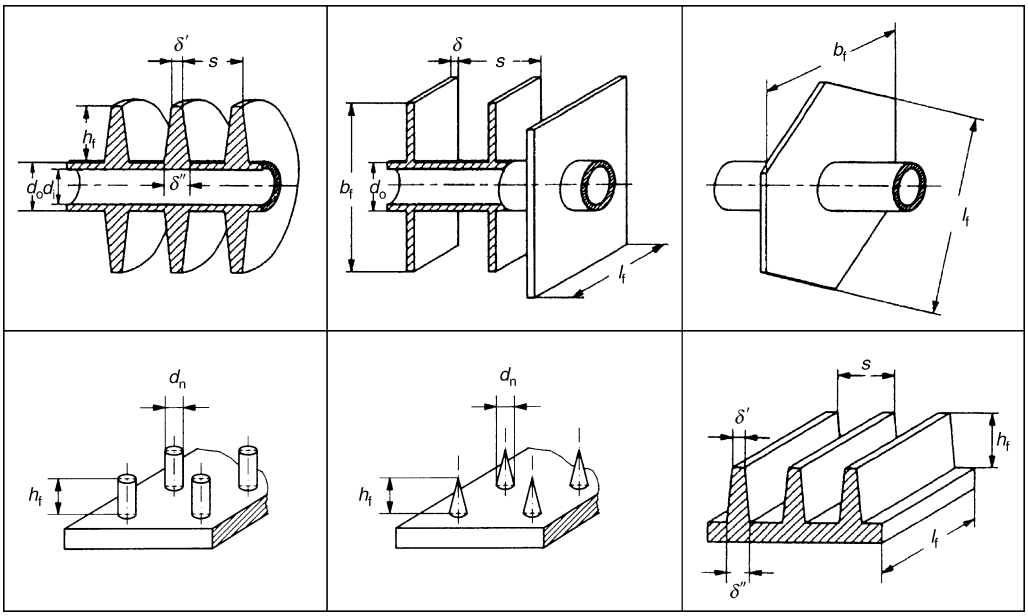
The formal way to calculate fin efficiency is

$$\eta_f = \frac{\tanh X}{X} \tag{7}$$

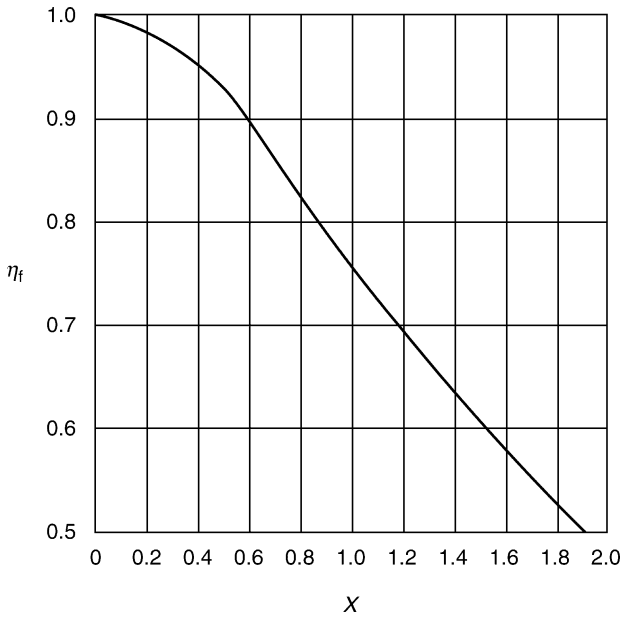
with

$$X = \varphi\frac{d_0}{2}\sqrt{\frac{2\alpha_m}{\lambda_f\delta}}. \tag{8}$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_50,



M1. Fig. 1. Different designs for finned surfaces.



M1. Fig. 2. Efficiency factor of finned surfaces.

In Eq. (8) the product $\varphi d_0/2$ has the meaning of a weighted fin height which incorporates the design δ stays for the fin thickness. The function $\eta_f = f(X)$ is plotted in Fig. 2. The analytical calculation can be done by

$$\eta_f = \frac{\tanh X}{X} = \frac{1}{X}\frac{e^X - e^{-X}}{e^X + e^{-X}}. \tag{9}$$

Commonly used fins types are discussed next.

2 Examples for Fin Geometry

2.1 Circular Fins

$$\varphi = \left(\frac{D}{d_0} - 1\right)\left[1 + 0.35\ln\left(\frac{D}{d_0}\right)\right]. \tag{10}$$

For conic fins with thickness δ'' at the base and δ' at the tip, the mean δ is defined by

$$\delta = \frac{1}{2}(\delta'' + \delta'). \tag{11}$$

2.2 Rectangular Fins

$$\varphi = (\varphi' - 1)(1 + 0.35\ \ln\ \varphi'), \tag{12}$$

$$\varphi' = 1.28\frac{b_f}{d_0}\sqrt{\left(\frac{l_f}{b_f} - 0.2\right)}. \tag{13}$$

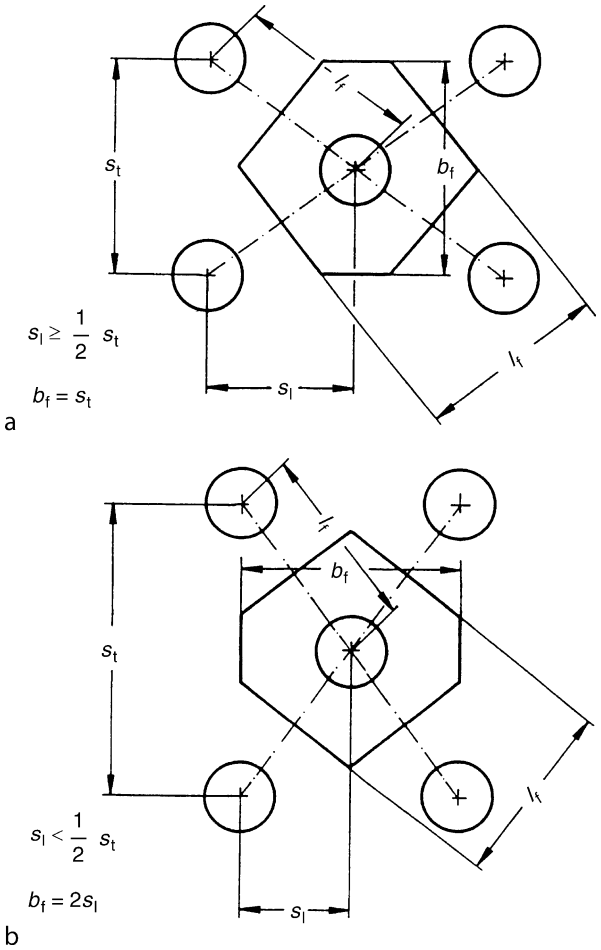
2.3 Adjacent Fins

For arrangements with in-line banks Eqs. (12) and (13) are valid.

For staggered banks a hexagon fin is to be defined for every tube with

$$\varphi' = 1.27\frac{b_f}{d_0}\sqrt{\left(\frac{l_f}{b_f} - 0.3\right)} \quad \text{with } l_f = \sqrt{s_1^2 + \frac{s_f^2}{4}}. \tag{14}$$

Along with the spacing two arrangements are to be distinguished according to Fig. 3 [5].



M1. Fig. 3. Schematic picture of different gaps in the hexagonally designed cross sections between parallel finned tubes in a bundle.

2.4 Straight Fins on Flat Plate

For this case in Eq. (8) the expression $\varphi d_0/2$ has to be substituted by the height of fin h_f and δ becomes

$$\delta = \frac{3}{4}\delta'' + \frac{1}{4}\delta'$$

2.5 Pin or Tip Needles on Flat Plate

Here the expression $\varphi d_0/2$ in Eq. (8) has to be substituted by the height of fin h_f and δ becomes

$$\delta = \frac{1}{2} d_n \quad \text{for pins}$$

$$\delta = \frac{9}{8} d_n \quad \text{for needles}$$

2.6 Heat Transfer in Banks of Finned Tubes in Cross Flow

Heat transfer in banks of finned tubes depends on geometric factors, physical properties, and the velocity of the fluid between the fins and the rows. Inflow pattern and the formation of microturbulences by surface roughness play an important role and are difficult to control. An all-in-one solution for a variety of applications and design cannot be given.

The advice to solve given problems of heat transfer in banks of finned tubes is to look for an empirical calculation formula on the base of experimental data [6–10]. The following equations are derived from industrial data [11] and the comparison with [12, 13].

This leads to more than four rows and

- Inline arrangement

$$\mathrm{Nu_d} = 0.22\mathrm{Re_d^{0.6}}\left(\frac{A}{A_{t0}}\right)^{-0.15}\mathrm{Pr}^{1/3}. \qquad (15)$$

- Staggered banks

$$\mathrm{Nu_d} = 0.38\mathrm{Re_d^{0.6}}\left(\frac{A}{A_{t0}}\right)^{-0.15}\mathrm{Pr}^{1/3}. \qquad (16)$$

The suffix d prompts to take as characteristic length the outer diameter d_0 of the tube. For circular fins, the ratio A/A_{t0} of the finned surface to the surface of the base tube becomes

$$\frac{A}{A_{t0}} = 1 + 2\frac{h_f(h_f + d_0 + \delta)}{s d_0}. \qquad (17)$$

The most important factors in this Eq. (17) are height h and spacing s (Fig. 1). They are essential for the formation of flow between fins and tubes and vary widely in industrial applications.

Calculations with the given Eqs. (15) and (16) were fitted within a range of ±10% to ±25% for $10^3 < \mathrm{Re_d} < 10^5$ and $5 \leq A/A_{t0} \leq 30$

For banks with one to three rows, it is recommended to modify the factor C of the Nusselt power equation

$$\mathrm{Nu_d} = C\mathrm{Re_d^{0.6}}\left(\frac{A}{A_{t0}}\right)^{-0.15}\mathrm{Pr}^{1/3}. \qquad (18)$$

For in-line arrangement $C = 0.20$, for staggered arrangement with two rows $C = 0.33$, and for three rows $C = 0.36$.

Example

Air has to be heated up from 90 to 120°C. Heating fluid is vapour condensing at 130°C. The mass flow of air is 1.92 kg/s.

The required power then is 59 kW.

Circular fin tubes	D = 56 mm, d_0 = 25.4 mm, δ = 0.4 mm	
	a = 2.42 mm, d_i = 21 mm	
Material	Aluminum with λ = 209 W/(m K)	
Arrangement	9 fins/in.	
	Spacing fins	s = 2.82 mm
	Spacing transversal	s_t = 60 mm
Inflow cross section	1 m^2	
Inflow velocity	2 m/s, calculated from mass flow and temperature	

Heat transfer coefficient	α_i = 10,454 W/(m^2 K)	
Width heat exchanger	17 tubes parallel -- >	17 s_t = 1.02 m
Height heat exchanger	1 m^2/1.02 m = 0.98 m	
Number fins single tube	0.98 m/0.00282 m = 348 fins	
A_f single fin	$A_f = 2\frac{\pi}{4}(D^2 - d_0^2)$ $= 2\frac{\pi}{4}(56^2 - 25.4^2)10^{-6}\,\text{m}^2$ $= 3.913 \cdot 10^{-3}\,\text{m}^2$	
A_f per tube	$A_f = 348 \cdot 3.913 \cdot 10^{-3}\,\text{m}^2$ $= 1.362\,\text{m}^2$	
A_t per tube	$A_t = (348+1)\pi d_0 a$ $= 349 \cdot \pi \cdot 25.4 \cdot 2.42 \cdot 10^{-6}\,\text{m}^2 = 0.067\,\text{m}^2$	
A_{t0} per tube	$A_{t0} = \pi \cdot d_0 \cdot 0.98m$ $= \pi \cdot 25.4 \cdot 10^{-3}\,\text{m} \cdot 0.98\,\text{m} = 0.078\,\text{m}^2$	
A per tube	$A = 1.362\,\text{m}^2 + 0.067\,\text{m}^2 = 1.429\,\text{m}^2$	
A_i per tube	$A_i = 0.98\,\text{m} \cdot \pi \cdot d_i$ $= 0.98\,\text{m} \cdot \pi \cdot 21 \cdot 10^{-3}\,\text{m} = 0.065\,\text{m}^2$	

We assume a heat exchanger with circular fins and in-line arrangement.

Straitened cross section of flow:

$$\frac{A_0}{A_s} = \frac{s_t(a+\delta)}{(s_t - d_0)a + (s_t - D)\delta} = \frac{60 \cdot 2.82}{(60 - 25.4) \cdot 2.42 \cdot (60 - 56) \cdot 0.4} = 1.984.$$

Flow velocity in the smallest cross section:

$$w_s = w_0 \frac{A_0}{A_s} = 2\text{m/s} \cdot 1.984 = 3.97\,\text{m/s}.$$

Influence of temperature:

$$w_{sT} = w_s \frac{273 + \frac{1}{2}(120+90)}{273+90} = 3.97\ \text{m/s} \cdot 1.04 = 4.13\ \text{m/s}.$$

Ratio of surfaces

$$\frac{A}{A_{t0}} = \frac{1.429\,\text{m}^2}{0.078\,\text{m}^2} = 18.321\ \text{(note : Eq.(17) will give 18.558)}.$$

Heat transfer air side

$$\text{Re}_d = \frac{d_0 w_{sT} \rho_{air}}{\eta_{air}} = \frac{0.0254\,\text{m} \cdot 4.13\,\text{m/s} \cdot 0.909\,\text{kg/m}^3}{22.37 \cdot 10^{-6}\,\text{kg/(ms)}} = 4,236,$$

$$\text{Nu}_d = 0.22\text{Re}_d^{0.6}\left(\frac{A}{A_{to}}\right)^{-0.15} \cdot \text{Pr}^{1/3} = 0.22 \cdot 4263^{0.6} \cdot 18.321^{-0.15} \cdot 0.706^{1/3} = 19.07,$$

$$\alpha_m = \frac{\text{Nu}_d \lambda_{air}}{d_0} = \frac{19.07 \cdot 0.0321\,\text{W/(m K)}}{0.0254\,\text{m}} = 24.10\,\text{W/(m}^2\text{K)}.$$

Fin efficiency: Circular fins in-line Eq. (10)

$$\varphi = \left(\frac{D}{d_0} - 1\right)\left[1 + 0.35\,\ln\left(\frac{D}{d_0}\right)\right] = 1.54,$$

$$X = \varphi \frac{d_0}{2}\sqrt{\frac{2\alpha_m}{\lambda_f \delta}} = 1.54\frac{0.0254\,\text{m}}{2}\sqrt{\frac{2 \cdot 24.14\,\text{W/(m}^2\text{K)}}{209\ \text{W/(mK)} \cdot 0.0004\,\text{m}}} = 0.47,$$

$$\eta_f = \frac{\tanh X}{X} = \frac{1}{X}\frac{e^X - e^{-X}}{e^X + e^{-X}} = \frac{1}{0.47}\frac{e^{0.47} - e^{-0.47}}{e^{0.47} + e^{-0.47}} = 0.93,$$

$$\alpha_v = \alpha_m\left[1 - (1 - \eta_f)\frac{A_f}{A}\right] = 24.10\left[1 - (1 - 0.93)\frac{1.362}{1.429}\right]\text{W/(m}^2\text{K)} = 22.49\,\text{W/(m}^2\text{K)}$$

$$\frac{1}{k} = \frac{1}{\alpha_v} + \frac{A}{A_i}\left(\frac{1}{\alpha_i} + \frac{d_0 - d_i}{2\lambda_t}\right) = \left[\frac{1}{22.49} + \frac{1.429}{0.065}\left(\frac{1}{10{,}454} + \frac{0.0254 - 0.021}{2 \cdot 209}\right)\right]\text{m}^2\text{K/W} = 0.0468\,\text{m}^2\text{K/W},$$

$$k = 21.37\,\text{W/m}^2\text{K}.$$

Logarithmic mean temperature difference

$$\Delta\Theta_{LM} = \frac{\Theta_{out} - \Theta_{in}}{\ln\frac{\Theta_{tube} - \Theta_{in}}{\Theta_{tube} - \Theta_{out}}} = \frac{30}{\ln\frac{40}{10}} = 21.64\,\text{K}.$$

Heat transfer surface necessary

$$A = \frac{\dot{Q}}{k\Delta\Theta_{LM}} = \frac{59{,}000}{21.37 \cdot 21.64}\,\text{m}^2 = 127.58\,\text{m}^2.$$

Number of rows

$$\text{NR} = \frac{127\,\text{m}^2}{17 \cdot 1.429\,\text{m}^2} = 5.25 \rightarrow 6\ \text{rows}.$$

Six rows are chosen.

A	total outer surface
A_s	smallest cross-sectional area
A_t	free outer surface of tube
A_{to}	surface of bare tube without fins
A_i	inside surface of tubes
A_f	fin surface
A_0	inflow cross-sectional area

M10 Heat Transfer and Momentum Flux in Rarefied Gases

Arnold Frohn · Norbert Roth · Klaus Anders†
Stuttgart, Germany

1 Introduction

Within the kinetic theory of gases heat transfer and flow processes of rarefied gases are described by the Boltzmann equation [1–14]. To this nonlinear integro-differential equation belong two characteristic lengths, namely the mean free path l of the molecules and a macroscopic length L characteristic for the body dimensions. The ratio of these quantities gives the Knudsen number

$$\mathrm{Kn} = l/L \tag{1}$$

as dimensionless parameter. At normal density, the mean free path is of the order of 10^{-7} m. In many technical applications, it can therefore be assumed that one has for the Knudsen number $\mathrm{Kn} \ll 1$. The term "rarefied gases" means that l is not negligibly small in comparison with L. This condition is often fulfilled at low density of the surrounding air, as for example in the higher layers of the earth's atmosphere. Similar conditions occur in vacuum or space technology. It should be mentioned that large values of the Knudsen number occur at normal density when very small particles are involved. Examples are aerosols in the atmosphere of the earth, fine powders in process engineering, or medical aerosols for inhalation.

For sufficiently small values of the Knudsen number fluid dynamic systems can be described with the Navier–Stokes equations of the continuum theory. These equations are obtained from macroscopic relations for conservation of mass, momentum, and energy. Viscous stress and heat conduction are described by empirical relations of the continuum theory, which depend linearly on the gradients of velocity and temperature. Within the continuum theory, the coefficients in these equations, heat conductivity λ, and viscosity η must be determined by experimental methods. In the kinetic theory of gases, the Navier–Stokes equations are obtained with the Chapman–Enskog method as solution of the Boltzmann equation for small values of the Knudsen number [5, 6]. With this method, the fluid properties λ and η can be determined theoretically from the law of the interaction force between the molecules. It follows from these calculations that λ and η for ideal gases are functions of the temperature, but do not depend on the gas density ρ. This result means that heat conduction in an ideal gas is independent of the density of the heat conducting gas. It is easy to see that this result can be valid only for a limited density range, since the heat conducting medium disappears when the density tends to zero and heat conduction is no longer possible. Similar considerations show that the viscous forces which are proportional to η must vanish when the density ρ tends to zero.

For large Knudsen numbers in the free-molecule regime, the number of molecular wall collisions becomes larger than the number of intermolecular collisions. Therefore, the influence

†Deceased

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_59,

of collision processes can be neglected when solving the Boltzmann equation. In this regime, the molecules move independently from each other and transport energy and momentum directly from one wall to another. This means that the molecular transport of energy and momentum is proportional to the density. In vacuum technology manometers of the Pirani type take advantage of the density dependence of heat conduction at low densities. After calibration such instruments are used for pressure measurements in an approximate range from 10^{-3} to 1 mbar [15, 16].

Theoretical solutions of the Boltzmann equation are mathematically extremely difficult in the transition regime between the continuum and the free-molecule regime. Here, exact analytical solutions of the Boltzmann equation are available only in very idealized cases. Analytical approximate solutions have been presented for systems without flow or for simple geometrical configurations. The purpose of the present section is to describe the distinction between continuum theory and kinetic theory, i.e., between solutions of the Navier–Stokes equations and the Boltzmann equation. Some solutions of the Boltzmann equation for rarefied gases are discussed. Energy transfer by radiation is not taken into account, although its influence increases with decreasing density and becomes the only mechanism of energy transfer under high-vacuum conditions. Details of this energy transport by electromagnetic waves are discussed in Chaps. K1–K3.

2 Theory

2.1 Introduction

In the kinetic theory, the thermodynamic state of a gas is described with the molecular velocity distribution function. This central function which describes the statistical distribution of the molecular velocities has to be found as solution of the Boltzmann equation. The thermodynamic variables are then calculated as moments of the molecular velocity distribution function. For the special case of a gas in thermodynamic equilibrium one has the well-known Maxwellian distribution [7]. Using this distribution function, one obtains for the mean magnitude of the molecular velocity

$$\bar{c} = \sqrt{\frac{8kT}{m\pi}} = \sqrt{\frac{8RT}{\pi}} = \sqrt{\frac{8\,\tilde{R}T}{\pi\tilde{M}}}, \tag{2}$$

where k is the Boltzmann constant, m the mass of a molecule, T the temperature, $R = k/m$ the individual gas constant, $\tilde{R}$ the universal gas constant, and $\tilde{M}$ the mole mass. It should be mentioned that from the definition of mass density, pressure, and temperature as moments of the distribution function the thermal equation of state follows in the form

$$p = nkT = \rho RT \tag{3}$$

for arbitrary distribution functions, which means that Eq. (3) holds for arbitrary deviations from thermodynamic equilibrium. With the relation

$$\rho = mn \tag{4}$$

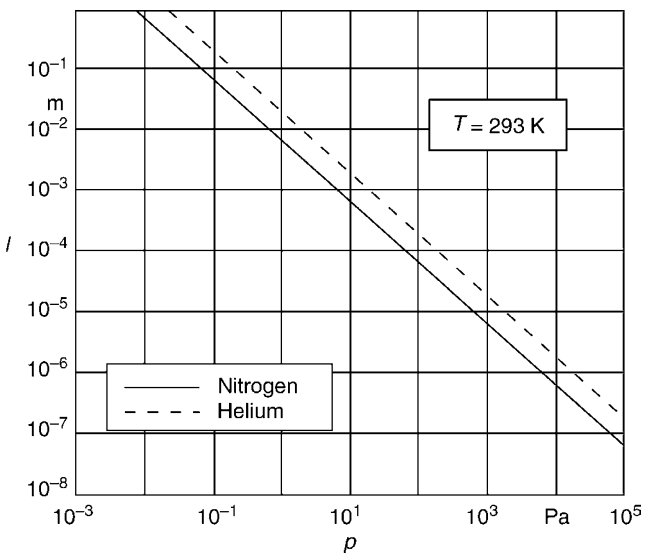
the mass density ρ can be determined from the number density n of the molecules and the mass of a molecule m.

In the continuum regime with small values of the Knudsen number, one has only small deviations from thermodynamic equilibrium, which also means small deviations from a locally Maxwellian distribution function. In this case, the Boltzmann equation can be linearized. Different mathematical methods and physical models for solving the resulting equations have been developed. The most important method for practical applications in fluid mechanics is the Chapman–Enskog method, which has been described comprehensively in the literature, for example in [5–7]. With this approach, one obtains the Navier–Stokes equations with the usual linear relations for macroscopic heat conduction and momentum flux processes.

The components of the heat flux vector are given by the well-known relation $\boldsymbol{q} = -\lambda \operatorname{grad} T$. Calculations of the heat conductivity coefficient λ using the intermolecular force law show that λ is a function of the temperature T, but it does not depend on the gas density ρ. Similarly, the viscosity η, which determines the components of the stress tensor, depends on the temperature but not on the density. The possibility to determine the temperature dependence of the transport coefficients theoretically is of practical importance when extrapolations of the transport coefficients λ and η for high temperatures are needed, for which experimental results are not available. According to Chapman and Cowling [5], the molecular model for elastic rigid spheres gives for the viscosity

$$\eta = \frac{5\pi}{32}\rho l\bar{c} \approx 0.5\rho l\bar{c}. \tag{5}$$

This relation can be used to determine the mean free path l from experimental results for the viscosity η. Figure 1 shows the mean free path for the gases helium and nitrogen at constant temperature as a function of pressure. The results have been obtained using Eqs. (2) and (5) with thermodynamic properties from



M10. Fig. 1. Mean free path for nitrogen and helium as a function of pressure according to Eqs. (2) and (5) with thermodynamic properties from Subchap. D3.1.

Subchap. D3.1 With the same molecular model one obtains for the heat conductivity coefficient

$$\lambda = \frac{25\pi}{64}\rho \bar{l} \bar{c} c_v, \tag{6}$$

where c_v is the specific heat capacity at constant volume [5]. For monatomic gases with the ratio of specific heats $\kappa = c_p/c_v = 5/3$ the Prandtl number is

$$\mathrm{Pr} = \frac{\eta\, c_p}{\lambda} = \frac{2}{3} \approx 0.67. \tag{7}$$

In the limit of a highly rarefied gas, i.e., at very large Knudsen numbers $\mathrm{Kn} \gg 1$, the molecular heat transport to a wall depends directly on the number of molecules incident on and reflected by the wall. For simple geometrical configurations of the walls, analytical expressions for the macroscopic heat transfer can be deduced. It has already been mentioned in the introduction that it is characteristic for the free-molecule regime that the heat flux is proportional to the density of the gas. In the transition regime, the heat flux has to be calculated as moment of the distribution function, which must be determined as solution of the Boltzmann equation.

Among the approaches used to solve the Boltzmann equation are expansions of the distribution function about absolute thermodynamic equilibrium or about local thermodynamic equilibrium, replacing the nonlinear collision term of the Boltzmann equation by a simpler mathematical model [14] or evaluation of momentum equations [17, 18]. In the past years, numerical calculations using Monte Carlo simulations or molecular gas dynamics have become more important [2, 19–21]. A critical discussion has been given by Bird [22]. Solutions of the Boltzmann equation have been presented mainly for problems with simple geometries, such as parallel plates, concentric cylinders, or concentric spheres. For technical applications, it would be important to have solutions for polyatomic gases. For this case, the Boltzmann equation becomes obviously too complicated. Available solutions are based on empirical assumptions. Usually, solutions for monatomic gases are modified by introducing macroscopic thermodynamic properties of polyatomic gases.

For convenience the following flow regimes may be defined:

$\mathrm{Kn} < 0.01$	continuum regime
$0.01 < \mathrm{Kn} < 0.1$	slip-flow and temperature-jump regime
$0.1 < \mathrm{Kn} < 10$	transitional regime

In the continuum regime, the Navier–Stokes equations with the usual expressions for heat flux and viscous stress are valid. This regime is a subject of the field of classical fluid mechanics and heat transfer [23–25]. In the slip-flow and temperature-jump regime the Navier–Stokes equations remain valid, but due to the rarefaction the gas adjacent to a wall no longer assumes the velocity or the temperature of the wall. The gas slips along the wall and a finite temperature jump between the gas and wall is observed. Temperature and velocity jumps can be taken into account by modified boundary conditions. In the transition regime, the Boltzmann equation has to be solved in its general form.

In the free-molecule regime it becomes easier to find solutions of the Boltzmann equation, since the effect of collisions vanishes and the collision term tends to zero. For this regime solutions exist for various special problems. Since it is extremely difficult to obtain solutions of the Boltzmann equation that cover the entire Knudsen number range, it has been tried to obtain approximate solutions by interpolation between solutions for the continuum regime and solutions for the free-molecule regime. It has been assumed that heat flow $\dot{Q}$ for arbitrary Knudsen numbers can be described by the heat transfer for the continuum regime $\dot{Q}_{\mathrm{Kont}}$ and the heat transfer for the free-molecule regime $\dot{Q}_{\mathrm{FM}}$ according to

$$\frac{1}{\dot{Q}} = \frac{1}{\dot{Q}_{\mathrm{Kont}}} + \frac{1}{\dot{Q}_{\mathrm{FM}}}. \tag{8}$$

It has been shown that this empirical rule can be useful for special cases, even for other quantities for example, the drag coefficient [26].

2.2 Boundary Conditions

In a problem, for the calculation of the heat transfer and the momentum flux at very small Knudsen numbers, i.e., in the continuum regime, knowledge of the boundary conditions is sufficient. In general, it is assumed that the heat conducting medium at the wall attains the wall temperature and velocity. With increasing Knudsen number, the gas temperature and velocity may show finite jumps at the wall. A theoretical description based on the kinetic theory needs as boundary condition the distribution function of the molecules reflected by the wall in dependence of the distribution function of the incident molecules [14]. This detailed description is usually too complicated for practical applications and is replaced by a simplified model based on the so-called accommodation coefficients. These coefficients describe the changes of certain moments of the distribution function by the interaction with the wall. The accommodation coefficient for the energy or temperature is defined, for example, by

$$\gamma = \frac{T_r - T_c}{T_w - T_c}. \tag{9}$$

In this equation, T_c represents the temperature of the molecules incident on the wall, T_w the wall temperature, and T_r the temperature of the molecules reflected by the wall. One has $T_r = T_e$ for $\gamma = 0$ and $T_r = T_w$ for $\gamma = 1$. In a similar way, accommodation coefficients can be defined for tangential and normal momentums of the molecules. The values of accommodation coefficients for technical surfaces are in a complicated way dependent on the state of the gas and the solid surface. An unambiguous prediction of these coefficients may be problematic. These questions have been discussed extensively in the literature [27, 28]. It has been mentioned that rarefied gases exhibit finite jumps of velocity and temperature at solid walls. The slip velocity at the wall for small but not negligible values of the Knudsen number can be expressed by

$$u(y=0) = \zeta \left(\frac{\partial u}{\partial y}\right)_{y=0}, \tag{10}$$

where y is a coordinate normal to the wall. A more detailed investigation gives for the molecular model of rigid spheres for the parameter of the slip velocity

$$\zeta = 2\,c\frac{2-\beta}{\beta}\,l \tag{11}$$

with $c = 0.4909 \approx 0.5$ and $0 < \beta < 1$, where β can be considered accommodation coefficient of the velocity tangential to the solid wall [11]. It can be seen that ζ is of the order of the mean free path. For the temperature of the gas adjacent to the solid wall, one assumes in a similar way

$$T\,(y=0) = T_{\mathrm{W}} + g\left(\frac{\partial T}{\partial y}\right)_{y=0}. \tag{12}$$

Here, the coefficient of the temperature jump g according to Kennard [11] is given by the relation

$$g = \frac{2-\gamma}{\gamma}\frac{15}{8}f\,l, \tag{13}$$

with

$$f = \frac{16}{15}\frac{\lambda}{\eta c_{\mathrm{v}}}\frac{1}{\kappa+1} = \frac{16}{15}\frac{1}{\mathrm{Pr}}\frac{\kappa}{\kappa+1}. \tag{14}$$

In problems containing the macroscopic length L, the ratio

$$\frac{g}{L} = \frac{2-\gamma}{\gamma}\frac{15}{8}f\,\mathrm{Kn} \tag{15}$$

plays an important role. Solutions presented in the literature are often for monatomic gases without inner degrees of freedom, therefore

$$\frac{\lambda}{\eta c_{\mathrm{v}}} = \frac{5}{2}, \quad c_{\mathrm{v}} = \frac{3}{2}R, \quad c_{\mathrm{p}} = \frac{5}{2}R, \quad \text{and} \quad \kappa = \frac{5}{3}. \tag{16}$$

In this case the correction factor is $f = 1$. Assuming additionally perfect accommodation, one has

$$g/l = \frac{15}{8}\mathrm{Kn}. \tag{17}$$

It can be seen that g is of the order of the mean free path l. It must be recognized that the coefficient g remains finite for perfect thermal accommodation. This means that temperature jumps also occur for $\gamma = 1$. For a stringent theory of polyatomic gases, one should introduce a proper molecular model, in practical applications the corresponding thermodynamic property values of polyatomic gases are introduced into Eq. (14). Under these conditions, one has in general $f \neq 1$ for the correction factor [29]. In the discussion of the solutions in Sects. 3 and 4 of this chapter, the changes caused by this approximate method are explained.

In the past years, more numerical solutions of the Boltzmann equation have been presented for special problems. This work deals with the numerical determination of the coefficients of the temperature jump and the slip velocity [30, 31], with the simulation of gas flow through pores and fine channels [32, 33] and with the heat transfer in rarefied gases including evaporation and condensation [34]. A few papers deal with mixtures of rarefied gases [35–39].

3 Solutions for Gases at Rest

3.1 Introduction

For small values of the Knudsen number $\mathrm{Kn} < 0.01$, the solution of the Boltzmann equation is in agreement with the results of the continuum theory, thus one has for the heat flux $\dot{q} = -\lambda$ grad T, which leads to the heat-conduction equation with the usual boundary conditions. Solutions for this Knudsen number range are not discussed here, as they are the same as those for solid bodies [23]. For the temperature-jump and slip-flow regime in the Knudsen number range $0.01 < \mathrm{Kn} < 0.1$ the heat-conduction equation of the continuum theory is still valid, but the temperature-jump boundary conditions of Eq. (12) must be introduced.

Using the temperature-jump boundary conditions, solutions of the heat-conduction equation are presented in the following for a few simple geometrical configurations, namely for parallel plates, for concentric cylinders, and for concentric spheres. As mentioned before, solutions of the continuum regime will be extended to the temperature-jump regime. The results obtained with this method, which generally are valid only for Knudsen numbers $\mathrm{Kn} < 0.1$, show characteristic features of the behavior of rarefied gases. In addition, approximate analytical solutions of the Boltzmann equation obtained from moment equations are discussed [7, 18]. The solutions of this approach are valid for an extended Knudsen number range.

By comparison with experiments, it can be shown that the heat flux obtained with the temperature-jump boundary condition for the case of plane parallel plates is valid for all Knudsen numbers. This result is probably due to the simple geometry. The solutions obtained with the temperature-jump boundary condition for concentric cylinders and concentric spheres are valid only for a limited Knudsen number range, which depends on the radii of the geometrical configuration. A discussion of the cylindrical case may be found in [7].

If not mentioned otherwise, the relations presented in the following are based on the assumptions of monatomic gases, perfect accommodation at the walls, and small temperature differences, i.e., for $|T_1/T_2 - 1| \ll 1$. Due to the assumption of small temperature differences, the calculations can often be performed with constant property values.

3.2 Plane Geometry

3.2.1 Steady Heat Conduction Between Parallel Planes for Knudsen Numbers Kn < 0.1

Solving the heat-conduction equation in a gas bounded by two plates for the steady case gives the linear temperature profile

$$T = b_1 y + b_0. \tag{18}$$

For plates with the distance s and the temperatures T_1 and T_2 one finds for the heat flux in the continuum regime

$$\dot{q}_{\mathrm{Kont}} = -\lambda\frac{\mathrm{d}T}{\mathrm{d}y} = \frac{\lambda}{s}(T_1 - T_2). \tag{19}$$

For the extension of this result to the temperature-jump regime $0.01 < \mathrm{Kn} < 0.1$ the boundary conditions of the temperature-jump regime Eq. (12) are introduced. One obtains the relations

$$\begin{aligned} T(y=0) &= b_0 = T_1 + g_1 b_1, \\ T(y=s) &= b_1 s + b_0 = T_2 - g_2 b_1, \end{aligned} \tag{20}$$

which allow to determine the constants b_0 and b_1. For the temperature distribution, it follows

$$\frac{T(y) - T_2}{T_1 - T_2} = \left(1 - \frac{y + g_1}{s + g_1 + g_2}\right) \tag{21}$$

and for the heat flux

$$\dot{q} = -\lambda \frac{\mathrm{d}T}{\mathrm{d}y} = \frac{\lambda}{s + g_1 + g_2}(T_1 - T_2). \tag{22}$$

Comparing this result with the classical solution for the continuum regime Eq. (19), one recognizes that the temperature-jump at the walls caused by the rarefaction of the gas reduces the heat flux and is equivalent to an increase of the plate distance from s to $s + g_1 + g_2$. The coefficient g is therefore often called temperature-jump distance. Figure 2 shows the temperature distribution between two parallel plates according to Eq. (21) schematically. Assuming small temperature differences and equal values of the accommodation coefficients at both walls, g_1 and g_2 have practically the same value. For monatomic gases, perfect accommodation, with $g_1 = g_2 = g$ and using Eq. (17), one gets for the temperature distribution between the plates

$$\frac{T(y^*) - T_2}{T_1 - T_2} = \left(1 - \frac{y^* + (15/8)\mathrm{Kn}}{1 + (15/4)\mathrm{Kn}}\right), \tag{23}$$

where $y^* = y/s$ and $\mathrm{Kn} = l/s$ have been introduced. This relation is represented in Fig. 3 for different values of the Knudsen number. The temperature distribution between the plates is still linear, and the temperature gradient is smaller in comparison with the continuum solution. For the ratio of the heat flux of a rarefied gas to the heat flux in the continuum, it follows

$$\frac{\dot{q}}{\dot{q}_{\mathrm{Kont}}} = \frac{\dot{Q}}{\dot{Q}_{\mathrm{Kont}}} = \frac{1}{1 + (15/4)\mathrm{Kn}}. \tag{24}$$

This means, for example, that for the plate distance of 1 cm the pressure of the heat conducting gas must be reduced by a factor of 100 in comparison with normal pressure, in order to reduce the heat flux by 0.25%.

In the following it is shown that Eq. (24), though it has been derived for the temperature-jump regime, is valid for the entire Knudsen number range.

Example 1

The space between two parallel plates with the distance $s = 1$ cm contains helium at the pressure $p = 1{,}000$ hPa. The temperatures of the plates are $T_1 = 273$ K and $T_2 = 278$ K, the accommodation coefficients of both plates are $\gamma = 1$. (a) Calculate the heat flux, (b) What is the heat flux when the pressure is reduced to 0.2 hPa? (c) What is the temperature-jump at the cold plate for case (b)?

Solution

(a) Mean free path and Knudsen number: From Eq. (5) it follows:

$$l = \frac{2\eta}{\rho \bar{c}}.$$

From Eq. (2) it follows for the mean molecular velocity at the cold plate:

$$\bar{c} = \sqrt{\frac{8 \cdot 2{,}080 \cdot 273}{3.1415}} = 1202.5 \ \mathrm{m/s}.$$

With Eqs. (3) and (4) one obtains $\rho = p/(RT_1) = 10^5/(2{,}080 \cdot 273) = 0.176\ \mathrm{kg/m^3}$.

With η from Subchap. D3.1 it follows

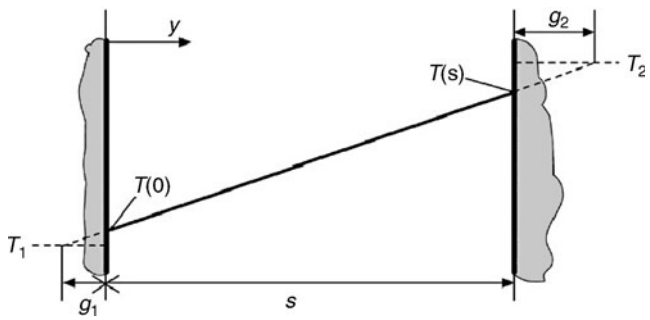
$$l_1 \approx \frac{2 \cdot 1.89 \cdot 10^{-5}}{0.176 \cdot 1202.5} = 1.79 \cdot 10^{-7}\mathrm{m}.$$

At the hot plate one obtains with the higher temperature

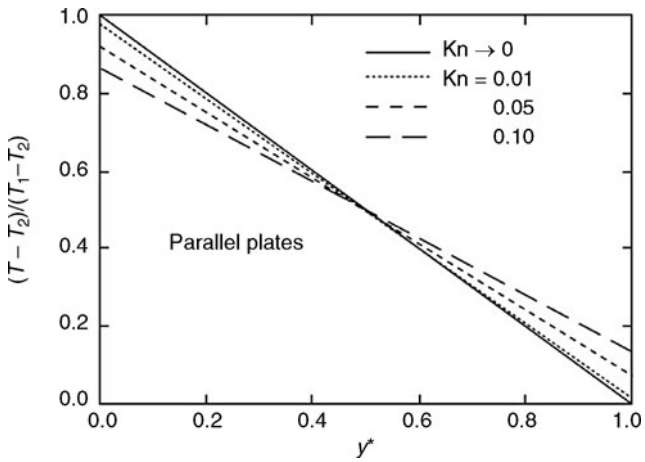
$$l_2 \approx \frac{2 \cdot 1.89 \cdot 10^{-5}}{0.173 \cdot 1213.5} = 1.80 \cdot 10^{-7}\mathrm{m},$$

where as an approximation, the value for the viscosity η at 273 K has been used. Since $l_1 \approx l_2$ one obtains for the Knudsen number

$$\mathrm{Kn} = \frac{l}{s} = \frac{1.8 \cdot 10^{-7}}{0.01} = 1.8 \cdot 10^{-5}.$$



M10. Fig. 2. Schematic representation of temperature distribution for gas between two parallel flat plates in temperature-jump regime. The effect of the temperature-jump distances g_1 and g_2 is equivalent to an enlarged plate distance $s + g_1 + g_2$.



M10. Fig. 3. Temperature distribution for gas between two parallel plates with different values of the Knudsen number.

Since Kn < 0.01 the equations of the continuum theory apply, here Eq. (19) can be used. With the heat conductivity λ for the temperature 273 K from Subchap. D3.1 one has

$$\dot{q}_{\text{Kont}} = (0.143/0.01)\ (273 - 278) = -71.5\ \text{W/m}^2.$$

(b) The initial pressure p must be reduced by the factor 5,000 to reach the pressure 0.2 hPa. At constant temperature this means that the mean free path increases by the same factor. It follows $l = 9 \cdot 10^{-4}$ m and Kn = 0.09.

This means that Eq. (24) must be used to determine the heat flux. It follows

$$\dot{q} = \frac{\dot{q}_{\text{Kont}}}{1 + (15/4)\text{Kn}} = \frac{-71.5}{1 + 3.75 \cdot 0.09} = -53.46\ \text{W/m}^2.$$

(c) The temperature jump at the cold wall can be determined with Eq. (21). Since helium is a monatomic gas, Eq. (16) holds. With Eq. (13) and $\gamma = 1$, it follows

$$g = (15/8)l = 1.875 \cdot 9 \cdot 10^{-4} = 1.69 \cdot 10^{-3}\ \text{m}.$$

With Eq. (21) one obtains

$$\frac{T(0) - T_2}{T_1 - T_2} = \left(1 - \frac{1.69 \cdot 10^{-3}}{0.01 + 1.69 \cdot 10^{-3} + 1.69 \cdot 10^{-3}}\right) = 0.874$$

and

$$T(0) = 0.874 \cdot (273 - 278) + 278 = 273.63\ \text{K}.$$

For the temperature jump at the cold wall one has

$$T(0) - T_1 = 0.63\ \text{K}.$$

3.2.2 Unsteady Heat Conduction for Knudsen Numbers Kn < 0.1

In the following, a special solution of the unsteady heat-conduction equation is considered for a semi-infinite gas bounded by the plane $y = 0$ and extending in the direction of y positive. For $t \leq 0$, the temperature is T_0 everywhere. For $t > 0$, the temperature of the wall at $y = 0$ is T_1. It should be mentioned that no characteristic macroscopic length exists in this case, which could be used to define a Knudsen number. Using the temperature-jump boundary condition of Eq. (12) leads to the temperature distribution

$$\frac{T(y,t) - T_0}{T_1 - T_0} = \left[1 - \text{erf}\left(\frac{y}{g_1}\frac{g_1}{2\sqrt{at}}\right) - \exp\left(\frac{y}{g_1} + \frac{1}{4}\frac{4at}{g_1^2}\right) \cdot \text{erfc}\left(\frac{y}{g_1}\frac{g_1}{2\sqrt{at}} + \frac{2\sqrt{at}}{2g_1}\right)\right], \tag{25}$$

where

$$\text{erf}(\chi) = \frac{2}{\sqrt{\pi}}\int_0^{\chi} \exp(-\omega^2)\,\text{d}\omega \tag{26}$$

is the error function, and

$$\text{erfc}(X) = 1 - \text{erf}(X) \tag{27}$$

the complementary error function and a the thermal diffusivity [7]. The quantity $\sqrt{at}$ in Eq. (25) has the physical dimension of a length and may be considered a characteristic length of the problem. In the solution for the continuum regime, the gas assumes for $t > 0$ the temperature of the wall, without delay. It is characteristic for rarefied gases that the gas needs a finite time to attain the temperature of the wall. From Eq. (25) one obtains with $y = 0$ the temperature of the gas at the wall as a function of time:

$$\frac{T(0,t) - T_0}{T_1 - T_0} = 1 - \exp\left(\frac{at}{g_1^2}\right)\text{erfc}\left(\frac{\sqrt{at}}{g_1}\right). \tag{28}$$

Example 2

A plane wall with the temperature $T_1 = 303$ K comes suddenly in contact with a gas of the temperature 298 K. The pressure is 150 Pa. It is assumed that the wall temperature does not change with time and that the accommodation is perfect. What is the temperature at the wall after 0.05 ms? For an estimate of this temperature, use constant physical properties of air at $T_0 = 298$ K.

Solution

To determine the temperature at the wall as a function of time Eq. (28) is used. The quantity $\sqrt{at}$ can be considered a characteristic length of the problem.

From Eq. (3) one obtains

$$\rho = p/(RT_0) = 150/(287.2 \cdot 298) = 1.75 \cdot 10^{-3}\ \text{kg/m}^3.$$

Using the physical properties of air from Subchap. D2.2 one has for the heat diffusivity

$$a = \lambda/(\rho c_p) = 26.06 \cdot 10^{-3}/(1.75 \cdot 10^{-3} \cdot 1{,}007) = 1.479 \cdot 10^{-2}\ \text{m}^2/\text{s}.$$

Calculation of the mean free path: using Eq. (5) one obtains

$$l \approx \frac{2\eta}{\rho\bar{c}}.$$

From Eq. (2) it follows

$$\bar{c} = \sqrt{\frac{8 \cdot 287.22 \cdot 298}{3.1415}} = 466.9\ \text{m/s}.$$

With η from Subchap. D2.2 one finds

$$l \approx \frac{2 \cdot 18.48 \cdot 10^{-6}}{1.75 \cdot 10^{-3} \cdot 466.9} = 4.52 \cdot 10^{-5}\text{m}.$$

For the argument of the exponential function and the complementary error function in Eq. (28) one obtains with Eq. (13) the expression

$$\frac{\sqrt{at}}{g} = \frac{8\sqrt{at}}{15fl}.$$

The correction factor f differs from unity since air is a mixture of polyatomic gases. Using physical properties of air from Subchap. D2.2 with Eq. (14) gives

$$f = \frac{16}{15} \cdot \frac{1}{0.7141} \cdot \frac{1.4}{1+1.4} = 0.871.$$

It follows

$$\frac{\sqrt{at}}{g} = \frac{8\sqrt{1.479 \cdot 10^{-2} \cdot 0.05 \cdot 10^{-3}}}{15 \cdot 0.871 \cdot 4.52 \cdot 10^{-5}} = 11.65.$$

For large values of the argument, the complementary error function can be represented by a series expansion [7]. One has

$$\operatorname{erfc}(\chi) = \frac{\exp(-\chi^2)}{\sqrt{\pi}} \left(\frac{1}{\chi} - \frac{1}{2\chi^3} + \frac{1 \cdot 3}{2^2 \cdot \chi^5} - \cdots + \cdots \right).$$

For $\chi > 6$, the remainder after the first three terms can be neglected. Thus, one obtains for Eq. (28) the relation

$$\frac{T - T_0}{T_1 - T_0} = 1 - \exp(11.65^2) \cdot \frac{\exp(-11.65^2)}{\sqrt{\pi}} \cdot \left(\frac{1}{11.65} \cdot \frac{1}{2 \cdot 11.65^3} + \frac{1 \cdot 3}{2^2 \cdot 11.65^5} \right) = 0.952.$$

The temperature of the air at the wall is

$$T = 0.952\ (303 - 298) + 298 = 302.76\ \text{K}.$$

3.2.3 Extensions to Arbitrary Knudsen Numbers

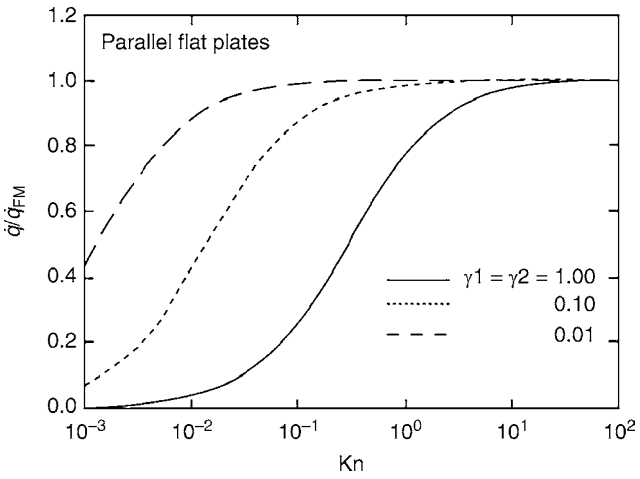
The results presented in Sect. 3.2.1 have been derived for moderate rarefaction, i.e., for Knudsen numbers Kn < 0.1. Using moment equations, Lees and Liu derived an approximate analytical solution of the Boltzmann equation [17, 18, 40]. It has been shown by different experimental investigations that the theoretical results of Lees and Liu are in excellent agreement with experiments for all values of the Knudsen number [41–44]. The results which Lees and Liu derived for complete accommodation, $Y_1 = Y_2 = 1$, can be extended to include incomplete accommodation, i.e., accommodation coefficients less than unity. The result can be written as

$$\frac{\dot{q}}{\dot{q}_{\text{FM}}} = \frac{\dot{Q}}{\dot{Q}_{\text{FM}}} = \left[1 + \frac{4}{15\,\text{Kn}} \frac{\gamma_1 \gamma_2}{\gamma_1 + \gamma_2 - \gamma_1 \gamma_2} \right]^{-1}, \qquad (29)$$

where

$$\dot{Q}_{\text{FM}} = A \frac{\gamma_1 \gamma_2}{\gamma_1 + \gamma_2 - \gamma_1 \gamma_2} \frac{c_v + R/2}{\sqrt{2\pi RT}} p(T_1 - T_2) \qquad (30)$$

is the heat flow in the free-molecule regime [11]. In these equations, A represents the surface of a plate, while γ_1 and γ_2 are the accommodation coefficients of the plates. In the free-molecule regime, intermolecular collisions become negligible and the trajectories of the molecules are independent of each other. The molecules transport energy and momentum directly from one wall to another. Thus, the molecular transport of energy, i.e., the heat flow, is proportional to the number of molecules or to the density of the gas. The heat flow in the free-molecule regime does not depend on the distance between the plates. The ratio of the heat flux $\dot{q}$ to $\dot{q}_{\text{FM}}$ according to Eq. (29) is shown in Fig. 4 for different values of the accommodation coefficient. It is found that the empirical relation equation (8) proposed by Sherman [26] is valid in the present case of parallel flat plates. According to Sherman, the heat flow for arbitrary Knudsen numbers $\dot{Q}$ can be expressed by the heat flow of the limiting cases of the continuum $\dot{Q}_{\text{Kont}}$ and the free-molecule regime $\dot{Q}_{\text{FM}}$. One has



M10. Fig. 4. Dimensionless representation of heat flux between parallel flat plates according to Eq. (29) for different values of the accommodation coefficient.

$$\frac{\dot{Q}}{\dot{Q}_{\text{FM}}} = \frac{1}{1 + \dot{Q}_{\text{FM}}/\dot{Q}_{\text{Kont}}}. \qquad (31)$$

Using the thermal equation of state equations (3) and (5), the density ρ can be expressed as a function of the mean free path and the viscosity. With $\gamma_1 = \gamma_2 = 1$ and introducing Eqs. (22) and (30) one finds the relation

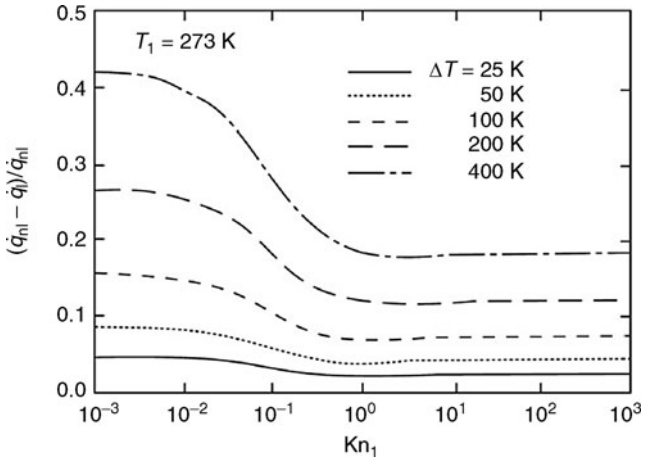
$$\frac{\dot{Q}_{\text{FM}}}{\dot{Q}_{\text{Kont}}} = \frac{1}{2} \frac{s}{l} (c_v + R/2) \frac{\eta}{\lambda}. \qquad (32)$$

For monatomic gases Eq. (16) holds, thus one has

$$Q_{\text{FM}}/Q_{\text{Kont}} = 4/(15\ \text{Kn}). \qquad (33)$$

Combining this result with Eq. (31) gives Eq. (29) for the special case of complete accommodation. It should be mentioned that the relations derived here are for monatomic gases and for small temperature differences. By multiplying the Knudsen number with the correction factor f of Eq. (14) in Sect. 2, one can derive equations for polyatomic gases.

The solutions presented so far make use of linearization based on the assumption of small temperature differences. Analytical solutions for large temperature differences are not available. To get an impression of the deviations from solutions obtained by linearization, Braun [42] studied numerical solutions of moment equations for parallel flat plates, without the assumption of small temperature differences. In Fig. 5, the difference between nonlinear and linear solutions is shown as a function of Knudsen number for different temperatures. At a temperature difference of 400 K deviations up to 40% are found.



M10. Fig. 5. Difference between nonlinearized solution q_{nl} and linearized solution q_l for heat flux between flat plates as a function of Knudsen number according to Braun [42]. Here, $\Delta T = T_2 - T_1$ is the temperature difference between the plates. It should be mentioned that the Knudsen number has been evaluated for the state of the gas at the cold plate.

Example 3

For the measurement of the accommodation coefficient of argon in a new material, a heat transfer cell with parallel flat plates is used. The distance of the plates is s = 1 mm. It is assumed that the accommodation coefficients of the plates have the same value. In order to obtain clean conditions for the measurements, the pressure in the cell is reduced to 10^{-4} Pa at the beginning of an experiment. At this pressure one has free-molecule conditions. It can be assumed that the gas between the plates consists of water vapor which comes from the re-evaporation of water molecules formed at higher pressures as film on the walls. To determine the heat transferred by radiation, a measurement is made under vacuum conditions with the wall temperatures T_1 = 278 K and T_2 = 268 K. Under these conditions, a heat flux of 10 W/m^2 is measured.

(a) Determine the heat flux of water vapor under the assumption of complete accommodation.

(b) Argon is introduced into the cell until the pressure is 0.1 Pa. By adjusting the heating power the wall temperatures T_1 = 278 K and T_2 = 268 K are obtained. The measured heat flux is 10.4 W/m^2. What is the value of the accommodation coefficient for the investigated material?

Solution

(a) In the measurements under vacuum conditions, one has for the Knudsen number Kn $\gg$ 10. This can be shown by calculation in a similar way as in Examples 1 and 2. For the heat flux in the free-molecule regime Eq. (30) is used. With $c_v = c_p - R$ and c_p from Subchap. D3.1 it follows

$$\dot{q}_{FM} = \frac{\dot{Q}_{FM}}{A} = \frac{c_p - R/2}{\sqrt{2\pi RT}} p(T_1 - T_2)$$
$$= \frac{1864 - 461.4/2}{\sqrt{2 \cdot 3.1415 \cdot 461.4 \cdot 273}} 10^{-4} \cdot 10 = 1.84 \text{ mW/m}^2,$$

For T, the arithmetic mean value of the temperatures T_1 and T_2 has been introduced. This value of the heat is negligibly small in comparison with 10 W/m^2 obtained under vacuum conditions. It is therefore assumed that the heat flux of 10 W/m^2 is due to thermal radiation. This value has to be subtracted from the values measured at higher pressures.

(b) At the pressure 0.1 Pa one has the Knudsen number Kn $\gg$ 10. Thus, one has free-molecule conditions, and Eq. (30) can be used. With the relations for monatomic gases in Eq. (16) one obtains

$$\dot{q}_{FM} = \frac{\dot{Q}_{FM}}{A} = \frac{\gamma}{2-\gamma} \frac{2R}{\sqrt{2\pi RT}} p(T_1 - T_2),$$

$$10.4 - 10 = \frac{\gamma}{2-\gamma} \frac{2 \cdot 208.13}{\sqrt{2 \cdot 3.1415 \cdot 208.13 \cdot 273}} 0.1 \cdot 10$$
$$= \frac{\gamma}{2-\gamma} 0.697.$$

It follows γ = 0.729. It should be mentioned that under the described conditions thermal radiation gives an essential contribution to the heat transfer.

3.3 Concentric Cylinders

3.3.1 Steady Heat Conduction Between Concentric Cylinders for Knudsen Numbers Kn < 0.1

Using the temperature-jump boundary condition of Eq. (12), one obtains for concentric cylinders the heat flux

$$\dot{q} = \frac{\lambda}{r_1} \frac{(T_1 - T_2)}{\ln[(r_2 + g_2)/(r_1 - g_1)]}, \tag{34}$$

where r_1 is the radius of the inner cylinder and r_2 the radius of the outer cylinder. Since Kn < 0.1 one has $g_1 \ll r_1$ and $g_2 \ll r_2$, and the logarithm in Eq. (34) may be expanded in a series to give

$$\dot{q} = \frac{\lambda}{r_1} \frac{(T_1 - T_2)}{\ln(r_2/r_1) + g_1/r_1 + g_2/r_2}. \tag{35}$$

For $g_1 \to 0$ and $g_2 \to 0$ one obtains the special case of the continuum regime:

$$\dot{q}_{Kont} = \frac{\lambda}{r_1} \frac{T_1 - T_2}{\ln(r_2/r_1)}. \tag{36}$$

Combining Eqs. (35) and (36) and using Eq. (17) one has

$$\frac{\dot{q}}{\dot{q}_{Kont}} = \frac{\dot{Q}}{\dot{Q}_{Kont}} = \frac{\ln r_2^*}{\ln r_2^* + (15/8)\text{Kn}_1(1 + 1/r_2^*)} \tag{37}$$

with $r_2^* = r_2/r_1$, Kn = l/r_1, and $g_1 = g_2 = g$. This relation is valid only for Knudsen numbers Kn < 0.1 which in general holds true for all results based on temperature-jump boundary conditions. Some results for an extended Knudsen range are discussed in the next chapter. In the unsteady case solutions based on the temperature-jump boundary conditions lead to Bessel functions. Such solutions are important for the evaluation of experimental

results for the heat conductivity at higher densities as described in the literature [43].

3.3.2 Generalizations for Arbitrary Knudsen Numbers

Using momentum equations, Lees and Liu found an approximate analytical solution of the Boltzmann equation for the heat transfer between concentric cylinders. By comparison with experimental results it has been shown that the solution of Lees and Liu is in good agreement with experimental results for $0 < \mathrm{Kn} < \infty$, whereas Eq. (37) is wrong by a factor 2 in the free-molecule regime [40]. According to Lees and Liu, the relation

$$\frac{\dot{Q}}{\dot{Q}_{\mathrm{Kont}}} = \left(1 + \frac{15}{4}\frac{1}{\gamma_1}\frac{\mathrm{Kn}_1}{\ln r_2^*}\right)^{-1} \tag{38}$$

is valid for all Knudsen numbers. Here, γ_1 is the accommodation coefficient of the surface of the inner cylinder. It should be mentioned that the accommodation coefficient of the outer cylinder is irrelevant if $r_2^* \gg 1$. For the regime of free-molecule flow, Kennard [11] has derived

$$\dot{Q}_{\mathrm{FM}} = A_1\left[\frac{1}{\gamma_1}\frac{1}{r_2^*}\left(\frac{1}{\gamma_2} - 1\right)\right]^{-1}\frac{c_v + R/2}{\sqrt{2\pi RT}}p(T_1 - T_2), \tag{39}$$

where A_1 is the surface of the inner cylinder. According to Hurlbut [44] one has

$$\frac{\dot{Q}}{\dot{Q}_{\mathrm{FM}}} = \left(1 + \frac{4}{15}\gamma_1\frac{\ln r_2^*}{\mathrm{Kn}_1}\right)^{-1}. \tag{40}$$

From Eqs. (38) and (40) it follows $\dot{Q}/\dot{Q}_{\mathrm{Kont}} + \dot{Q}/\dot{Q}_{\mathrm{FM}} = 1$, which means that Sherman's empirical rule equation (8) is valid here. According to Lees and Liu [41], it follows for the steady temperature field in the gas between concentric cylinders

$$\frac{T(r) - T_2}{T_1 - T_2} = \left\{1 - \varphi\left[\frac{1}{2} + \frac{1}{\pi}\arccos(1/r^*)\right] - (1 - \varphi)\frac{\ln r^*}{\ln r_2^*}\right\}, \tag{41}$$

with

$$\varphi = \left(1 + \frac{4}{15}\frac{\ln r_2^*}{\mathrm{Kn}_1}\right)^{-1}. \tag{42}$$

The described relations have been obtained for monatomic gases. Using the correction factor introduced in Sect. 2 they can be applied to polyatomic gases. For this purpose, the Knudsen number has to be multiplied with the correction factor f of Eq. (14). It has been shown by Westerdorf [43] that calculations based on this method are in good agreement with experimental results for the polyatomic gases such as nitrogen and water vapor.

Example 4

Measurements of the heat conductivity λ are often performed by the so-called hot-wire method, which uses a cell consisting of a cylindrical tube that is kept at a fixed temperature. A fine wire is stretched along the axis of the tube. The wire is heated electrically, and the dissipated electrical power can be determined by measuring the electrical current and voltage. Consider a cylindrical cell of diameter 2 cm with an electrically heated platinum wire of diameter 0.1 mm. In order to minimize the end effects of the cell only the central length of the wire $L_D = 0.4$ m is used for the measurements. The dissipated electrical power $\dot{Q}_M = 32$ mW is determined. The cell contains nitrogen. The accommodation coefficient for nitrogen on platinum is $\gamma_1 = 0.53$. The temperature of the wire is 298 K, and the temperature of the cylinder is 293 K. From measurements at very low pressure, i.e., for $p \to 0$, it is found that the heat flow due to thermal radiation is $\dot{Q}_S = 2$ mW. Calculate the pressure in the heat transfer cell.

Solution

Using the heat conductivity of Subchap. D3.1, it follows for the heat flux in the continuum regime from Eq. (36)

$$\dot{Q}_{\mathrm{Kont}} = 2\pi r_1 L_D \dot{q}_{\mathrm{Kont}} = 2 \cdot 3.1415 \cdot 0.4 \cdot 0.026\ (298 - 293)/\ln(1 \cdot 10^{-2}/0.05 \cdot 10^{-3}) = 61.7\ \mathrm{mW}.$$

The conduction for arbitrary Knudsen numbers is given by Eq. (38). This equation has been derived for monatomic gases. It can be applied to nitrogen when the Knudsen number is multiplied with the correction factor f of Eq. (14). With property values for nitrogen at 298 K from Subchap. D3.1 one obtains $\mathrm{Pr} = 0.71$ and $\kappa = 1.4$. Thus, one finds for nitrogen

$$f = \frac{16}{15}\cdot\frac{1}{0.71}\cdot\frac{1.4}{1 + 1.4} = 0.876.$$

From the measurements, it follows

$$\dot{Q}/\dot{Q}_{\mathrm{Kont}} = (\dot{Q}_M - \dot{Q}_S)/\dot{Q}_{\mathrm{Kont}} = (32 - 2)/61.7 = 0.486.$$

With Eq. (38) one gets the Knudsen number

$$\mathrm{Kn}_1 = \frac{4}{15}\frac{\gamma_1 \ln r_2^*}{f}\left(\frac{\dot{Q}_{\mathrm{Kont}}}{\dot{Q}} - 1\right) = \frac{4}{15}\cdot\frac{0.53\ln 200}{0.876}\left(\frac{1}{0.486} - 1\right) = 0.904.$$

With Eqs. (1–5) and the viscosity value from Sect. 3.1, the Knudsen number can be used to evaluate the pressure. One has

$$p = \sqrt{\frac{\pi}{2}}\frac{\eta\sqrt{RT}}{\mathrm{Kn}_1 r_1} = 1.253\frac{1.78 \cdot 10^{-5}\sqrt{296.8 \cdot 298}}{0.904 \cdot 0.05 \cdot 10^{-3}} = 147\ \mathrm{Pa}.$$

3.4 Spherical Geometry

3.4.1 Steady Heat Conduction Between Concentric Spheres for Knudsen Numbers Kn < 0.1

With the temperature-jump boundary condition of Eq. (12) one obtains for the heat flux at the surface of the inner sphere of two concentric spheres

$$\dot{q} = \frac{\lambda}{r_1^2}\frac{T_1 - T_2}{g_1/r_1^2 + g_2/r_2^2 + 1/r_1 - 1/r_2}, \tag{43}$$

where r_1 is the radius of the inner sphere and r_2 the radius of the outer sphere. Introducing the known solution of the continuum regime,

$$\dot{q}_{\mathrm{Kont}} = \frac{\lambda}{r_1^2} \cdot \frac{T_1 - T_2}{1/r_1 - 1/r_2} \tag{44}$$

it follows for monatomic gases with Eq. (17) and with $g_1 = g_2 = g$ the equation

$$\frac{\dot{q}}{\dot{q}_{\mathrm{Kont}}} = \frac{\dot{Q}}{\dot{Q}_{\mathrm{Kont}}} = \frac{1 - 1/r_2^*}{(15/8)\mathrm{Kn}_1[1 + (1/r_2^*)^2] + 1 - 1/r_2^*}. \tag{45}$$

As in the case with cylindrical symmetry, the radius r_1 is used to define the dimensionless quantities $r_2^* = r_2/r_1$ and $\mathrm{Kn}_1 = l/r_1$. For the temperature distribution one obtains with $r^* = r/r_1$ the equation

$$\frac{T(r^*) - T_2}{T_1 - T_2} = \frac{(15/8)\mathrm{Kn}_1(1/r_2^*)^2 + 1/r^* - 1/r_2^*}{(15/8)\mathrm{Kn}_1[1 + (1/r_2^*)^2] + 1 - 1/r_2^*}. \tag{46}$$

From these equations follow of course with $r_2 \to \infty$ the results for a single sphere.

3.4.2 Unsteady Heat Conduction of Single Sphere for Knudsen Numbers Kn < 0.1

For a single sphere with constant wall temperature T_1 which suddenly comes in contact with a surrounding gas of the temperature T_0, the unsteady heat-conduction equation with the temperature-jump boundary condition gives for the temperature distribution in the gas:

$$\frac{T(r^*, t^*) - T_0}{T_1 - T_0} = \frac{8/(15\,\mathrm{Kn}_1)}{r^*[1 + 8/(15\,\mathrm{Kn}_1)]} \cdot \left\{1 - \mathrm{erf}\,\frac{r^* - 1}{2\sqrt{t^*}} - \left[1 - \mathrm{erf}\left(\frac{r^* - 1}{2\sqrt{t^*}} + \left(1 + 8/(15\mathrm{Kn}_1)\sqrt{t^*}\right)\right)\right] \cdot \exp[(1 + 8/(15\,\mathrm{Kn}_1)(r^* - 1) + \left(1 + 8/(15\,\mathrm{Kn}_1)^2 t^*\right))]\right\}, \tag{47}$$

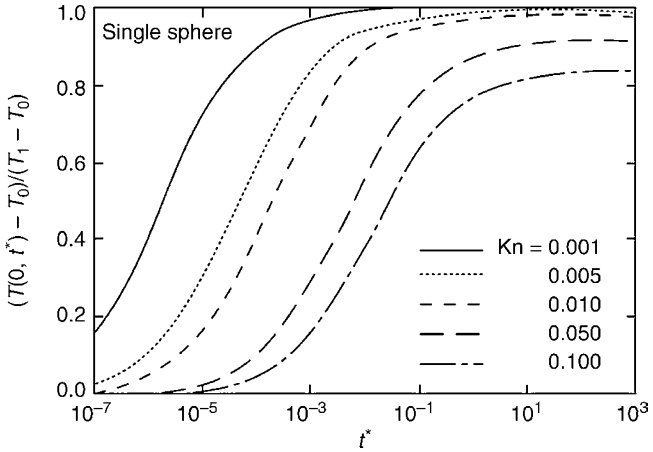
where $t^* = t/t_{\mathrm{T}}$ with

$$t_{\mathrm{T}} = \frac{\rho C_p r_1^2}{\lambda} = \frac{r_1^2}{a}, \tag{48}$$

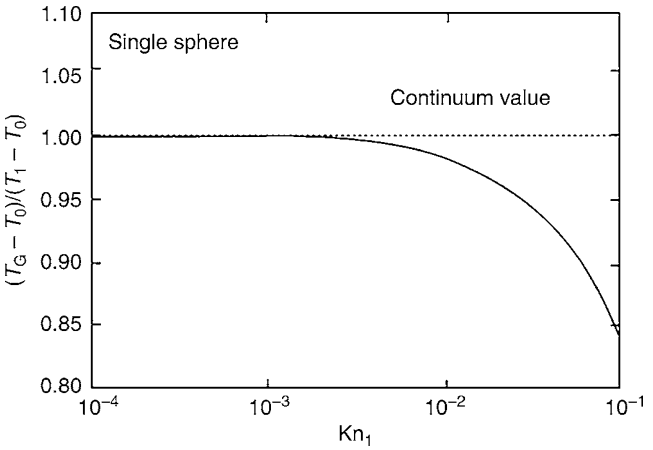
and a is the heat diffusivity. The characteristic time t_{T} for a spherical particle of radius 10 µm in air at standard conditions with property values from Subchap. D3.1 is approximately 5 µs. With $r^* = 1$ one finds for the temporal evolution of the gas temperature at the surface of the sphere

$$\frac{T(0, t^*) - T_0}{T_1 - T_0} = \frac{8/(15\,\mathrm{Kn}_1)}{1 + 8/(15\,\mathrm{Kn}_1)} \cdot \left\{1 - \left[1 - \mathrm{erf}(1 + 8/(15\,\mathrm{Kn}_1))\sqrt{t^*}\right] \cdot \exp\left[(1 + 8/(15\,\mathrm{Kn}_1))^2 t^*\right]\right\}. \tag{49}$$

As mentioned already in Sect. 3.1.2 for the plane case, a rarefied gas needs a finite time to assume the final gas temperature T_{G} at the wall according to the temperature-jump boundary conditions. Figure 6 shows the temperature at the surface as a function of t^* for different values of the Knudsen number according to Eq. (49). It can be seen that the gas temperature for large times, $t^* \to \infty$, tends to T_{G}. The temperature limit T_{G} is shown in Fig. 7 as a function of the Knudsen number.



M10. Fig. 6. Gas temperature at the surface of a single sphere as a function of time for different values of the Knudsen number.



M10. Fig. 7. Temperature limit for large values of t^* at surface of single sphere as a function of Knudsen number.

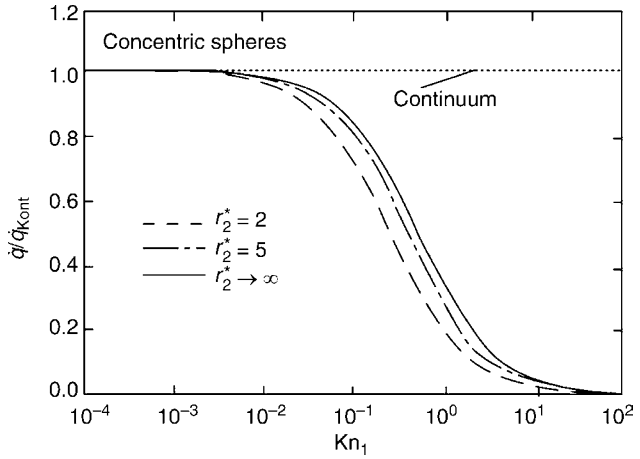
3.4.3 Generalizations for Arbitrary Knudsen Numbers

For the steady heat conduction between concentric spheres, Lees has presented approximate analytical solutions of the Boltzmann equation, using the same method as described in the cases of plane and cylindrical geometry. The results are valid for all Knudsen numbers [18]. For the heat flux, Lees obtains

$$\frac{\dot{q}}{\dot{q}_{\mathrm{Kont}}} = \frac{\dot{Q}}{\dot{Q}_{\mathrm{Kont}}} = \frac{1}{1 + (15/4)\,\mathrm{Kn}_1 r_2^*/(r_2^* - 1)} \tag{50}$$

and for the temperature distribution

$$\frac{T(r^*) - T_2}{T_1 - T_2} = \left\{1 - \frac{\varphi}{2}\left[1 + \sin\left(\arccos\left(\frac{1}{r^*}\right)\right)\right] - (1 - \varphi)\frac{(r^* - 1)r_2^*}{(r_2^* - 1)r^*}\right\}, \tag{51}$$



M10. Fig. 8. Heat flux $\dot{q}/\dot{q}_{cont}$ for concentric spheres as a function of Knudsen number with ratio of radii as parameter.

where

$$\varphi = \left(1 + \frac{4}{15}\frac{1}{\mathrm{Kn}_1}\frac{r_2^* - 1}{r_2^*}\right)^{-1}. \tag{52}$$

The heat flux according to Eq. (50) is shown in Fig. 8 for a wide range of the Knudsen numbers with the ratio of radii as parameter. For the free-molecule regime, Kennard has derived the formula

$$\dot{Q}_{FM} = A_1\left[\frac{1}{\gamma_1} + \left(\frac{1}{r_2^*}\right)^2\left(\frac{1}{\gamma_2} - 1\right)\right]^{-1} \cdot \frac{c_v + R/2}{\sqrt{2\pi RT}}p(T_1 - T_2), \tag{53}$$

where A_1 is the surface of the inner sphere, and γ_1 and γ_2 are the accommodation coefficients [11]. Springer and Wan [45] give the formula

$$\frac{\dot{q}}{\dot{q}_{kont}} = \frac{\dot{Q}}{\dot{Q}_{Kont}} = \left(1 + \frac{15}{4}\frac{\mathrm{Kn}_1}{\gamma_1}\frac{r_2^*}{r_2^* - 1}\right)^{-1}, \tag{54}$$

where γ_1 is the accommodation coefficient of the inner sphere. It should be mentioned that the accommodation coefficient of the outer cylinder is irrelevant if $r_2^* \gg 1$. Sherman's rule in Eq. (8) is valid here. The relations described in this section have been obtained for monatomic gases. The results can be extended to polyatomic gases by multiplying the Knudsen number with the correction factor f defined by Eq. (14).

4 Solutions for Gases in Motion

4.1 Introduction

In the previous chapters, heat conduction in rarefied gases at rest has been discussed. The Knudsen number $\mathrm{Kn} = l/L$ also plays, of course, an important role for rarefied gases in motion. With Eqs. (4) and (5), the Knudsen number can be expressed as a function of the viscosity as

$$\mathrm{Kn} = 2\eta/(\rho\bar{c}L). \tag{55}$$

Introducing a characteristic velocity u of the flow one obtains with Eq. (2) the relation

$$\mathrm{Kn} \approx \mathrm{Ma}/\mathrm{Re}, \tag{56}$$

where $\mathrm{Ma} = u/\sqrt{\kappa RT}$ is the Mach number and $\mathrm{Re} = (\rho\ u\ L)/\eta$, the Reynolds number. In the literature, results for rarefied gases in motion are therefore often represented as function of Re/Ma. At high Mach numbers the compressibility of the medium has to be taken into account. Studies of rarefied gases at high Mach numbers are of special importance for hypersonic flows [46–49]. In the following, a few examples of internal flows at low Mach numbers are discussed. Therefore, one has in this case $\mathrm{Ma}^2 \ll 1$. Due to the low Mach number, rarefaction effects play a role only when the Reynolds number does not become too large. For Mach numbers of 0.25 and Reynolds numbers up to approximately 40, the Knudsen number is of the order of 0.01. Compressible flows are discussed by Knobling [50].

4.2 Plane Couette Flow for Arbitrary Knudsen Numbers

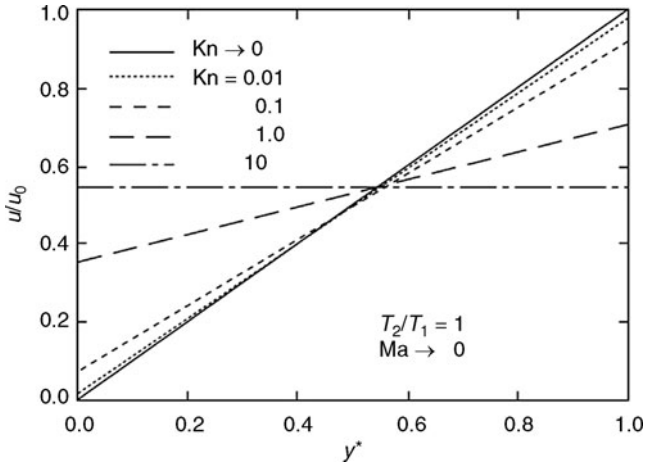
The plane Couette flow deals with the viscous flow between parallel plane plates. It is assumed that the lower plate is at rest, whereas the upper plate moves with the velocity u_0. The distance of the plates is s. In general, the temperatures of the two plates may be different from each other. For the following it is assumed that the temperature is T_1 for the lower plate and T_2 for the upper plate. In the continuum regime with very small Knudsen numbers $\mathrm{Kn} < 0.01$, the gas does not slip over the walls and assumes the temperatures of the plates. This behavior corresponds to the classical boundary conditions of the continuum theory. It is well known that for $T_1 = T_2$ one has a linear velocity profile. With increasing Knudsen number temperature and velocity jumps are observed at the walls. As a consequence, the heat and momentum flux to the walls decrease when the gas becomes rarefied. Liu and Lees made use of a momentum method to obtain an approximate analytical solution of the Boltzmann equation for the problem of plane compressible Couette flow [51]. The results obtained are valid for all values of Knudsen number, Mach number, and temperature ratio T_2/T_1. For the representation of the results the Stanton number

$$\mathrm{St}_1 = \frac{\dot{q}y}{\rho_1\, c_{p,1}\, u_0\, (T_1 - T_2)} \tag{57}$$

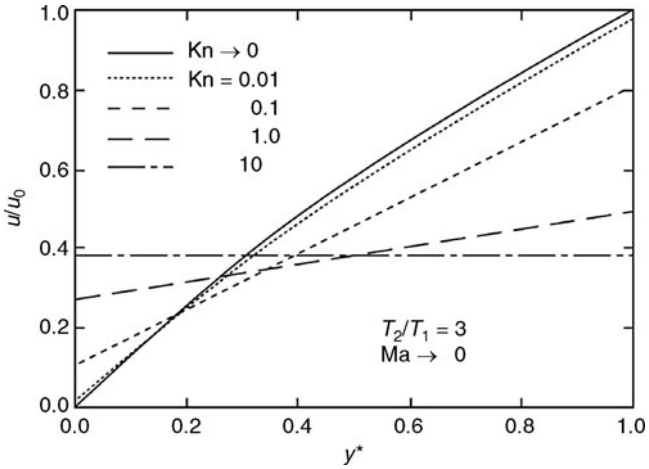
and the drag coefficient

$$c_{D,1} = \frac{p_{xy}}{1/2\rho_1\, u_0^2} \tag{58}$$

are introduced. The quantity q_y represents the heat flux perpendicular to the plates and p_{xy} the shear stress. For the limit of small Mach numbers, i.e., for $\mathrm{Ma}^2 \ll 1$, Liu and Lees obtained analytical expressions for density, temperature, pressure, and velocity, which depend only on the temperature ratio T_2/T_1 and on the Knudsen number $\mathrm{Kn}_1 = l_1/s$. The same holds for the product of drag coefficient and Mach number $c_{D,1}\,\mathrm{Ma}_1$ and for the product of Stanton number and Mach number $\mathrm{St}_1\,\mathrm{Ma}_1$, where $\mathrm{Ma}_1 = u_0/\sqrt{\kappa RT_1}$. For higher Mach numbers, the equations in [51] have to be solved by iteration. Figure 9 shows the

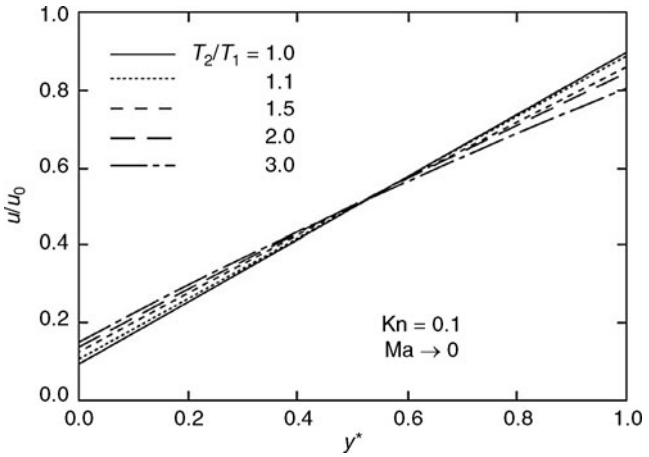


M10. Fig. 9. Velocity profile for plane Couette flow with $T_2 = T_1$ for various values of Knudsen number.



M10. Fig. 10. Velocity profile for plane Couette flow with $T_2/T_1 = 3$ for various values of Knudsen number.

results of the method for the velocity of monatomic gases between the plates as a function of $y^* = y/s$ for $T_1 = T_2$ and different values of the Knudsen number. All velocity profiles exhibit a constant slope. The velocity jump at the walls increases with increasing Knudsen number and has the same magnitude at both boundaries. The solid line for the continuum regime shows no temperature jump. Figure 10 shows velocity profiles for the temperature ratio $T_2/T_1 = 3$ and for different values of the Knudsen number. The profiles show a curvature, which decreases with increasing Knudsen number. The temperature jumps are in this case larger at the hot wall than at the cold wall. In Fig. 11, the influence of the temperature ratio on the velocity profile is visible for constant Knudsen number. With increasing temperature ratio the velocity jump at the wall increases. In Fig. 12, the quantity $St_1 \cdot Ma_1$ is shown as a function of the Knudsen number Kn_1 for different temperature ratios.



M10. Fig. 11. Velocity profile for plane Couette flow at Kn = 0.1 for various values of temperature ratio.

4.3 Cylindrical Poiseuille Flow at Constant Wall Temperature for a Wide Knudsen Number Range

The fully developed steady laminar viscous flow in a long tube of circular cross section is described by Poiseuille's formula. In the deduction, it is assumed that the pressure is constant over any cross section of the tube. In the continuum regime, the gas layer in contact with the wall adheres to it. It is well known that the resulting velocity profile is described by a parabola, whereas the flow rate is proportional to the pressure drop and to the fourth power of the tube radius. In the slip-flow regime, a Knudsen number effect is expected [11–13, 25]. The Knudsen number is defined by

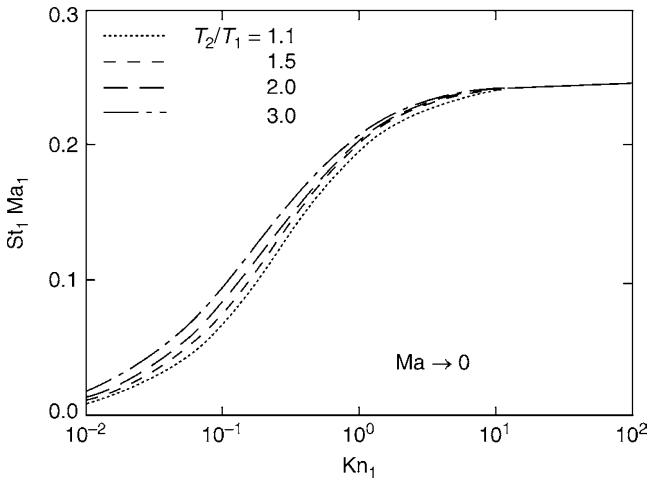
$$\mathrm{Kn} = l/r_0, \tag{59}$$

where r_0 is the radius of the tube. In the literature, the so-called rarefaction parameter

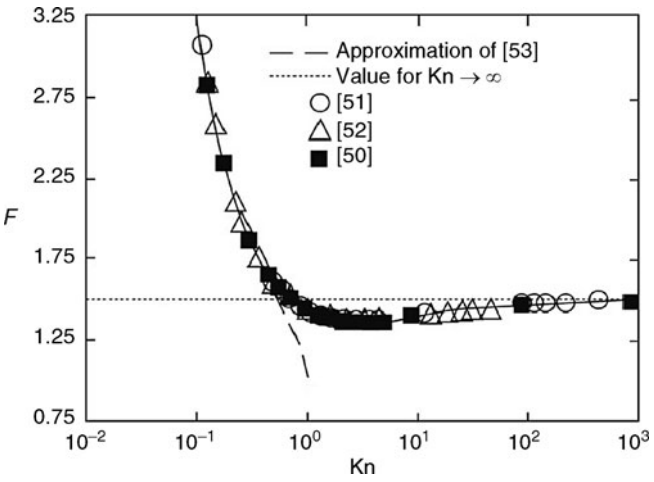
$$\delta = \frac{\sqrt{\pi}}{2}\frac{r_0}{l} \sim \frac{1}{\mathrm{Kn}} \tag{60}$$

is often used instead of the Knudsen number [52]. Besides velocity jumps at the walls, a new phenomenon may be observed in flows through very long tubes, where the pressure drop along the tube may cause an increase of the mean free path so large that the Knudsen number changes by orders of magnitude. As a consequence different flow regimes may develop in the gas flow along the tube, in extreme situations from the continuum to the free-molecule regime. This is discussed later.

The problem of cylindrical tube flow in rarefied gases has been the subject of numerous investigations. In 1909, Knudsen described experiments in which he found a minimum of the mass flow for decreasing pressure [53]. In search for explanation of this minimum various methods for the solution of the linearized Boltzmann equation for Poiseuille flow in tubes have been developed [4, 54–58]. Many investigators made two assumptions. Entrance effects were neglected, which means that the length of the tube L is much larger than the tube radius r_0. In order to justify the linearization of the Boltzmann equation, it was assumed that the Mach number is small. For the pressure difference, it is assumed



M10. Fig. 12. Product of Stanton number and Mach number for plane Couette flow as a function of Knudsen number with temperature ratio as parameter.



M10. Fig. 13. Mass flow according to Eq. (65) for isothermal cylindrical Poiseuille flow as a function of Knudsen number.

$$\frac{|p_1 - p_2|}{\bar{p}} \leq 1 \quad \text{with } \bar{p} = (p_1 + p_2)/2, \tag{61}$$

where $p_1 - p_2$ is the driving pressure difference. For technical applications, the paper by Sharipov and Seleznev is useful since it discusses the results for the flow of a rarefied gas through a tube with circular cross section for large pressure differences at constant temperature [52]. Sharipov and Seleznev show that linearization of the Boltzmann equation is allowed only for the general conditions

$$\frac{r_0}{L}\frac{|p_1 - p_2|}{\bar{p}} \ll 1 \quad \text{for } \overline{\text{Kn}} \geq 1 \tag{62}$$

or

$$\frac{1}{\overline{\text{Kn}}}\frac{r_0}{L}\frac{|p_1 - p_2|}{\bar{p}} \ll 1 \quad \text{for } \overline{\text{Kn}} \leq 1, \tag{63}$$

where the Knudsen number $\overline{\text{Kn}}$ is based on the mean free path

$$\bar{l} = (l_1 + l_2)/2 \tag{64}$$

as an average of states 1 and 2. At large pressure differences, a mixed flow with a transition from continuum conditions at the tube entrance to free-molecule conditions at the exit of the tube prevails. In the literature, the mass flow $\dot{M}$ is often described by the dimensionless quantity

$$F = \frac{-\dot{M}\sqrt{2RT}}{(\mathrm{d}p/\mathrm{d}x)\pi r_0^3}. \tag{65}$$

It should be mentioned that the quantity F changes its value in the case of the described mixed flow since it depends on the pressure gradient $\mathrm{d}p/\mathrm{d}x$. In Fig. 13, the quantity F is presented on the basis of a chart in [51]. In the same figure, the approximation

$$F = 0.2216\ \text{Kn}^{-1} + 1.0162 + 0.6194\ \text{Kn} - 0.7743\ \text{Kn}^2 \tag{66}$$

which according to Lo and Loyalka [58] is valid for small Knudsen numbers. The quantity F has a minimum in the transition regime, as can be seen in Fig. 13. It is interesting to mention that with Sherman's Eq. (8) this minimum is not obtained [58]. The mass flow $\dot{M}$ is of course constant. Sharipov and Seleznev therefore characterize the mass flow with the quantity

$$B = -\frac{L}{(p_1 - p_2)}\frac{M\sqrt{2RT}}{\pi r_0^3} \tag{67}$$

which is constant over the entire length of the tube. It can be shown that the value of this quantity can be obtained from F with the relation

$$B(\delta_1,\ \delta_2) = F((\delta_1 + \delta_2)/2) \tag{68}$$

for arbitrary pressure differences, if the conditions of Eqs. (62) and (63) are fulfilled. The values of B as a function of the rarefaction factor at the entrance and at the exit of the tube δ_1 and δ_2 may be found in [52].

Example 5

For determining the mass flow in a long tube the pressure is measured at two positions with the distance $L_1 = 1$ m. The measurements give the values $p_1 = 12$ Pa and $p_2 = 10$ Pa. The gas of the flow is nitrogen with the temperature 298 K. The radius of the tube is 5 mm.

(a) What is the mass flow?
(b) What is the mean flow velocity?

Solution

(a) Using Eqs. (1–5), the mean Knudsen number $\overline{\text{Kn}}$ is determined with the values of the dynamic viscosity from Subchap. D3.1:

$$\overline{\text{Kn}} = \sqrt{\frac{\pi}{2}}\frac{\eta\sqrt{RT}}{\bar{p}r_0} = 1.253\frac{1.78 \cdot 10^{-5}\sqrt{296.8 \cdot 298}}{11 \cdot 5 \cdot 10^{-3}} = 0.1206.$$

For the Knudsen numbers at the entrance and at the exit one finds $\text{Kn}_1 = 0.1206 \cdot 11/12 = 0.1106$ and $\text{Kn}_2 = 0.1206 \cdot 11/10 = 0.1327$. The gas is therefore in the slip-flow regime. For

determining the mass flow Eq. (65) is used. The quantity F can be taken from Fig. 13, or for the present case can be calculated with the approximation of Eq. (66) for $\overline{\mathrm{Kn}}$. One finds $F = 2.917$. With Eq. (65) it follows

$$\dot{M} = \frac{-F\mathrm{d}p/\mathrm{d}x\pi r_0^3}{\sqrt{2RT}} = \frac{(-2.917)\cdot(-2/1)\cdot 3.1415\cdot(5\cdot 10^{-3})^3}{\sqrt{2\cdot 296.8\cdot 298}} = 5.45\cdot 10^{-9}\ \mathrm{kg/s}.$$

(b) For the density one has $\bar{\rho} = \bar{p}/(\mathrm{RT}) = 11/(296.8\cdot 298) = 1.244\cdot 10^{-4}\ \mathrm{kg/m^3}$ and thus from the volume flow $\dot{M}/\rho$ the mean velocity

$$\bar{u} = \dot{M}/(\rho\pi r_0^2) = 5.45\cdot 10^{-9}\Big/\left(1.244\cdot 10^{-4}\cdot 3.1415\cdot(5\cdot 10^{-3})^2\right) = 0.56\ \mathrm{m/s}.$$

4.4 Cylindrical Poiseuille Flow with Constant Heat Flux at Wall for Knudsen Numbers Kn < 0.1

The relations described in the preceding chapter are for the isothermal case. Solutions for the temperature-jump and slip-flow regime have been described by Sparrow and Lin [59]. These authors deal with the case of constant wall temperature as well as with the case of constant heat flux at the wall. Velocity jumps as well as temperature jumps had to be taken into account. For constant heat flux at the wall the authors give for the Nusselt number the relation

$$\mathrm{Nu} = \frac{\frac{24}{11}}{1-\frac{6}{11}\frac{u(r_0)}{\bar{u}}+\frac{1}{11}\left(\frac{u(r_0)}{\bar{u}}\right)^2+\frac{24}{11}\frac{g}{r_0}}. \tag{69}$$

Here, the velocity ratio

$$\frac{u(r_0)}{\bar{u}} = \frac{1}{1+r_0/(4\zeta)} \tag{70}$$

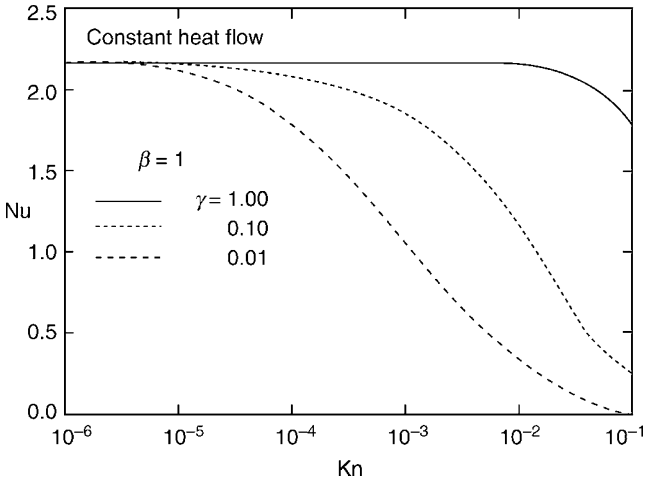
and the coefficient g defined by Eqs. (13) and (14) have been used, and $\overline{u}$ is the velocity averaged over the cross section of the tube. The quantities $u(r_0)$ and ζ are defined in Eqs. (10) and (11), and the Nusselt number is given by

$$\mathrm{Nu} = \frac{\dot{q}}{(T_W-\bar{T})}\frac{r_0}{\lambda}, \tag{71}$$

where

$$\bar{T} = \frac{\int_0^{r_0} 2\pi r u(r)T(r)\mathrm{d}r}{\int_0^{r_0} 2\pi r u(r)\mathrm{d}r}. \tag{72}$$

Figure 14 shows a graphical represention of Nu according to Eq. (69) for monatomic gases as a function of Knudsen number for various values of the accommodation coefficient γ. The solution for the case of constant wall temperature cannot be given in closed form. It has, however, been shown that the Nusselt number for this case does not deviate much from the values in Fig. 14. They are approximately 5% higher [59].



M10. Fig. 14. Nusselt number according to Eq. (69) for laminar tube flow with constant heat flux at the wall as a function of Knudsen number.

Example 6

Consider the laminar flow of air in a tube with radius 6 cm. The air is heated by a constant heat flow from the walls. The flow velocity averaged over a cross section is $\bar{u} = 10$ m/s. The average temperature in this cross section is 50°C, the wall temperature is 50.5°C, and the pressure is 7 Pa. The accommodation coefficient for the temperature has the value 0.5, and the accommodation coefficient for tangential momentum is 1. (a) What is the velocity at the wall? (b) What is the heat flow to the tube?

Solution

(a) By calculating the Knudsen number with Eqs. (1–5) and using the viscosity from Subchap. D2.2 one obtains

$$\mathrm{Kn} = \sqrt{\frac{\pi}{2}}\frac{\eta\sqrt{\mathrm{RT}}}{p r_0} = 1.253\frac{19.67\cdot 10^{-6}\sqrt{287.2\cdot 323}}{7\cdot 0.06} = 0.0179.$$

It follows that the flow is in the temperature-jump and slip-flow regime. This means that Eqs. (69–72) are valid. Using Eqs. (11) and (70) the velocity at the wall can be determined. With $\beta = 1$ Eq. (11) gives

$$\zeta = I = r_0\,\mathrm{Kn} = 1.07\,\mathrm{mm}$$

and thus

$$\frac{u(r_0)}{\bar{u}} = \frac{1}{1+r_0/(4\cdot\zeta)} = \frac{1}{1+0.06/(4\cdot 1.07\cdot 10^{-3})} = 6.66\cdot 10^{-2}.$$

It follows $u\,(r_0) = 0.66$ m/s.

(b) The Nusselt number can be determined with Eq. (69). The temperature-jump coefficient g follows from Eq. (13). With

$$f = \frac{16}{15}\cdot\frac{1}{0.711}\cdot\frac{1.4}{1+1.4} = 0.875.$$

Equation (14) gives

$$g = \frac{2-0.5}{0.5}\cdot\frac{15}{8}\cdot 0.875\cdot 1.07\cdot 10^{-3} = 5.26\cdot 10^{-3}\ \text{m} \quad \text{and} \quad g/r_0 = 0.088.$$

With Eq. (69) it follows for the Nusselt number

$$\text{Nu} = \frac{24/11}{1-\frac{6}{11}6.66\cdot 10^{-2}+\frac{1}{11}(6.66\cdot 10^{-2})^2+\frac{24}{11}0.088} = 1.89$$

With the value of the heat conductivity of air from Subchap. D2.2, it follows from the definition of the Nusselt number in Eq. (71) for the heat flux at the wall

$$\dot{q} = 1.89\cdot 27.88\cdot 10^{-3}\cdot(323.5-323)/0.06 = 0.44\ \text{W/m}^2.$$

M11 Spontaneous Condensation and Cavitation

Karlheinz Schaber[1] · *Günter H. Schnerr*[2]
[1]Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany
[2]Technische Universität München, Garching, Germany

1 Introduction

A spontaneous phase transition can be defined as the formation of a disperse phase in a supersaturated – i.e., metastable – bulk liquid or gaseous phase. As a characteristic feature the phase transition enthalpy of the growing disperse phase is provided or absorbed by the bulk phase, resulting in a change of the bulk phase temperature.

In contrast to this, phase transitions in technical processes usually take place at cooled or heated surfaces, and the phase transition enthalpy is transferred as a heat flow through a heat exchange surface.

In general, suspensions of tiny droplets or solid particles formed by spontaneous phase transitions or other mechanisms in a bulk gas phase are called aerosols. Suspensions of liquid droplets are also termed as fog or mist [1, 2]. Typical aerosol droplet sizes are smaller than 10 µm (1 µm = 10^{-6} m). Aerosols possess a degree of stability with respect to settling in a gravitational field. This is due to the thermal or Brownian motion of molecules and its impact on the dynamics of tiny particles.

For suspensions of bubbles in a liquid bulk phase there exists no special term. In contrast to aerosols, bubble suspensions are highly dynamic systems because after formation a rapid phase separation in the presence of a gravitational field takes place.

Nevertheless, although the dynamic behavior of aerosols and bubble suspensions is rather different, their formation by spontaneous phase transitions is dominated by the same basic mechanisms: the phase transition is initiated by nucleation in a supersaturated phase. Afterward, the nuclei grow by diffusion, coagulation, and/or coalescence.

Supersaturation of a bulk gaseous or liquid phase is a necessary precondition for nucleation. In order to quantify supersaturation of a liquid or gaseous phase a saturation ratio S can be defined in various ways. Here, an isothermal definition which relates the actual state of the supersaturated phase to the equilibrium state at the same temperature and composition is used.

For a gaseous phase the dew point is used as a reference

$$S = p_{\mathrm{vap}}(T, y_1, \ldots, y_{K-1}) / p_{\mathrm{sat}}(T, y_1, \ldots, y_{K-1}). \qquad (1a)$$

For a liquid phase the bubble point is used as a reference

$$S = p_{\mathrm{vap}}(T, x_1, \ldots, x_{K-1}) / p_{\mathrm{sat}}(T, x_1, \ldots, x_{K-1}), \qquad (1b)$$

where p_{vap} is the actual total pressure of all condensable (vapor) components i ($i = 1, \ldots, K$). Inert components such as carrier

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_60,

gases can be excluded, if they are not relevant for the phase equilibrium, i.e., if they are not soluble in the liquid phase.

Supersaturation ($S > 1$) may appear in various technical processes. Typical examples are

(1) Adiabatic mixing of gas–vapor mixtures with different temperatures.
(2) Simultaneous heat and mass transfer during absorption, evaporation, and condensation in the presence of inert gases can entail an intersection of the dew point line by the process trajectory, describing the change of state of the gas phase.
(3) Chemical reactions in the gas phase followed by desublimation of the generated substances.
(4) Due to the temperature and pressure drops during the adiabatic expansion of pure gases or mixtures the dew point may be exceeded.
(5) In rapid flows of liquids and in reflected shock waves the pressure can drop below the vapor pressure.

Supersaturation is a necessary but not a sufficient precondition for a spontaneous phase transition. The saturation must exceed a critical value S_{crit} before a phase transition is initiated either by heterogeneous or homogeneous nucleation. Heterogeneous nucleation requires foreign nuclei in the supersaturated bulk phase. If a sufficiently high concentration of nuclei is present, and if those are activated under the actual process conditions, nucleation usually takes place at values of S_{crit} close to 1.

In contrast to this, homogeneous nucleation requires a high degree of saturation because for the formation of critical molecule clusters (= homogeneous nuclei) a high activation energy barrier has to be surmounted.

The key parameter in nucleation is the nucleation rate J which is defined as the number of nuclei formed by homogeneous nucleation or activated in heterogeneous nucleation per unit volume and time. The dimension of J is usually given in $m^{-3}\ s^{-1}$ or $cm^{-3}\ s^{-1}$.

The critical saturation S_{crit} can be defined as the saturation S for which a spontaneous phase transition can be observed and measured, i.e., for which the nucleation rate is high enough

$$S_{crit} = S(J = 10^z\ \mathrm{cm^{-3}s^{-1}}). \tag{2}$$

The exponent z must be chosen according to the time scale of the considered process.

In Atmospheric Sciences it is convenient to choose $z = 0$.

In Process Technology where the flow residence time in an apparatus or in a machine is in the range of seconds usually z is chosen between 4 and 6 [3].

Gases or liquids under technical process conditions always contain a certain amount of small particles which can be activated as nuclei in supersaturated phases.

Consequently, in Process Technology heterogeneous and homogeneous nucleation often take place simultaneously.

Furthermore, there is no sharp transition between nucleation and growth. Both mechanisms overlap. During a nucleation event, even if the first formed nuclei would be growing, nucleation goes on until the saturation of the bulk phase drops to values lower than S_{crit}.

In this chapter of the Heat Atlas gas-to-liquid and liquid-to-gas spontaneous phase transitions in flowing media are considered.

2 Spontaneous Condensation

2.1 Nucleation

2.1.1 Homogeneous Nucleation of Pure Substances

The kinetics of a phase transition can be explained on a microscopic scale as a statistical phenomenon. Colliding molecules form clusters which decompose again at low supersaturations. Increasing supersaturation increases the probability that molecule clusters or the so-called embryos reach a critical size. Such critical molecule clusters are called nuclei. In the classical theory of homogeneous nucleation, the nucleation rate J, which is the number of emerging nuclei per unit volume and time, can be predicted by the basic equation for nucleation phenomena

$$J = K \exp\left(-\frac{\Delta G^*}{kT}\right), \tag{3}$$

where K is a frequency factor which indicates the number of collisions per unit volume and time, and the exponential term is the probability of the formation of critical clusters.

G^* is the Gibbs free energy required to form a nucleus of critical radius r^*, and k is the Boltzmann constant.

The nucleus is considered a small sphere of radius r^* forming an unstable thermodynamic equilibrium with the surrounding supersaturated gas phase which is determined by the Kelvin equation (capillarity approximation)

$$r^* = \frac{2\sigma v_L \widetilde{M}}{\Delta\mu}, \tag{4}$$

where σ is the surface tension, v_L is the specific liquid volume, and $\Delta\mu$ the difference of the pure component chemical potentials between the supersaturated gas phase and the liquid phase at bulk gas phase conditions (p_{vap}, T). For an incompressible nucleus

$$\begin{aligned}\Delta\mu &= \mu_{vap}(p_{vap}, T) - \mu_L(p_{vap}, T)\\ &= \tilde{R}T \ln\frac{\varphi p_{vap}}{\varphi_{sat} p_{sat}(T)} - \tilde{v}_L(p_{vap} - p_{sat}(T)).\end{aligned} \tag{5}$$

For pressures sufficiently far below the critical pressure the second term of Eq. (5) can be neglected. Furthermore, if the vapor behaves like an ideal gas the fugacity coefficients φ and φ_{sat} at bulk gas phase and at saturation conditions, respectively, can be set to 1, and Eq. (5) can be written

$$\Delta\mu^{id} = \tilde{R}T \ln S, \tag{6}$$

where $S = p_{vap}/p_{sat}(T)$ is the saturation ratio.

The Gibbs free energy for the formation of a nucleus is given by

$$\Delta G^* = (4/3)\pi\sigma r^{*2}. \tag{7}$$

Inserting Eq. (4) yields

$$\Delta G^* = \frac{16}{3}\pi\frac{\sigma^3 v_L^2 \widetilde{M}^2}{(\Delta\mu)^2}. \tag{8}$$

If the exponent of Eq. (3) is represented by Eqs. (6) and (8) one obtains

$$(\Delta G^*/kT)^{\mathrm{id}} = \frac{16\pi}{3\mathrm{k}}\left(\frac{\sigma}{T}\right)^3\left[\frac{\nu_\mathrm{L}\widetilde{M}}{\tilde{R}\ln S}\right]^2. \tag{9}$$

The characteristic feature of Eq. (9) is the strong dependence of the exponent on surface tension, temperature, and saturation degree.

The classical theory of homogeneous nucleation has been developed mainly by Volmer and Weber, Farkas, Becker and Döring, Zeldovich, and Frenkel [4]. Summaries on comprehensive treatments of nucleation are given in various publications [1, 5–7].

For the calculation of the frequency factor K, the Volmer–Frenkel approach modified by Feder et al. is used [8]

$$K = \Theta Z \alpha_\mathrm{c}\left(\frac{1}{4}n_1\bar{c}_1\mathrm{O}^*\right)n_1. \tag{10}$$

where n_1 is the number density of monomers, and $\bar{c}_1$ the mean monomer velocity

$$\bar{c}_1 = \left(\frac{8\tilde{R}T}{\pi\widetilde{M}}\right)^{1/2}. \tag{11}$$

The condensation coefficient α_c (sticking coefficient) multiplied by the collision rate ($n_1\ \bar{c}_1\ O^*/4$) describes the number of monomers impacting on the surface O^* ($= 4\pi r^{*2}$) of a critical cluster. For the condensation coefficient α_c usually values between 0.5 and 1 are assumed. The nonisothermal factor Θ

$$\begin{aligned}\Theta &= b^2/(b^2+q^2),\ b^2 = \tilde{R}T^2\\ &\left\{\left(\tilde{c}_{\mathrm{v,vap}}+\frac{\tilde{R}}{2}\right)+\frac{1-y_\mathrm{vap}}{y_\mathrm{vap}}\sqrt{\frac{\widetilde{M}_\mathrm{vap}}{\widetilde{M}_\mathrm{cg}}}\left(\tilde{c}_{\mathrm{v,cg}}+\frac{\tilde{R}}{2}\right)\right\},\\ q^2 &= \left\{\tilde{h}_\mathrm{vap}(T,p_\mathrm{vap})-\tilde{h}_{\mathrm{L,sat}}(T)-\frac{\tilde{R}}{2}T-\frac{2}{r^*}\frac{\sigma\widetilde{M}_\mathrm{vap}}{\rho_{\mathrm{L,sat}}}\right\}\end{aligned} \tag{12}$$

covers the deviation from the isothermal nucleation model. For gas–vapor mixtures with extreme low concentrations of the condensing vapor Θ tends toward 1.

The Zeldovich factor Z

$$Z = \left(\frac{\Delta G^*}{3\pi kT(i^*)^2}\right)^{1/2} \tag{13}$$

can be interpreted as a correction in order to guarantee a steady-state population of subcritical clusters during nucleation. Therefore, growing nuclei have to be replaced by new monomers. The number of monomers i^* on a critical cluster (nucleus) is given by a simple geometric approach

$$i^* = \frac{4}{3}\pi\frac{(r^*)^3}{m_1\nu_\mathrm{L}}, \tag{14}$$

where m_1 is the mass of a molecule, and ν_L the specific liquid volume.

The classical nucleation theory is a sufficiently good approach for a great variety of technical nucleation problems [9–19]. The isothermal dependence of the nucleation rate on saturation ratio is well predicted: experimental and theoretical slopes of J versus S are in good agreement. But the temperature dependence of the nucleation rate is often systematically different from that predicted by the classical theory. To overcome this problem Wölk et al. suggest empirical correction functions for the nucleation rate based on precise experimental data [20].

Some authors suggest introducing the factor $(1/S)$ in Eq. (10). It results from a correct treatment of the nucleation kinetics [6]. Nearly all comparisons of classical nucleation theory with experiment have omitted this factor, but it would be more correct to include it. Furthermore, one must be aware that in principle the surface tension of nuclei with typical diameters in the range of 1 nm is a function of the droplet radius [21]. But this fact is normally neglected in literature.

Finally, recent progress in applying molecular dynamic simulation to nucleation of pure substances should be mentioned. With this method it is possible to predict realistic nucleation rates if the intermolecular interactions of the substance can be described by simple but suitable molecular models [7, 22].

The following example should give an insight in the order of magnitude of the relevant nucleation parameters. Based on Eqs. (3), (9), (10–13) the values of Table 1 have been calculated for the nucleation of pure water vapor at $t = 20°\mathrm{C}$ (and 60°C) assuming $\alpha_\mathrm{C} = 1$. Water vapor is treated as an ideal gas.

Following properties have been used:

For 20°C: $p_\mathrm{sat}(T) = 23.37$ mbar; $\rho_\mathrm{vap} = 0.0173$ kg/m^3; $\sigma = 0.07274$ N/m; $\rho_\mathrm{L} = 988$ kg/m^3;

For 60°C: $p_\mathrm{sat}(\mathrm{T}) = 199.0$ mbar; $\rho_\mathrm{vap} = 0.1302$ kg/m^3; $\sigma = 0.06619$ N/m; $\rho_\mathrm{L} = 983$kg/m^3.

The values of Table 1 demonstrate the distinguishing feature of Eq. (3) which is the extremely sharp dependence of the nucleation rate on the saturation degree. But it is obvious that the frequency factor K is nearly independent of the saturation degree S.

With increasing temperature the nucleation rate increases at constant saturation. For a temperature of 60°C nucleation rates in the order of 10^6 cm^{-3} s^{-1} arise at $S = 2.8$.

Furthermore, in the presence of an inert gas the nonisothermal factor Θ and consequently, the nucleation rate would increase.

2.1.2 Homogeneous Nucleation of Binary Mixtures

The extension of the classical nucleation theory to binary mixtures was pioneered by Flood [23], Neumann und Döring [24],

M11. Table 1. Nucleation rate J of pure water vapor at 20°C dependent on the saturation S

S	r^*, 10^{-9} m	K, cm^{-3} s^{-1}	$\exp(-\Delta G^*/kT)$	J, cm^{-3} s^{-1}
2	1.55	6.0×10^{23}	2.2×10^{-79}	1.3×10^{-55}
3	0.98	1.4×10^{24}	4.9×10^{-32}	6.8×10^{-8}
3.5	0.86	1.9×10^{24}	8.3×10^{-25}	1.6×10^{0}
4	0.78	2.5×10^{24}	2.2×10^{-20}	5.4×10^{4}
4.2	0.75	2.8×10^{24}	4.5×10^{-19}	1.2×10^{6}
4.5	0.71	3.2×10^{24}	2.0×10^{-17}	6.3×10^{7}
5	0.67	3.9×10^{24}	2.6×10^{-15}	1.0×10^{10}
6	0.60	5.7×10^{24}	1.7×10^{-12}	9.6×10^{12}

and Reiss [25]. An actual survey on the state of the art is given, for instance, by Schmelzer [7] and Vehkamäki [26].

For condensing vapor mixtures the same basic Eqs. (3), (7), and (9) developed for pure vapors are applied. For pressures far below the component critical pressures, incompressible liquid droplets, and an ideal gas phase Eq. (9) can be written

$$(\Delta G^*/kT)^{\mathrm{id}} = \frac{16\pi}{3k}\left(\frac{\sigma(x^*)}{T}\right)^3\left[\frac{\nu_{\mathrm{L}}(x^*)\widetilde{M}(x^*)}{\tilde{R}\ln S}\right]^2. \tag{15}$$

The saturation ratio for a binary mixture of components A and B is defined according to Flood [23]

$$S = S_{\mathrm{A}}^{x^*} S_{\mathrm{B}}^{(1-x^*)}, \tag{16}$$

where S_{A} and S_{B} are the partial saturation degrees, and x^* is the mole fraction of component A in the critical cluster. The partial saturation ratios are defined in analogy to the pure component saturation ratio

$$S_i = p_i/p_{i,\mathrm{sat}}(x^*, T), \tag{17}$$

p_i is the partial pressure of component i in the supersaturated gas phase, and $p_{i,\mathrm{sat}}$ is the corresponding partial saturation pressure over a liquid solution with a flat surface and the composition x^* of the critical cluster. In order to calculate $p_{i,\mathrm{sat}}$ the extended Raoult's law can be applied

$$p_{i,\mathrm{sat}} = x_i^* \gamma_i \; p_{0i,\mathrm{sat}}(T), \tag{18}$$

where $p_{0i,\mathrm{sat}}$ is the pure component vapor pressure, and γ_i is the activity coefficient.

The composition of the critical nucleus can be determined using the generalized Kelvin equations (Gibbs–Thomson equations) for systems with an ideal gas phase

$$\tilde{R}T\ln S_i = \frac{2\sigma}{r^*}\tilde{v}_i(x^*), \tag{19}$$

where $\tilde{v}_i$ is the partial molar volume of the liquid mixture. Inserting A and B in Eq. (19) and division yields

$$\frac{\ln S_{\mathrm{A}}}{\ln S_{\mathrm{B}}} = \frac{\tilde{v}_{\mathrm{A}}(x^*)}{\tilde{v}_{\mathrm{B}}(x^*)}. \tag{20}$$

If the partial molar volumes as functions of the molar fractions x are known, the molar fraction x^* can be calculated by trial and error using Eq. (20) anticipating actual partial pressures of components A and B in the supersaturated gas phase. The partial molar volumes can be derived from the molar volume $\tilde{v}(T, p, x_i)$ of a binary mixture using the following equation:

$$\tilde{v}_i = \tilde{v} + (1 - x_i)\left(\frac{\partial\tilde{v}}{\partial x_i}\right)_{p,T}; \quad i = \mathrm{A}, \mathrm{B} \tag{21}$$

In order to estimate the frequency factor K, it has to be taken into account that in binary or multicomponent mixtures clusters of different composition exist. This leads to complex formulations which are described in the literature [26, 30].

For the rather frequent case, if one component (B) exists in great excess the frequency factor can be calculated with a simple equation [28]:

$$K = 4\pi r^{*2}\,\beta_{\mathrm{A}} n_{\mathrm{B}} \tag{22}$$

with

$$\beta_{\mathrm{A}} = n_{\mathrm{B}}\left(\frac{\tilde{R}T}{2\pi\widetilde{M}_{\mathrm{A}}}\right)^{1/2}, \tag{23}$$

where n_i are the number densities of molecules A and B.

The frequency factors for mixtures are in the same order of magnitude like those for pure components at similar conditions (T, p, S). That means, the nucleation rate or critical saturation according to Eq. (2) are dominated by the exponential factor in Eq. (3), too. Investigations of the binary systems HCl–H_2O [3] and HNO_3–H_2O [29] in the temperature range between 20°C and 60°C yield similar results for the critical saturation like those of water according to Table 1, if the excess component is water. In contrast to this, the H_2SO_4–H_2O system (with H_2O as excess component) shows different behavior [30]. Due to the extreme vapor pressure minimum at the azeotropic point the critical saturation for nucleation is higher than that for pure water ($S_{\mathrm{crit}} = 9$ at 25°C).

The saturation degree S^* of the classical nucleation theory defined by Eq. (16) is different from that defined by Eq. (1). By means of the latter it is possible to check quickly if a homogeneous gas phase is supersaturated or not. The calculation of S^* requires a heterogeneous system with nuclei of critical composition x^*.

Nevertheless, it has been shown for the HCl–H_2O system that S and S^* differ only in the range of 1% [3]. In contrast to this, for the H_2SO_4–H_2O system, which exhibits extreme phase behavior, the differences between S and S^* can be in the range of 5–30% [31].

2.1.3 Heterogeneous Nucleation

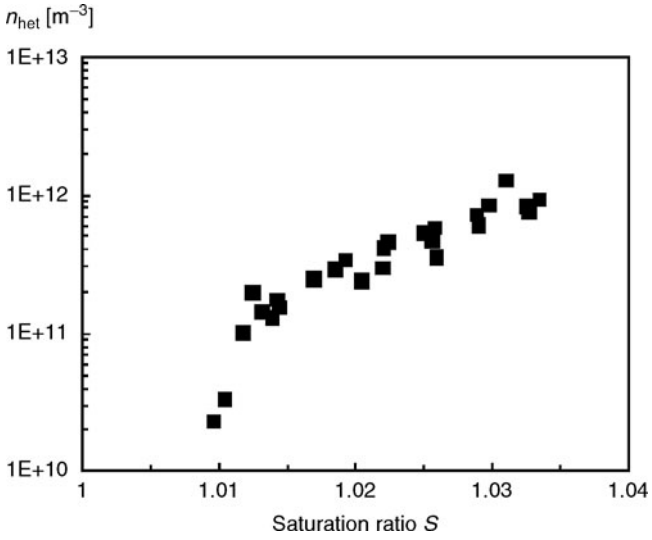
Heterogeneous nucleation requires foreign particles at which condensation or evaporation is already initiated in a slightly supersaturated gaseous or liquid phase.

If in a gaseous phase the foreign particles are insoluble in the condensing vapor, and if they are completely wettable (contact angle between liquid and solid equals to 180°), the critical saturation ratio can be estimated easily by the Kelvin equation which one obtains from Eqs. (4) and (6) for a pure component.

$$\tilde{R}T\,\ln\,S_{\mathrm{crit}} = \frac{2\sigma}{\mathrm{r}}\tilde{v}_{\mathrm{L}}. \tag{24}$$

Anticipating complete wettability of the foreign particle the first condensing thin liquid film has nearly the same curvature like that of a corresponding liquid droplet with the diameter of the particle. Consequently, Eq. (24) can be applied to estimate the critical saturation. For water at 20°C and a foreign particle diameter of 10 nm one gets $S_{\mathrm{crit}} = 1.237$, and for a particle with a diameter of 100 nm one obtains $S_{\mathrm{crit}} = 1.0215$. If the wettability of the particles is lower, the critical saturation ratio increases.

In the case of soluble particles, for example salt particles in condensing water, the Kelvin effect is compensated by the vapor pressure depression and thus the critical saturation ratio can drop slightly below $S_{\mathrm{crit}} = 1$ [2].



M11. Fig. 1. Formation of HCl aerosols initiated by heterogeneous nucleation in a flue gas quench cooler. Number concentration of activated particles versus (theoretical) saturation ratio (Gas inlet temperature: 200°C; adiabatic saturation temperature: 45°C; inlet gas concentration of HCl: 500–2,000 mg/m^3) [31].

In spontaneous condensation processes initiated by heterogeneous nucleation the concentration and the properties of foreign particles are decisive for the final concentration and sizes of the generated aerosol. Atmospheric air always contains sufficient particles as numerous investigations show [2, 5]. Typical concentrations of atmospheric particles are in the range of 10^4 cm^{-3} in rural and 10^6 cm^{-3} in urban regions. In industrial process gases high concentrations of tiny foreign particles can occur. Especially, in flue gases number concentrations of foreign particles between 10^6 and 10^8 cm^{-3} have been measured [27, 31, 32]. But usually size distributions as well as surface properties of foreign particles in process gases are unknown.

In general, for modeling and simulation of spontaneous condensation processes initiated by heterogeneous nucleation the key parameter is the number concentration of foreign nuclei which are activated under the special conditions of the considered process [33, 34]. This relevant number concentration can be detected only by experimental methods [32].

The activation (wettability) of foreign particles depends on the maximum saturation ratio which is reached in the considered process. As an example, experimental results of a flue gas scrubbing process are shown in Fig. 1. It can be seen that the number concentration of acid aerosol droplets increases with increasing maximum saturation ratio [31]. That means, the higher the saturation ratio, the more particles are activated as condensation sites. In this case the foreign nuclei are mainly soot particles from a gas burner.

In literature, the principles of heterogeneous nucleation are mostly described for condensation processes. But the fundamental features of heterogeneous nucleation, i.e., critical saturation is close to 1 if sufficient foreign nuclei can be activated, and phase transition at nearly equilibrium conditions are the same for evaporation processes.

2.2 Growth of Droplets

2.2.1 Growth by Condensation

Growth by condensation is the predominant mechanism of aerosol droplet enlargement after nucleation. The growth of droplets can be described by the transport equations for heat and mass transfer between the aerosol droplets and the supersaturated gas phase as well as by mass and energy balances. As the relative velocity between the growing small aerosol droplet and the surrounding flowing gas can be neglected, the mass transfer can be considered stationary diffusion, and the heat transfer can be considered stationary conductive heat transfer in the continuum regime. If the droplet radii are lower than the gas mean free path Λ the growth is governed by the kinetic theory [1].

Fuchs and Sutugin proposed the following approximate interpolation formula for the droplet growth rate of a condensing pure vapor in an inert gas which can be applied in the entire Knudsen number range [1]

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{\alpha_c D \tilde{v}_L}{r\tilde{R}T}\left(p_{vap} - p_{sat,r}(T,r)\right)\left[\frac{1+2\mathrm{Kn}}{1+3.42\mathrm{Kn}+5.32\mathrm{Kn}^2}\right]. \quad (25)$$

D is the Diffusion coefficient of the vapor in the gas phase, $\tilde{v}_L$ the molar volume of the liquid, Kn = Λ/d is the Knudsen number, and $p_{sat,r}$ is the saturation vapor pressure of the condensing component at the droplet surface, which can be calculated using the Kelvin equation

$$p_{sat,r} = p_{sat}(T)\exp\left\{\frac{2\sigma}{\mathrm{r}}\tilde{v}_L\right\}. \quad (26)$$

Equation (25) is valid for ideal gas conditions at low gradients of partial pressures and temperatures when the vapor phase mass fraction is low [35].

The accommodation coefficient α_C must be determined experimentally. Usually, α_C is assumed to be 1.

A more rigorous approach for higher vapor phase mass fractions including energy transfer has been presented by Gyarmathy [36].

$$\frac{\mathrm{d}r}{\mathrm{d}t} = \frac{1}{\rho_L}\frac{1-\frac{r^*}{r}}{r+1.59\Lambda}\frac{\ln S}{\frac{\Delta h_v^2}{\lambda R_{vap}T^2}+\frac{p-p_{vap}}{p}\frac{R_{vap}T}{p_{vap}D}}, \quad (27)$$

where Λ is the molecule mean free path, λ the thermal conductivity, Δh_v the evaporation enthalpy, p_{vap} the partial vapor pressure in the bulk phase, and R_{vap} the individual gas constant of the vapor.

It has to be emphasized that the bulk partial pressure p_{vap} and the equilibrium partial pressure at the droplet surface $p_{sat,r}$ as well as the temperatures change during droplet growth. The growth is finished if the saturation ratio in the bulk phase reaches $S = 1$.

In general, the growth of pure or multicomponent droplets has to be calculated by solving the mass and heat transfer equations simultaneously as shown in various publications [33, 34, 37].

In the pure vapor limit as the inert gas concentration tends to zero, transfer processes across the Knudsen layer may dominate and other transfer models have to be used [38–40].

2.2.2 Growth by Coagulation

Coagulation of particles or droplets decreases the number concentration of an aerosol. For particles with diameters $d < 1$ µm coagulation due to Brownian motion is the dominating coagulation mechanism [2]. For the estimation of collision rates, a theory based on Fickian Diffusion of particles has been developed by Smoluchowski [5]. According to this theory, the span $(t - t_0)$ in which an initial number concentration n_0 decreases to $n(t)$ can be calculated for a monodisperse aerosol using the following equations:

$$t - t_0 = -\int_{n_0}^{n(t)} \frac{\mathrm{d}n}{K_c(n)n^2} \tag{28}$$

with

$$K_c = \frac{4kTC_c}{3\eta}, \tag{29}$$

and the Cunningham correction for the Knudsen regime

$$C_c = 1 + \frac{\Lambda}{d}\left[2.514 + 0.8\,\exp\left(-0.55\frac{d}{\Lambda}\right)\right], \tag{30}$$

where Λ is the mean free path of molecules, and η is the viscosity of the carrier gas.

Assuming spherical particles, the diameter of the monodisperse particles increases with decreasing number concentration

$$d = d_0\left(\frac{n_0}{n}\right)^{1/3}. \tag{31}$$

The following example demonstrates that high initial number concentrations are reduced rapidly.

Example: Carrier gas: air at $t = 25°C$, and $p = 1$ bar

Initial diameter	d_0/µm	0.01	0.05	0.01
Initial number concentration	n_0/cm^{-3}	10^{12}	10^{12}	10^9
Final concentration	n/cm^{-3}	10^9	10^9	10^8
Span	$(t - t_0)$/s	0.91	2.24	2.25

3 Adiabatic Expansion of Pure Vapors and Gas–Vapor Mixtures

For demonstration and because of its practical importance, this chapter focuses on condensation of water vapor in nozzles of small or moderate size that are typical of many technical applications. Initially, the vapor phase is unsaturated and due to the fast time scale of the expansion phase transition is not established at thermodynamic equilibrium. Pure vapors or vapor/carrier gas mixtures supersaturate and start to nucleate either heterogeneously, homogeneously, or simultaneously both together. At maximum supersaturation S_{max}, the so-called Wilson point, substantial condensation with macroscopic latent heat release to the flow starts to grow and change local pressure, temperature, density, and flow velocity. The trend of all variations is toward choking conditions with Mach number $M = w/c = 1$. Therefore, initially subsonic flow accelerates toward $M = 1$, whereas supersonic flow decelerates to $M = 1$ [41]. As distinct from choking in adiabatic flow due to area variation, this is called thermal choking. If the average cooling rate $-\mathrm{d}T/\mathrm{d}t$ (K/µs) is of O(1), the Wilson point locates typically in the transonic regime with Mach numbers M_c = 1.1–1.3 at the Wilson point. Here, even a very small amount of heat addition to the flow of $q/c_pT_{01} < 0.1$ may cause thermal choking with $M = 1$ within the condensation zone. Then the flow pattern changes significantly and forms additional steady or high frequency moving shocks. Because of the strong coupling of flow and thermodynamics the sudden temperature increase across shocks decreases instantaneously the supersaturation, the driving potential for nucleation, and droplet growth. These instabilities driven by nonviscous interaction of local heat source distributions and compressibility of the fluid are of great practical importance.

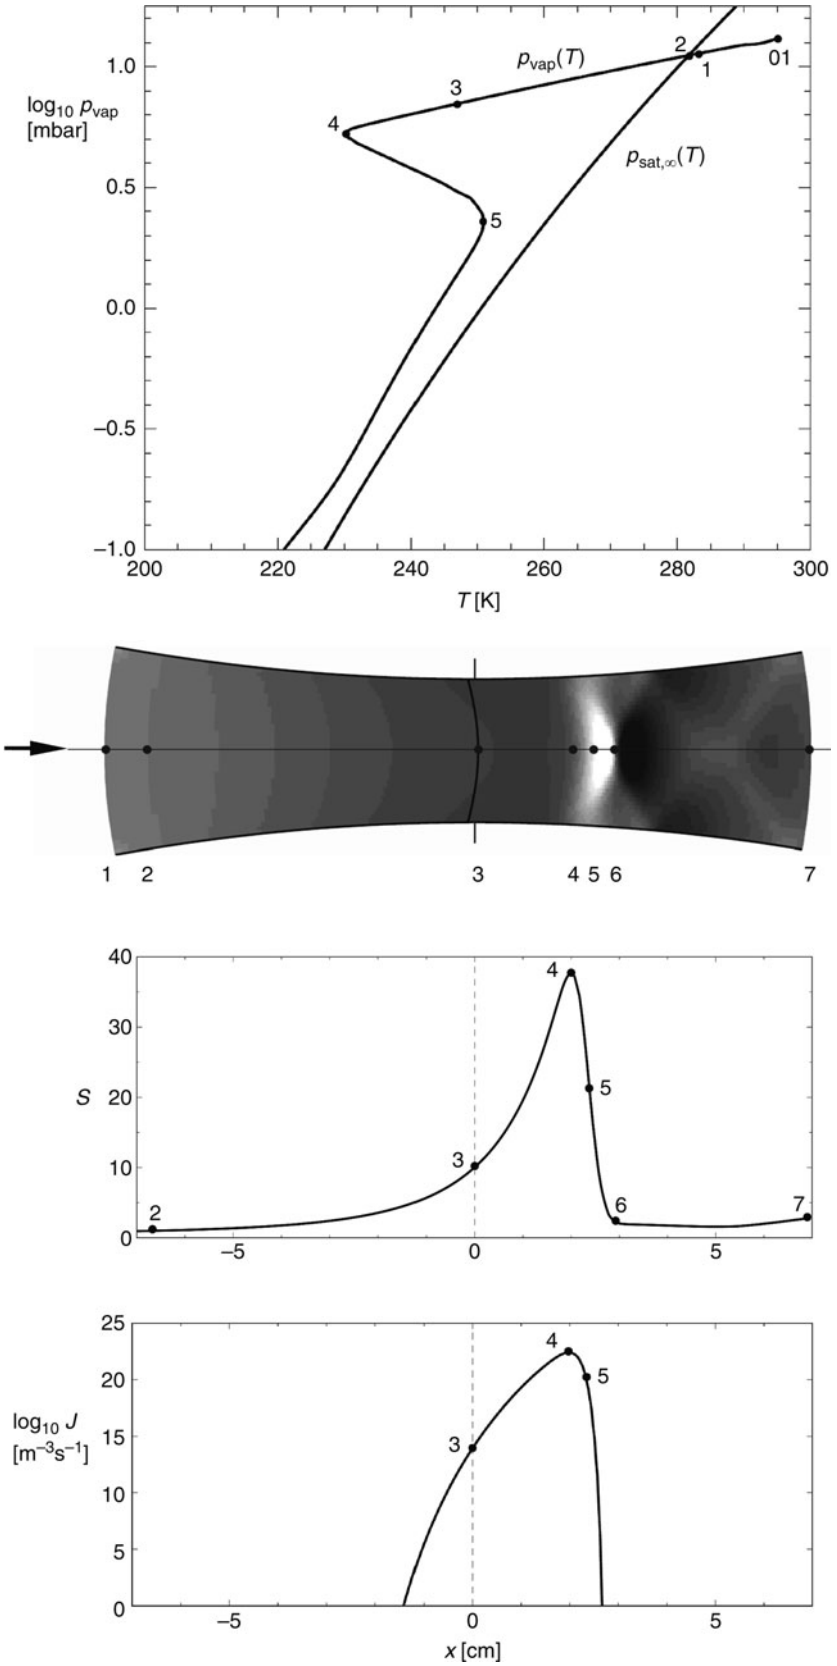
Adiabatic expansions of pure vapors can be modeled as isentropic flow, whereas in vapor/carrier gas mixtures the components undergo individual isentropic expansions only, if the molar specific heats are equal [41]. Depending on the cooling rate heterogeneous and homogeneous condensations separate quantitatively. Oswatitsch showed in his pioneering work [42, 43] that simultaneous heterogeneous condensation growing at natural impurities in atmospheric air does not alter quantitatively the homogeneous nucleation and droplet growth. However, artificial seeding with high particle concentration is well known for flow control to minimize nonequilibrium losses in low-pressure steam turbines.

Typical thermodynamic and flow dynamic properties of high-speed condensing water vapor flows are

Vapor phase initially unsaturated	
	$\rho_{vap} \approx$ O(10^{-2}–1 bar), $T \approx$ 300–450 K
	$\rho_{vap} \approx$ O(10^{-2}–1 kg m^{-3})
	$\rho_{carrier\ gas} \approx$ O(1 kg m^{-3})
	$\rho_{liq} \approx$ O(10^3 kg m^{-3})
Speed of sound	$c \approx$ O($4{\cdot}10^2$ m s^{-1})
Typically high flow speed	$M \approx$ O(1) transonic flow
Cooling rate	$-\mathrm{d}T/\mathrm{d}t \approx$ O(1 K/µs), nonequilibrium phase transition
Homogeneous nucleation	$J \approx$ O(10^{25} m^{-3} s^{-1})
Heterogeneous nuclei concentration	$n_{het} \approx$ O(10^{10} m^{-3})
Condensate mass fraction/wetness	$g/g_{max} \approx$ O(1–5·10^{-2})

3.1 Steady-State Phenomena

Figure 2 shows the numerical simulation of a quasi 1-D Laval nozzle flow with a weak supersonic compression caused by heat release after homogeneous nucleation and droplet growth. The adiabatic expansion of the vapor/carrier gas mixture crosses the equilibrium limit at (2) and continues until the Wilson point (4). Intense droplet growth decreases the vapor pressure of the mixture from (4)→(5), but simultaneously the static pressure of



M11. Fig. 2. Continuous supersonic compression in steady Laval nozzle flow due to homogeneous condensation of the moderate water vapor content of atmospheric air; reservoir conditions: $\Phi_0 = 50.0\%$, $T_{01} = 295.0$ K, $p_{01} = 1.0$ bar, $x = 8.26\ g_{vapor}/kg_{dry\ air}$, numerical simulation, inviscid flow modeling.

M11. Fig. 3. Shock in steady Laval nozzle flow due to homogeneous condensation of high relative humidity Φ_0 and high water vapor content of atmospheric air; reservoir conditions: Φ_0 = 65.0%, T_{01} = 295.0 K, p_{01} = 1.0 bar, x = 10.78 $g_{vapor}/kg_{dry\ air}$, numerical simulation, inviscid flow modeling.
From Top: phase diagram; numerical Schlieren picture – visualization of density gradients in main flow direction, saturation ratio S at the nozzle axis; and homogeneous nucleation rate J and growth of condensate mass fraction g/g_{max} at the nozzle axis.

the mixture increases. The remaining small supersaturation after (5) accounts for the fact that tiny droplets require a vapor pressure which is higher as that of a flat phase boundary. At (4) the supersaturation is $S \approx 40$ and the maximum nucleation rate is $J \approx 10^{22}$ m^{-3}s^{-1}. If the initial vapor pressure increases further a steady normal shock (4)→(5) forms (Fig. 3). At (5) after the shock, the flow remains still supersaturated and the complete latent heat addition happens downstream of the shock, starting in the local subsonic flow regime and reaccelerating to supersonic flow. Usually, the additional shock is called condensation shock, which is misleading to some extend, because the instantaneous temperature increase through this shock diminishes nucleation and further growth.

In practice it is important to know where condensation starts to grow in a nozzle with the given initial state. An empirical similarity law for the condensation onset defined by the Mach number M_c at the Wilson point was first published by Zierep and Lin [44, 45]. Here, thermodynamics of the problem is represented by a single parameter, the initial relative humidity Φ_0 at reservoir conditions, whereas flow dynamics, the time scale of the expansion, is represented by the exponent a. The time scale of the flow can be modeled either by the cooling rate $-dT/dt$ (K/μs) or by the temperature gradient $-dT/dx$ (K/cm). For slender plane nozzles, dT/dx depends on the wall curvature r^* and the height y^* at the throat

$$\left(-\frac{dT}{dx}\right)^* = 2 \cdot \frac{\gamma - 1}{\gamma + 1} \cdot T_{01} \cdot \sqrt{\frac{1}{\gamma + 1} \cdot \frac{1}{y^* r^*}} (\mathrm{K/cm}). \qquad (32)$$

Figure 4 shows equivalent nozzles with identical temperature gradients $-dT/dx$ (K/cm) at the axis.

Assuming isentropic expansion, the dependence of the Mach number M_c at the Wilson point can be formulated as

$$\Phi_0^a = \frac{\frac{\gamma+1}{2}}{1 + \frac{\gamma-1}{2} M_c^2} \quad 0 \le \Phi_0 \le 1. \qquad (33)$$

Increasing cooling rates at constant initial state result in higher onset Mach numbers M_c (Fig. 5). Equation (33) implies the limit of stability at $M_c = 1$. For condensation of water vapor in atmospheric air the parameter a was determined by Schnerr [46–48].

$$a = 0.0498 \cdot \left(-\frac{dT}{dx}(\mathrm{K/cm})\right)^{*0.3010}. \qquad (34)$$

If 2-D and 3-D flow pattern dominate, the previous slender nozzle approximation is no longer valid and the location of the condensation onset depends on the characteristic angle δ

$$\delta = \beta - \alpha, \qquad (35)$$

β is the angle between the isentropic iso-Mach line and the velocity vector at the onset, and α is the Mach angle (see Fig. 6).

If $\delta > 0$ close to local Wilson point conditions, weak wave interactions alter the flow structure only downstream of the condensation onset, as seen in Fig. 7. With increasing wall curvature the so-called X-shock becomes more distinct. It is caused by the intersection of characteristics of the same family. Obviously, the onset front of the parabolic white compression zone is not affected by these weak oblique shocks.

If $\delta < 0$ close to the local Wilson point, strong wave interaction alters the flow structure completely, including the location of the condensation onset. Close to the throat the condensation onset regime separates into parts (Fig. 8). In terms of gas dynamics, here the so-called subsonic heating fronts dominate.

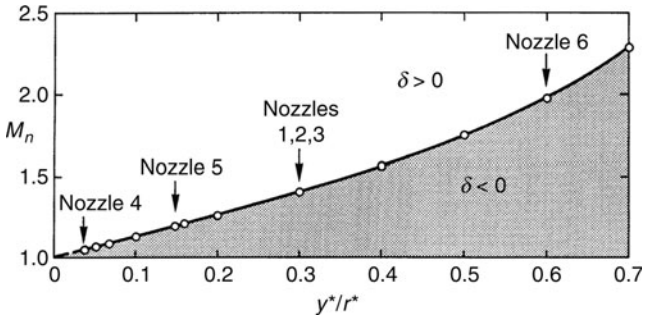
M11. Fig. 8. Complex interaction of pressure waves with homogeneous condensation in well curved circular arc nozzle S1; experimental Schlieren pictures, flow from left, relative humidity Φ_0 increases from top.
From top: Φ_0 = 62.2%, T_{01} = 288.8 K, x = 7.0 $g_{vapor}/kg_{dry\ air}$; Φ_0 = 63.2%, T_{01} = 293.0 K, x = 9.2 $g_{vapor}/kg_{dry\ air}$; Φ_0 = 71.3%, T_{01} = 286.8 K, x = 7.0 $g_{vapor}/kg_{dry\ air}$.

The limiting curve $\delta = 0$ separates these flow regimes. For $y^*/r^* < 0.3$ transonic condensation onset fronts predominate that remain undisturbed (Fig. 9).

If supersaturation in disperse two-phase flow mixtures increases again due to further expansion of the flow, a secondary nucleation zone establishes with quantitatively the same



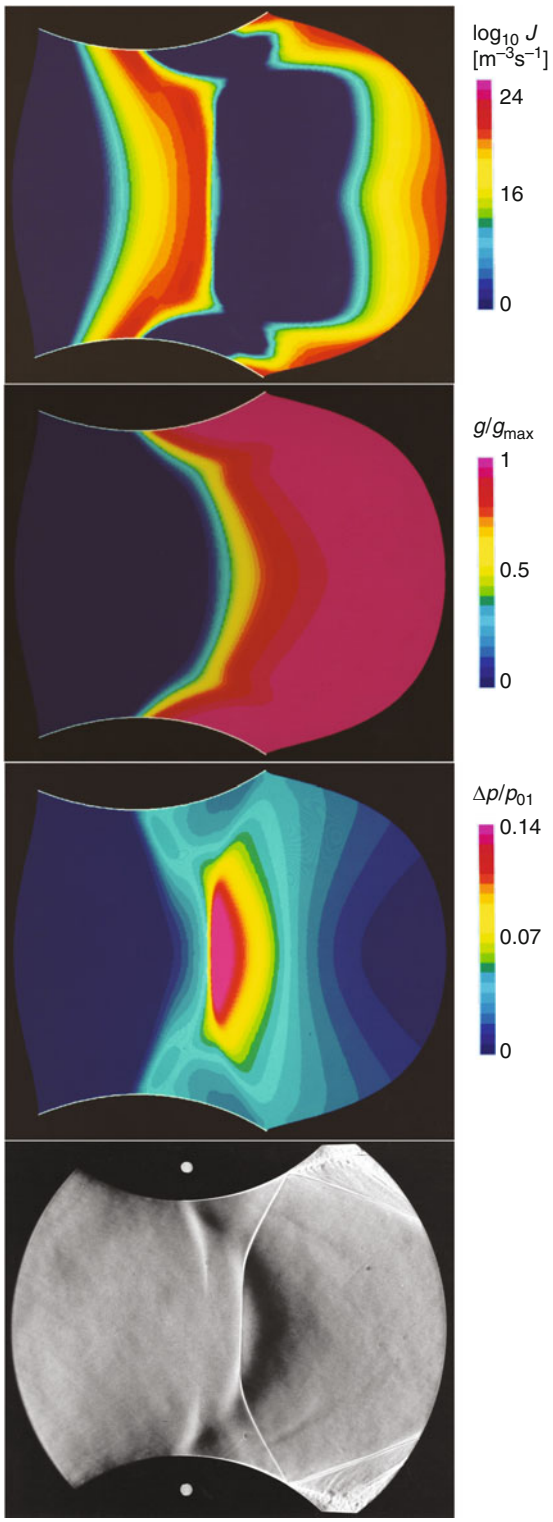
M11. Fig. 9. Limiting curve $\delta = 0$ dependent on wall curvature parameter y^*/r^* of circular arc nozzles – isentropic flow.

nucleation rate as in the primary zone [49]. Further grow of these additional nuclei to larger droplet size is not possible and the primary droplets dominate the condensate mass (Fig. 10).

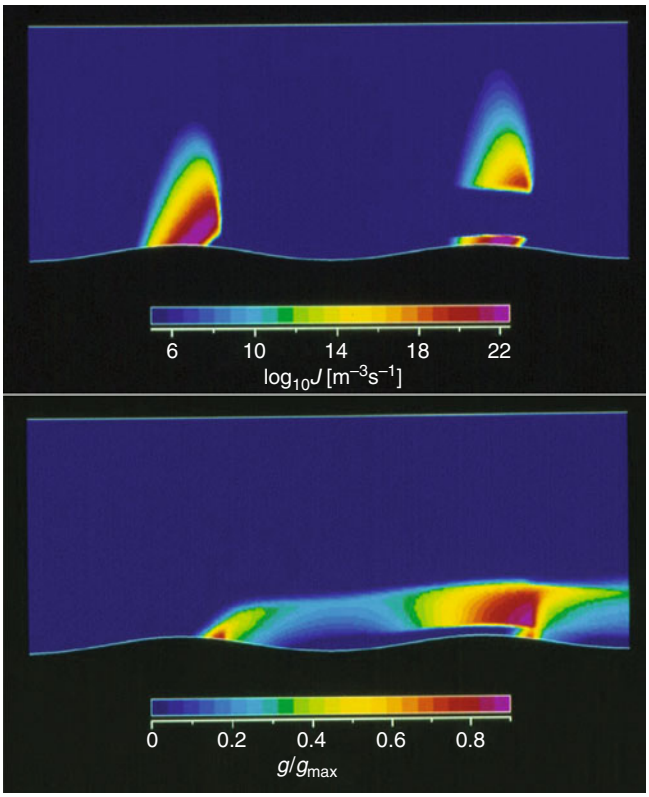
In multistage turbomachinery multiple expansion and compression of the fluid are typical. If the fluid condenses in the flow through a first blade row and if it evaporates partially weakly or instantaneously through aerodynamic shocks, ahead of the following stage the fluid consists of vapor and preexisting very tiny droplets – fog, with high number concentrations typical for homogeneous nucleation, 5–8 orders higher as compared with natural heterogeneous particle concentrations. This high droplet concentration produces a much higher condensate mass fraction, even if the cooling rates of the primary and secondary expansion zones are equal. Figure 11 demonstrates this phenomenon by a simplified flow model over a wavy wall with homogeneous nucleation in two local supersaturated regimes [50]. The first aerodynamic shock weakens with increasing distance from the wall. Close to the wall the shock is strong and the condensate evaporates completely, and the pressure and temperature return to unsaturated state. In far distance the shock is very weak but the supersaturation ahead of the shock is not high enough for substantial homogeneous nucleation and condensate formation. In between there is a regime where tiny droplets survive passing through the shock. If this fogy layer enters the second expansion zone the droplet size increases instantaneously, and the droplet size and condensate mass fraction increase up to one order higher as in the primary zone. Another example of multiple condensation in a low-pressure steam turbine stage is shown in Fig. 16.

3.2 Unsteady Phenomena – Self-excited Flow Instabilities

High initial vapor contents and low cooling rates $-dT/dt$ (K/μs) shift the location of the Wilson point close to $M_c = 1$ with thermal choking, the limit of stability. Then self-excited high frequency oscillatory instabilities start [51–58]. The sequence of Schlieren pictures in Fig. 12 visualizes one cycle of the interaction of the moving shock with the nucleation zone. The shock enters the nucleation zone and reduces instantaneously the local peak value of the nucleation rate (Fig. 13). If the shock



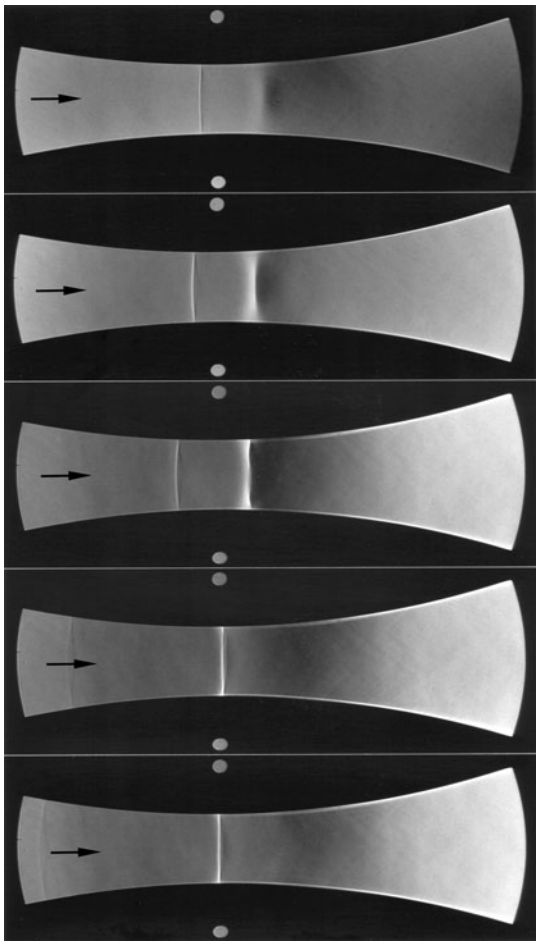
M11. Fig. 10. Homogeneous condensation in 2-D plane Laval nozzle S1 $y^* = 60$ mm, $r^* = 100$ mm, atmospheric moist air, flow from left; reservoir conditions: $\Phi_0 = 71.3\%$, $T_{01} = 286.8$ K, $p_{01} = 1.0$ bar, $x = 7.0\ g_{vapor}/kg_{dry\ air}$.
From top: homogeneous nucleation rate J within primary and secondary nucleation zone; condensate mass fraction g/g_{max}; diabatic compression ($p_{diabatic} - p_{adiabatic}/p_{01}$); experimental Schlieren picture, visualization of density gradients in main flow direction.



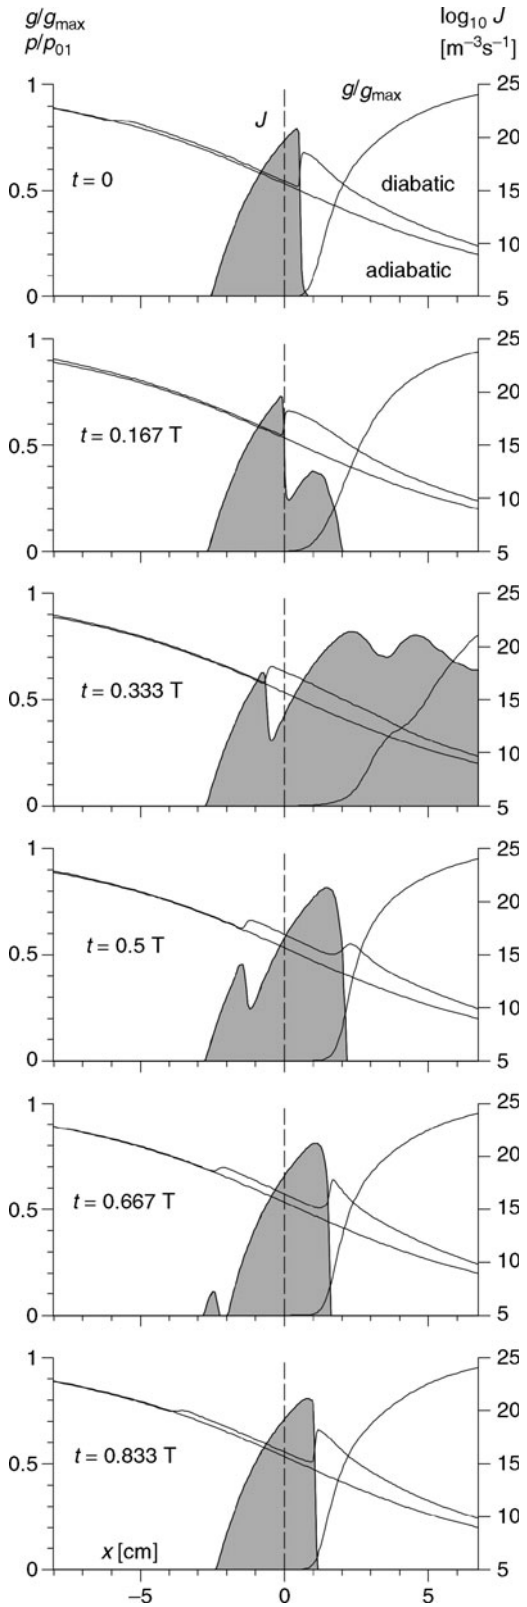
M11. Fig. 11. Periodic homogeneous condensation in transonic flow over a wavy wall with incomplete evaporation of condensate through the first shock; inviscid flow simulation, atmospheric moist air, flow from left with $M_{inlet} = 0.74$, thickness parameter of first bump $\tau_1 = 0.1096$ and of second bump $\tau_2 = 0.1$; reservoir conditions: $\Phi_0 = 50.0\%$, $T_{01} = 293.15$ K, $p_{01} = 1.0$ bar, $x = 7.36\ g_{vapor}/kg_{dry\ air}$.

approaches the throat region this interaction intensifies rapidly and is maximal exactly at the nozzle throat. Here, the nucleation rate decreases instantaneously 5 orders – lowermost picture of Fig. 12. In the next instant supersaturation and nucleation rate recover once again and a new shock of the following cycle builds up – first picture on top of Fig. 12.

Depending on the flow topology there exist different types of self-excited instabilities caused by homogeneous condensation. Figure 14 shows the frequency dependence of three different nozzle shapes on the relative humidity in the supply. Intuitively one would expect that the oscillation frequency increases monotonically with the vapor pressure content in the supply. As seen, this is not true for the quasi 1-D nozzle S2. At the limit of stability and with increasing vapor content the frequency decreases toward a sharp minimum and then it increases monotonically with the initial vapor pressure. Higher nozzle wall curvatures (nozzle S1) shift the limit of stability to higher values of Φ_0. If the scale of the temperature gradient varies substantially as for the nozzle A1 with parallel outflow with constant Mach number $M = 1.2$ at the nozzle exit, the topology of the frequency variation changes completely. Characteristic are two separated branches of low and high



M11. Fig. 12. One cycle of self-excited oscillation with frequency f = 1145 Hz of homogeneously condensing flow in 2-D plane Laval nozzle S2 y^* = 15 mm, r^* = 400 mm; experimental Schlieren pictures, atmospheric moist air, flow from left, time increases from top; reservoir conditions: Φ_0 = 91.0%, T_{01} = 291.65 K, p_{01} = 1.0 bar, x = 9.5 $g_{vapor}/kg_{dry\ air}$.



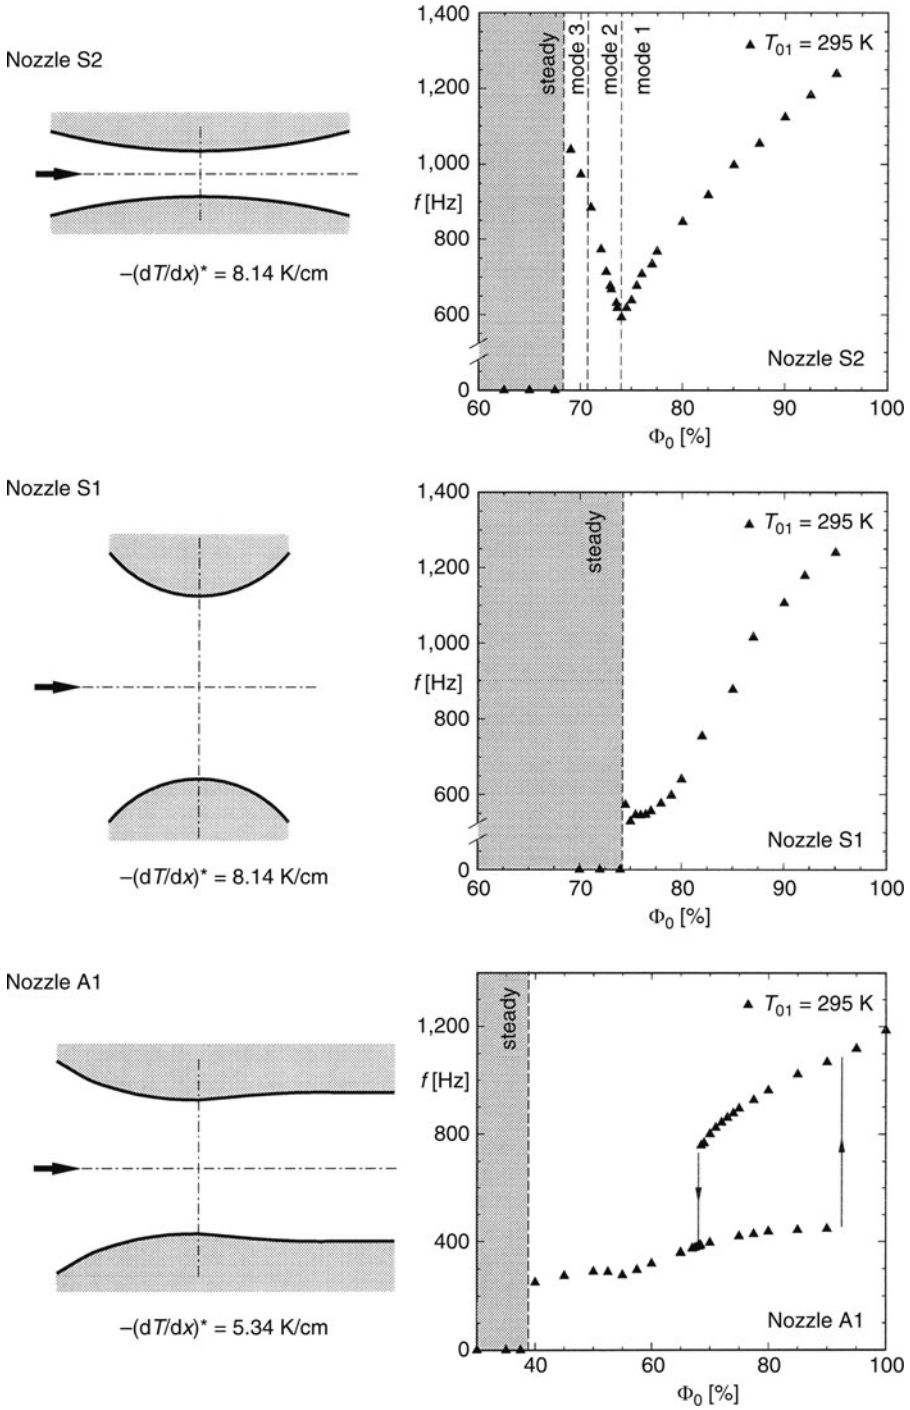
M11. Fig. 13. One cycle of self-excited oscillation in nozzle S2 according to Fig. 12, numerical simulation of static pressure ratio p/p_{01}, nucleation rate J (shaded area) and of condensate mass fraction g/g_{max} at the nozzle axis. The lower expansion curve starting at the ordinate at left depicts the steady-state adiabatic expansion.

frequencies and a hysteresis in between. Because of the sudden increase of the frequency by a factor of 2 or more, this higher order instability is of great practical importance. It was first detected by Adam and Schnerr [59–61] and its existence could be confirmed for a wide variety of nozzle shapes for flows of pure vapor [62] as well as for vapor/carrier gas mixtures [63].

The oscillation frequency f depends on the reservoir conditions, the time scale of the flow, defined by the geometry of the problem, and on fluid properties. In case of nozzle flows this results in

$$f = F_1\left(\underbrace{p_{01}, T_{01}, p_{vap,0}, p_{sat,\infty,0},}_{\text{reservoir state}}\ \underbrace{l, y^*,}_{\text{geometry}}\ \underbrace{c_p, c_{vap}, L, \tau_c}_{\text{fluid}}\right). \quad (36)$$

Using the Buckingham theorem and with the characteristic length $l = \sqrt{y^* r^*}$ this can be reduced to



M11. Fig. 14. Dynamics of periodic shock formation and self-excited flow oscillations of homogeneously condensing flow in 2-D plane nozzles; inviscid numerical simulation, atmospheric moist air.
From top: circular arc nozzle S2 y^* = 15 mm, r^* = 400 mm; circular arc nozzle S1 y^* = 60 mm, r^* = 100 mm; nozzle A1 with parallel outflow $M_{\text{isentropic}}$ = 1.2, y^* = 45 mm, r^* = 300 mm.

$$\bar{f} = \frac{f \cdot l}{c^*} = F_2\left(\frac{p_{\text{vap},0}}{p_{\text{sat},\infty,0}}, \frac{p_{\text{vap},0}}{p_{01}}, \frac{L}{c_p T_{01}}, \frac{y^*}{l}, \frac{\tau_c c^*}{l}, \gamma\right). \quad (37)$$

If the fluid is the same and if the flow starts at constant reservoir conditions for pressure and temperature this yields

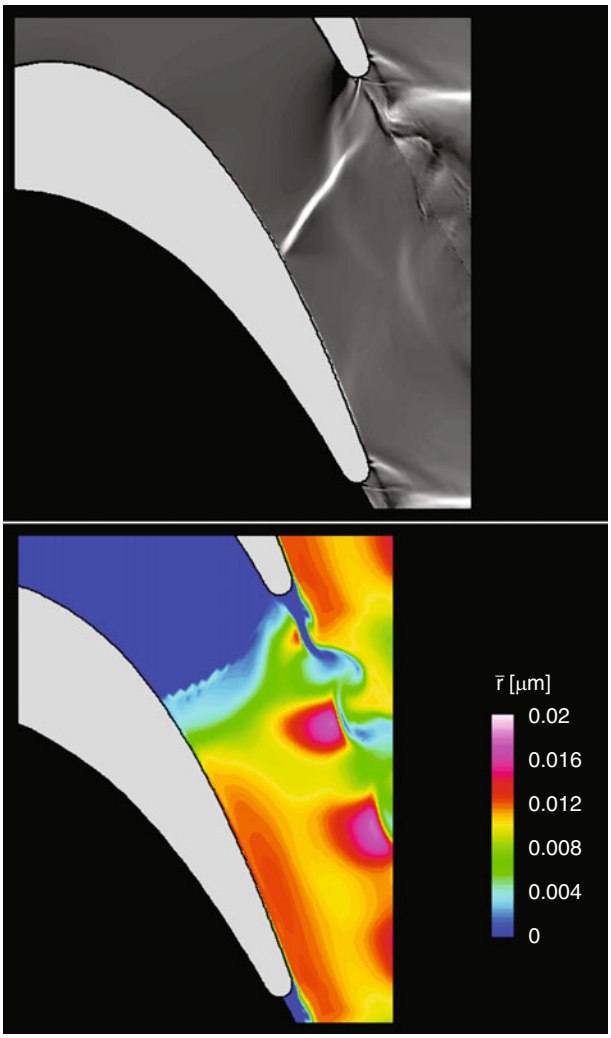
$$\bar{f} = \frac{f \cdot l}{c^*} = \mathrm{F}_3\left(\Phi_0, \frac{\tau_c}{\tau_f}\right), \quad (38)$$

where τ_c and τ_f are the characteristic time scale of phase transition and of the flow, respectively. For quasi 1-D nozzles with distinct frequency minimum the similarity law for the reduced frequency $\bar{f}$ dependent on the value of $\Phi_{0,\min}$ at the frequency minimum reads [59]

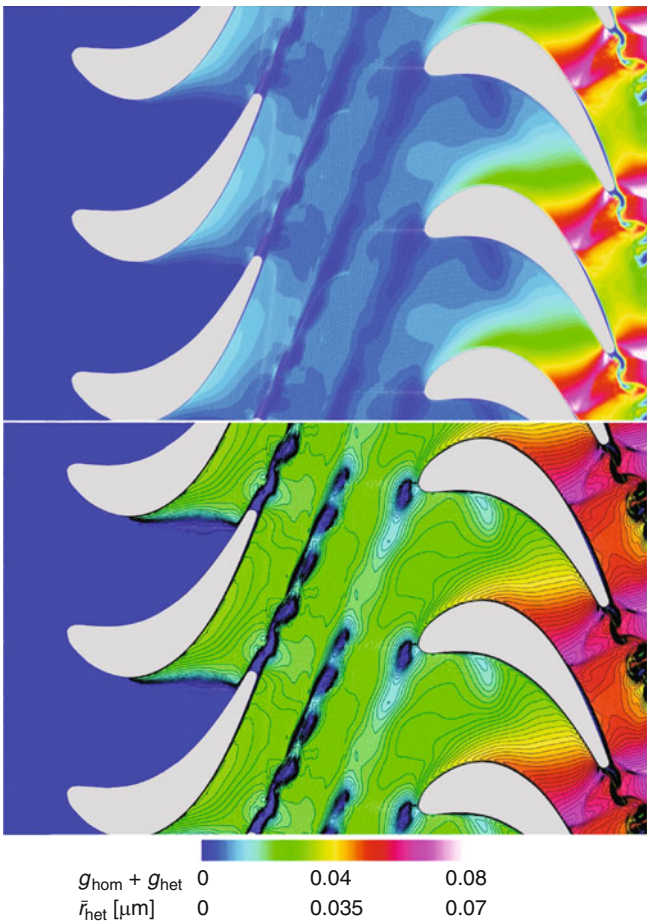
$$\bar{f} = \frac{f \cdot l}{c^*} = F_4\left(\Phi_0 - \Phi_{0,\min}\right). \quad (39)$$

In axial turbomachinery there exist additional excitation mechanisms such as periodic blade wake oscillations and rotor stator interactions [64]. The first mechanism is driven by shedding of shear layers from each blade trailing edge, whereas the second type concerns the convection of wakes with high dissipative losses and therefore with high temperature fluctuations from the stator into the rotating frame of reference. In contrast to the previously described self-excited instabilities both mechanisms are clearly driven by the fluid viscosity. If the origin of the shedding locates within the highly supersaturated regime with maximum nucleation rates, this source produces pressure and temperature fluctuations that interfere with nucleation dynamics within the blade-to-blade flow and triggers the instantaneous growth of the droplet size behind the blade row. This phenomenon is called wake chopping [65]. Figure 15 shows an example of turbulent vortex shedding behind a VKI 1 rotor blade. The strongest time-dependent variation of the nucleation rate happens just at the blade trailing edge and is of two orders of magnitude from $J = 10^{25}$ m^{-3} s^{-1} till 10^{27} m^{-3} s^{-1}. Close to the wake the droplet diameter increases periodically by a factor of 2 [63].

In case the nucleation and droplet growth had already begun in the stator, as seen in Fig. 16, the subsequent further growth of droplets in the disperse mixture in the rotor happens close to equilibrium $S \approx 1$. Despite the fact of the high cooling rate of the flow of O (1) nonequilibrium losses remain negligible, but the final maximum droplet size is much greater as without artificial seeding. Here, homogeneous and heterogeneous condensations are directly coupled, and due to the high concentration of seeding particles the phase transition process is dominated by heterogeneous condensation close to thermodynamic equilibrium [66].



M11. Fig. 15. Vortex shedding from trailing edge of axial VKI-1 turbine cascade, homogeneously condensing turbulent flow of pure steam; flow data: $T_{01} = 357.5$ K, $p_{01} = 0.417$ bar, cascade inflow angle $\beta_1 = 120°$, rotor exit pressure $p_2 = 0.194$ bar, Re = $1.13 \cdot 10^6$, vortex shedding frequency $f_{vs} = 22.5$ kHz, Strouhal number St = 0.22. From top: instantaneous numerical Schieren picture; instantaneous droplet radii distribution triggered by unsteady wake flow.



M11. Fig. 16. Rotor/stator interaction in condensing steam flow with artificial seeding through axial VKI-1 stage, numerical simulation of heterogeneously dominated condensing turbulent flow; flow data: $T_{01} = 357.5$ K, $p_{01} = 0.417$ bar, cascade inflow angle $\beta_1 = 120°$, rotor exit pressure $p_2 = 0.194$ bar, $M_{2,isentropic} = 1.13$, $Re_{rotor} = 1.13 \cdot 10^6$, vortex shedding frequency $f_{vs} = 22.5$ kHz, Strouhal number St = 0.22, initial particle number concentration $n_{het,0} = 10^{16}$ m^{-3}, seeding particle size $r_{het} = 10^{-8}$m. From top: total condensate mass fraction – dominated by heterogeneous growth; snapshot of heterogeneously controlled droplet size within stator and rotor.

3.3 CFD Modeling for Calculation of Condensing Flows

Numerical simulation of fluid mechanics requires the solution of the conservation laws for mass, momentum, and energy [63, 65]. If phase transition of the fluid takes place either by homogeneous or by heterogeneous condensation, closure of the set of conservation laws in differential form requires additional equations for modeling of nucleation, droplet growth, and for the transport of the condensate mass. In case of the classical nucleation theory coupled to appropriate droplet growth laws according to different Knudsen regimes $\mathrm{Kn} = \Lambda/d > 1$ or with $\mathrm{Kn} < 1$, the general form of the transport equation yields for any condensation process

$$\frac{\partial(\rho g)}{\partial t} + \nabla \cdot \left(\rho g \vec{v}\right) = \rho \cdot \frac{\mathrm{d}g}{\mathrm{d}t} = F_{\text{source term, condensation}}. \quad (40)$$

For homogeneous condensation this takes the form

$$\begin{aligned} &\frac{\partial}{\partial t}(\rho g_{\mathrm{hom}}) + \nabla \cdot (\rho g_{\mathrm{hom}} \vec{v}) \\ &\quad = \frac{4}{3}\pi \rho_{\mathrm{liq}} r_{\mathrm{hom}}^{*3} J_{\mathrm{hom}} + \rho_{\mathrm{liq}} \rho n_{\mathrm{hom}} \cdot \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{4}{3}\pi r_{\mathrm{hom}}^{3}\right), \\ &\frac{\partial}{\partial t}(\rho n_{\mathrm{hom}}) + \nabla \cdot (\rho n_{\mathrm{hom}} \vec{v}) = J_{\mathrm{hom}} \end{aligned} \quad (41)$$

with the homogeneous nucleation rate according to Volmer et al.

$$J_{\mathrm{hom}} = \left(\frac{p_{\mathrm{vap}}}{kT}\right)^2 \cdot \frac{1}{\rho_{\mathrm{liq}}} \cdot \sqrt{\frac{2k\sigma_\infty}{\pi R_{\mathrm{vap}}}} \cdot \exp\left(-\frac{4\pi r_{\mathrm{hom}}^{*2}\sigma_\infty}{3kT}\right). \quad (42)$$

For heterogeneous condensation [67–70] the transport equation reduces to

$$\frac{\partial}{\partial t}(\rho g_{\mathrm{het}}) + \nabla \cdot (\rho g_{\mathrm{het}} \vec{v}) = \rho_{\mathrm{liq}} n_{\mathrm{het}} \cdot \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{4}{3}\pi r_{\mathrm{het}}^{3}\right).$$

In case of $\mathrm{Kn} > 1$, if the mean free path Λ is larger as the droplet size d, for droplet growth the Hertz–Knudsen law [36] is appropriate

$$\frac{\mathrm{d}\bar{r}}{\mathrm{d}t} = \frac{\alpha}{\rho_{\mathrm{liq}}} \cdot \frac{p_{\mathrm{vap}} - p_{\mathrm{sat},r}}{\sqrt{2\pi R_{\mathrm{vap}} T}}, \quad (43)$$

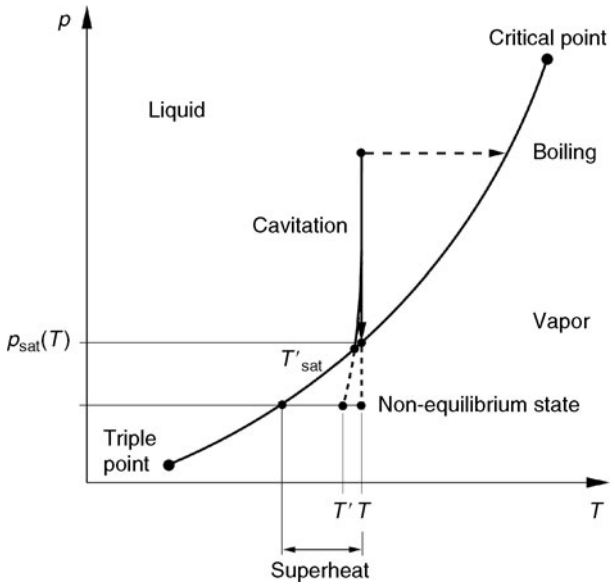
whereas in case of $\mathrm{Kn} < 1$ and for pure vapor flows the modified growth law of Gyarmathy can be used

$$\begin{aligned} \frac{\mathrm{d}r_{\mathrm{hom}}}{\mathrm{d}t} = &\frac{1}{\rho_{\mathrm{liq}}} \cdot \frac{1 + 2\mathrm{Kn}}{r \cdot (1 + 3.42\mathrm{Kn} + 5.32\mathrm{Kn}^2)} \cdot \left(\frac{1 - r^*}{r}\right) \cdot \\ &\left(\frac{\Lambda_{\mathrm{vap}} R_{\mathrm{vap}} T^2}{(h_{\mathrm{vap}} - h_{\mathrm{liq}})^2}\right) \cdot \ln(S). \end{aligned} \quad (44)$$

4 Cavitation

For evaporation of liquids two limiting processes can be defined: boiling that means heat addition at constant pressure and cavitation as adiabatic depressurization of liquids (Fig. 17). Cavitation as dynamic phase transition from liquid to vapor state is the natural counterpart to flow-induced condensation processes as treated in Sect. 3. The temperature decrease during adiabatic expansion of liquids is very low. One reason is the exceptional great density difference of liquid and vapor phases, for water at 293 K $\rho_{\mathrm{liq}}/\rho_{\mathrm{vap}} \approx 50,000$. As first approximation cavitation can be regarded as isothermal process, especially if pure liquid and pure vapor phases are modeled as incompressible fluids. A significant difference concerns the existence of nonequilibrium during the expansion. As seen in Sect. 3, in expanding vapor flows homogeneous nucleation establishes immediately, if the cooling rate excites a certain threshold. Additional natural heterogeneous nuclei may be present but they cannot alter the dominating homogeneous kinetics. Heterogeneously controlled processes become dominant if the cooling rate is low enough and/or if artificial seeding provides so many foreign additional surfaces, that substantial supersaturation is prevented. The important quantity is the necessary work for formation of clusters and critical nuclei which is substantially larger for homogeneous nucleation in the single component liquid bulk phase, provided that the liquid is artificially purified, as compared to that for homogeneous nucleation in the pure vapor phase [71–77].

Moderate convective acceleration of liquids depressurizes immediately to vapor pressure and – in tendency – further toward the so-called negative pressures, more precisely toward tensile stress in the liquid. Except well-defined test configurations, the practical cavitation threshold coincides with the equilibrium vapor pressure at given temperature. Technical fluids contain sufficient number concentrations of impurities such as particles or microbubbles which act as heterogeneous nuclei, and the intermolecular binding energy at least of artificially purified single component liquids requires tensile stresses of the order of 10^3 bar for homogeneous formation of microbubbles which is far beyond any observation in real processes.



M11. Fig. 17. Phase diagram with path lines for evaporation by cavitation and boiling; comparison of isothermal and adiabatic depressurization with final equilibrium temperature T'_{sat}. T' is the theoretical final temperature in case of substantial nonequilibrium.

If expanding liquids contain dissolved gas, dispersion of the gas starts immediately above the vapor pressure threshold. This degassing process, usually called pseudocavitation, is continuous and smooth compared with the instantaneous vapor formation due to cavitation.

Cavitation plays an important role in turbomachinery – pumps, turbines, ship propellers, in injection systems of combustion engines, in chemical engineering, in medical applications, and many others [78–81]. Depending on the parameter range the two-phase mixture implies a wide variety of topologies. Most characteristic is the intense coupling of flow and cavitation dynamics. Because of the strong gradients caused by the collapse of the vapor-filled cavities these flows are always 3-D and unsteady.

Typical thermodynamic and fluid dynamic properties of cavitating flow are

Initially single-phase liquid fluid	$p_{liq} \approx O(1–10^3$ bar), $T \approx$ 300–400 K
	$p_{vap} \approx O(10^{-2}–1$ bar)
	$\rho_{liq} \approx O(10^3$ kg m^{-3})
	$\rho_{vap} \approx O(10^{-2}–1$ kg m^{-3})
Void fraction	$0 \le \alpha \le 1$
Speed of sound	$c \approx O(1–10^3$ m s^{-1})
Typically low or high flow speed	$M \approx O(0–10^1)$
Heterogeneous nuclei concentration	$n_{het} \approx O(10^8$ m^{-3})
Characteristic length scale	$L \approx O(10^{-4}–10^{-1}$ m)
Characteristic flow time scale	$t \approx O(10^{-5}–10^{-2}$ s)

4.1 Types of Cavitation

The Bernoulli equation demonstrates immediately that moderate acceleration of an initial flow with 1 bar and flow velocity up to 14.3 m/s decrease the pressure to the vapor pressure at 293 K with initiation of evaporation of the liquid fluid (Fig. 18).

The most important parameter to characterize such flows is the so-called cavitation number

$$\sigma_{ref} = \frac{p_{ref} - p_{vap}(T)}{\Delta p}. \tag{45}$$

For cascades this takes the form

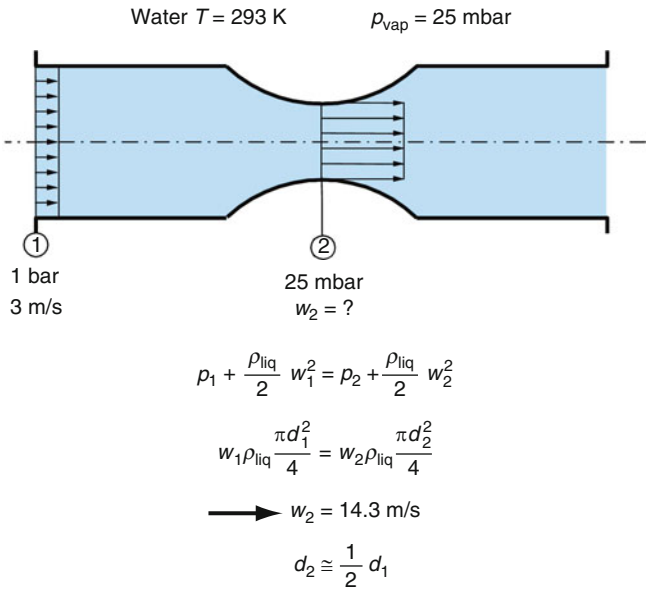
$$\sigma_{ref} = \frac{p_{downstream} - p_{vap}(T)}{p_{upstream} - p_{downstream}}. \tag{46}$$

For a hydrofoil placed in an open water channel at distance h below the free surface with pressure $\tilde{p}$ above and with the inflow velocity w, this yields

$$\sigma_{ref} = \frac{\tilde{p} + \rho_{liq} g h - p_{vap}(T)}{\frac{1}{2}\rho_{liq} w^2} \tag{47}$$

and for pump flow

$$\sigma_{ref} = \frac{p_{inlet} - p_{vap}(T)}{\rho_{liq} w_{rot}^2} \tag{48}$$



M11. Fig. 18. Estimation of cavitation onset at $p = p_{vap}$ (T_{sat}) in 1-D nozzle flow based on Bernoulli equation.

with u_{rot} as the rotational velocity at the outer diameter of the rotor. The definition of appropriate reference values, denoted by the subscript "ref," depends on the application under consideration and on the data that are available. Mostly, σ_{ref} is defined based on the inlet conditions. The vapor volume is characterized by the void fraction

$$\alpha = \frac{V_{vap}}{V_{vap} + V_{liq}} \tag{49}$$

and the vapor mass fraction x is defined by

$$x = \frac{m_{vap}}{m_{vap} + m_{liq}} = \frac{\alpha\rho_{vap}}{\alpha\rho_{vap} + (1-\alpha)\rho_{liq}}. \tag{50}$$

The Strouhal number is used for description of the shedding dynamics of sheets and clouds

$$St = \frac{f \cdot l}{w_{ref}}, \tag{51}$$

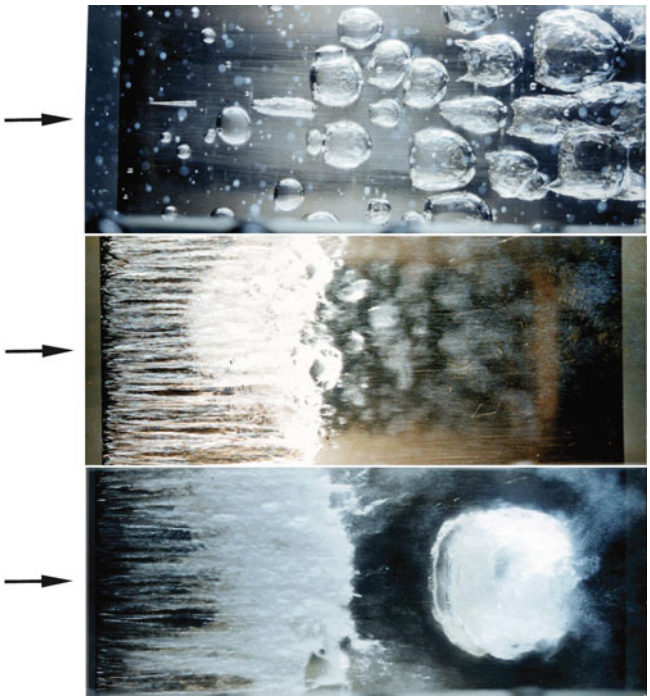
l is the typical length of the body or of the cavity itself. If viscosity plays a role, the dimensionless parameter is the Reynolds number

$$Re_{ref} = \frac{w_{ref} \cdot l}{\nu} \tag{52}$$

with ν as the kinematic liquid viscosity independent of the fact that in two-phase mixtures the viscosity decreases significantly. For characterization of pre-existing heterogeneous microbubbles the nuclei size r_0 and the number concentration n_0 (m^{-3}) are used.

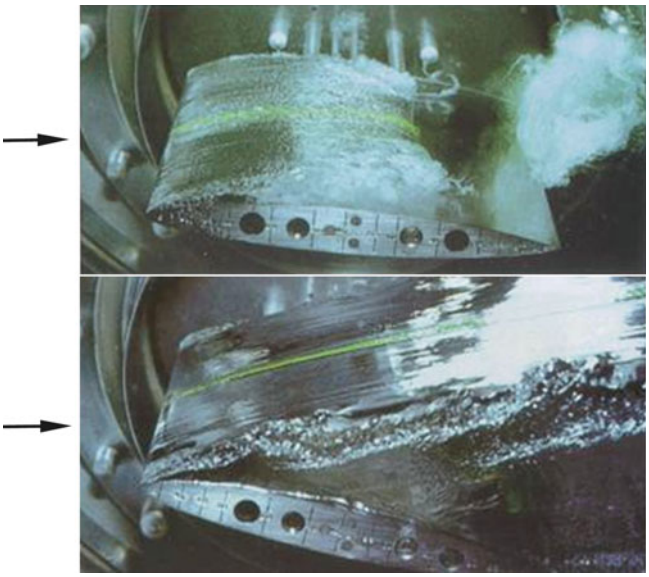
Based on the topology of the distribution of liquid and vapor phases the cavitating types can be distinguished as follows [82, 83]:

Bubble cavitation: Typically, for fluids with larger dissolved air contents, consisting of a small number of large bubbles, that are convected with the main flow (Fig. 19, top).



M11. Fig. 19. Evolution of cavitation topology at the suction side of a 2-D hydrofoil, flow from left, experiment Kuiper [110].
From top: traveling bubble cavitation; sheet cavitation; and cloud cavitation.

Sheet cavitation: Typically, at the leading edge of hydrofoils and propeller blades, a dispersed mixture of tiny vapor bubbles and liquid forms an attached sheet which becomes locally unstable in the collapse region (Fig. 19, middle).
Cloud cavitation: The entire cavitation regime consists of many small bubbles, large disperse two-phase mixtures grow up periodically, disperse clouds shed with high frequency from blade surfaces and collapse downstream – Fig. 19, bottom and Fig. 20, top. Concerning erosion, this is the most aggressive type.
Supercavitation: The vapor formation intensifies further, the blades or bodies are surrounded by large stable pure vapor pockets, and the solid bodies can become completely surrounded by vapor with significant reduction of viscous drag forces – Fig. 20, bottom.
Vortex cavitation: The characteristic pressure drop in vortex cores results in evaporation of the fluid in the core region, typically for ship propellers. Here, the collapse regions separate from solid walls and the erosion potential is less critical.
Based on the integral void fraction produced by cavitation the topology of these flows can be distinguished as
Incipient cavitation: Just the "onset" of cavitation with very low vapor formation, either as few single bubbles or as very thin attached sheets, not yet relevant for erosion. Modeling requires accurate parameter values of r_0, n_0, the Reynolds number Re_{ref}, and the degree of turbulence Tu.
Developed cavitation: Dominant is the strong unsteadiness of this type of flow, combined with chaotic cloud shedding and strong shock formation during collapse of the clouds. Concerning erosion, this is the most dangerous cavitation type, in technical applications such as turbines, pump flow,



M11. Fig. 20. Cloud cavitation and supercavitation, 2-D NACA 16012 hydrofoil, chord = 0.1 m, $Re_{chord} = 6{\cdot}10^5$, experiment Franc and Michel [111]. Top cloud cavitation 6° angle of attack, $\sigma_{ref} = 0.81$; bottom supercavitation 15° angle of attack, $\sigma_{ref} = 0.13$.

this is the predominating mechanism, it is inertia controlled, viscosity effects are less important and can be neglected.
Supercavitation: Maximum void fraction with extended pure vapor regimes, liquid and vapor are separated by sharp interfaces, steady with exception of the closure region of the cavity.

4.2 Developed Cavitation

Because of its practical importance developed cavitation is in focus of this chapter. It is always 3-D, unsteady and dominantly driven by inertia-controlled nonviscous effects. At global scale the flow can be regarded as periodic or cyclic. However, small-scale dynamic phenomena are chaotic. Modeling requires the formation and growth of disperse sheets, break-off and fragmentation of macroscopic clouds from the sheets, and the accurate description of the collapse dynamics, starting from large cloudy structures down to the scale of single bubbles. If the erosion mechanism is in focus, it is necessary to resolve all time scales of the problem including shock dynamics based on the liquid speed of sound of the order of 1,500 m/s. Averaged quantities based on reduced time scales are sufficient for calculation of performance and efficiency of hydraulic machinery.

4.3 Modeling of Developed Cavitation

4.3.1 Modeling of Single-phase Basic Flow

Because of the intensive coupling of single-phase basic flow and cavitation dynamics accurate modeling of the basic flow is important. Incompressible assumption for pure liquid and pure vapor phases excludes the dynamics of shocks and

expansion waves emerging at the final stage of the bubble collapse. To account for these aspects the compressibility of liquid and vapor must be modeled and the time stepping of the simulation must account for all time scales in the collapse region, molecular viscosity and turbulence can be neglected.

4.3.2 Modeling of Two-phase Flow

Except the very last instant at the final stage of the collapse, the assumption of equilibrium thermodynamics is accurate and nonequilibrium effects can be neglected. Phase boundaries can be modeled as sharp interfaces by direct tracking of the interface or by approximate methods that capture interfaces (VOF – Volume of Fluid method) by the discrete distribution of the void fraction α [85]. If dealing with developed cavitation it is impossible to capture the interfaces of every single bubble of the disperse mixture. Instead of separate models for simulation of the liquid and vapor phases or of sheet and cloud cavitation with the need of an additional transition model in between, the homogeneous mixture model is more promising. This model requires only one set of conservation equations for mass momentum and energy, the density, void fraction etc., are modeled as mixture quantities. The transition from disperse two-phase regimes to pure vapor with $\alpha = 1$ establishes automatically by the void fraction variation (Fig. 21).

The growth and collapse of the vapor phase can be modeled according to equilibrium thermodynamics. This requires appropriate equations of state for all regimes, liquid, vapor, and of the two-phase mixture regime. The alternative is the use of well-known equations for bubble dynamics, e.g., the Rayleigh–Plesset equation [82, 84]

$$r\ddot{r} + \frac{3}{2}\dot{r}^2 = \frac{p_{sat} - p_\infty(t)}{\rho_{liq}} + \frac{p_{gas,0}}{\rho_{liq}} \cdot \left(\frac{r_0}{r}\right)^{3\gamma} - \frac{2\sigma_\infty}{\rho_{liq} r} - \frac{4\eta_{liq}}{\rho_{liq}} \frac{\dot{r}}{r}, \quad (53)$$

neglecting nonlinear terms, the gas content, surface tension and η_{liq} in Eq. (53) yields the Rayleigh equation

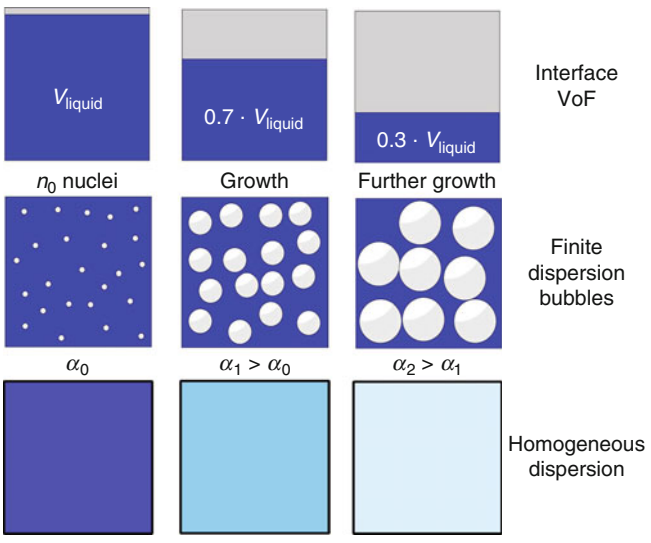
$$\dot{r} = \frac{dr}{dt} = \sqrt{\frac{2}{3} \cdot \frac{p_{sat} - p_\infty(t)}{\rho_{liq}}}. \quad (54)$$

Additional models are necessary to account for the interaction of bubbles in dispersed bubbly clouds [85]. As variants of Eq. (54) in the literature there exist many empirical modifications, typically in commercial CFD tools, to account for different time scales of evaporation and condensation. However, such corrections are only valid in a limited range of operating conditions and not generally valid.

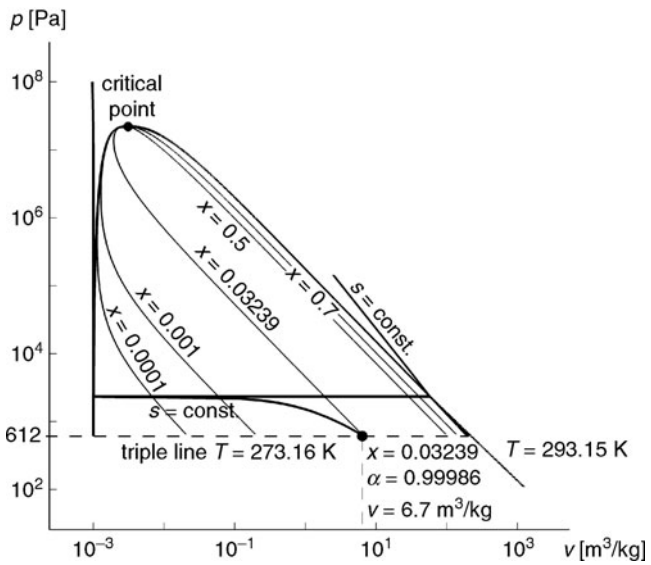
4.3.3 Modeling of Phase Transition

Neglecting molecular transport by viscosity and heat conduction the latent heat exchange, necessary for evaporation, is provided within the liquid bulk. Therefore, if the flow is isentropic at the inlet it remains isentropic throughout the evaporation, only the shock-like collapse produces strong vorticity. In equilibrium thermodynamics isentropes terminate inside the two-phase regime at the triple line. Therefore, isentropic evaporation is always incomplete, but quantitative effects on the void fraction α are negligible (Fig. 22).

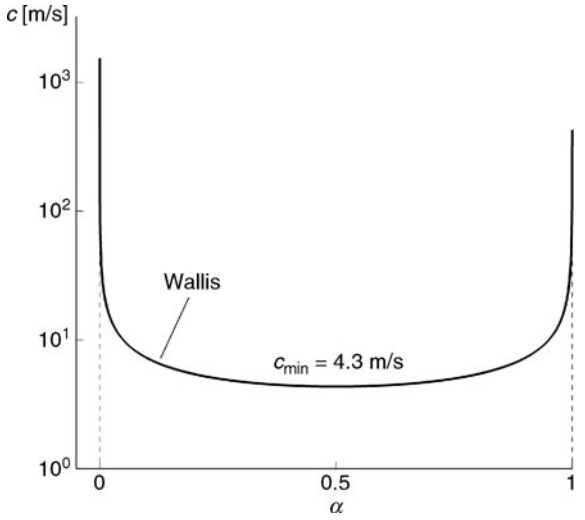
In two-phase regions the speed of sound decreases by several orders of magnitude. For two-phase mixtures without phase transition the well-known result of Wallis [84] is appropriate (Figs. 23 and 24)



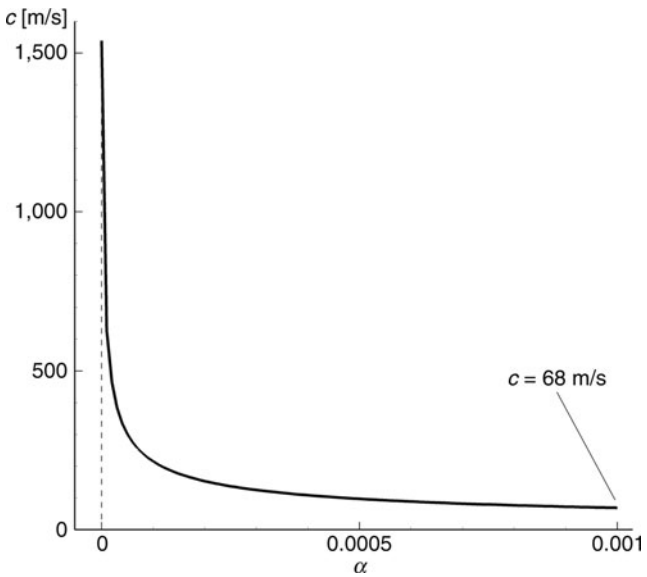
M11. Fig. 21. Alternative modeling of two-phase flow within a computational cell. *Rows*: top: stratified two-phase flow – interface Volume of Fluid (VoF); middle: bubbly two-phase flow – finite dispersed model; bottom: homogeneous mixture – small-scale structure excluded. *Columns*: left small void fraction $\alpha_0 \approx 0$; middle: mode void fraction $\alpha_1 \approx 0.3$; right: high void fraction $\alpha_2 \approx 0.7$.



M11. Fig. 22. *p*, v-diagram with two-phase regime and isentropic depressurization from pure liquid phase till maximum liquid mass fraction $x = 0.03239$ and maximum void fraction $\alpha = 0.99986$ at triple line.



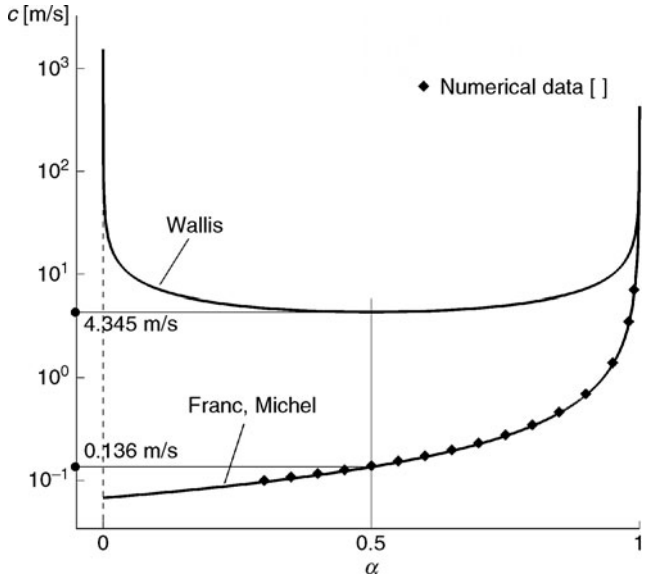
M11. Fig. 23. Equilibrium speed of sound *c* for two-phase mixtures without phase transition according to Wallis [84] – not valid for cavitating flows in thermodynamic equilibrium.



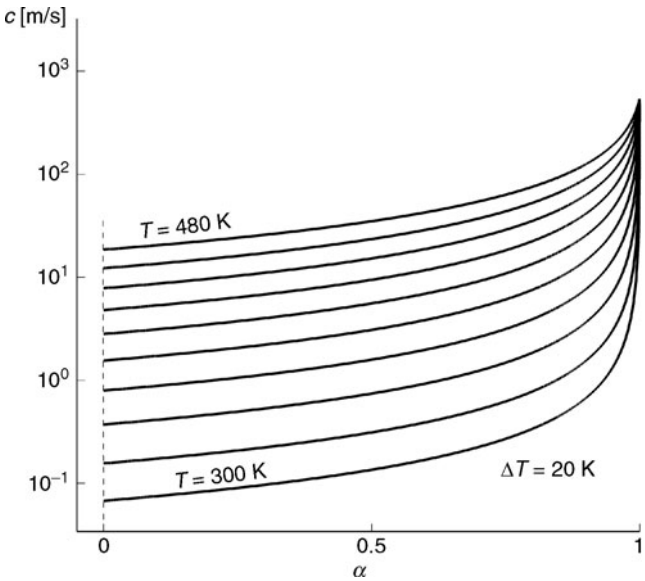
M11. Fig. 24. Strong decrease of equilibrium speed of sound c in two-phase mixtures without phase transition for small void fractions $\alpha < 10^{-3}$ – zoom of Fig. 23, not valid for cavitating flows in thermodynamic equilibrium.

$$\frac{1}{\rho c^2} = \frac{\alpha}{\rho_{vap} c_{vap}^2} + \frac{1-\alpha}{\rho_{liq} c_{liq}^2}. \tag{55}$$

In two-phase mixtures with phase transition, as in cavitating flows, the speed of sound decreases suddenly through a kink at the left-hand phase boundary, then it increases monotonically with increasing void fraction α [Eq. (56), Figs. 25 and 26 [82, 85]]. The extreme decrease of the speed of sound in disperse mixtures is important for the understanding of the propagation of waves and shocks in cavitating flows



M11. Fig. 25. Equilibrium speed of sound c in two-phase mixtures with phase transition with a distinct kink at the left-hand phase boundary, sudden decrease of *c* below O (1 m/s), and monotonic increase with increasing void fractionα, appropriate modeling for cavitating flow in thermodynamic equilibrium. Comparison of theoretical prediction of Franc and Michel [82] with numerical data [90].



M11. Fig. 26. Temperature dependence of the equilibrium speed of sound *c* for cavitating flows according to Fig. 25

$$\frac{1}{\rho c^2} \cong \frac{\alpha}{\rho_{vap} c_{vap}^2} + \frac{1-\alpha}{\rho_{liq} c_{liq}^2} + \frac{(1-\alpha)\rho_{liq} c_{p,liq} T}{\left(\rho_{vap} L_{vap}\right)^2}. \tag{56}$$

Homogeneous nucleation

Homogeneous nucleation can be modeled based on molecular dynamics [72] or by applying the classical capillary theory as

known from condensation in vapor [73]. Assuming purified single component liquids yields necessary supersaturation ratios S, i.e., tensile stress in the liquid of the order of 10^3 bar. In practice such extreme conditions have never been observed. In nucleating vapor flow the quantitative contribution of homogeneous and heterogeneous growth depends directly on the time scale of the flow. In micronozzles of injection systems depressurization from O (10^3 bar) down to O (1 bar) establishes typically within a few microseconds. This raises the question of the nature cavitating kinetics under such conditions that is unknown until now.

Heterogeneous nucleation

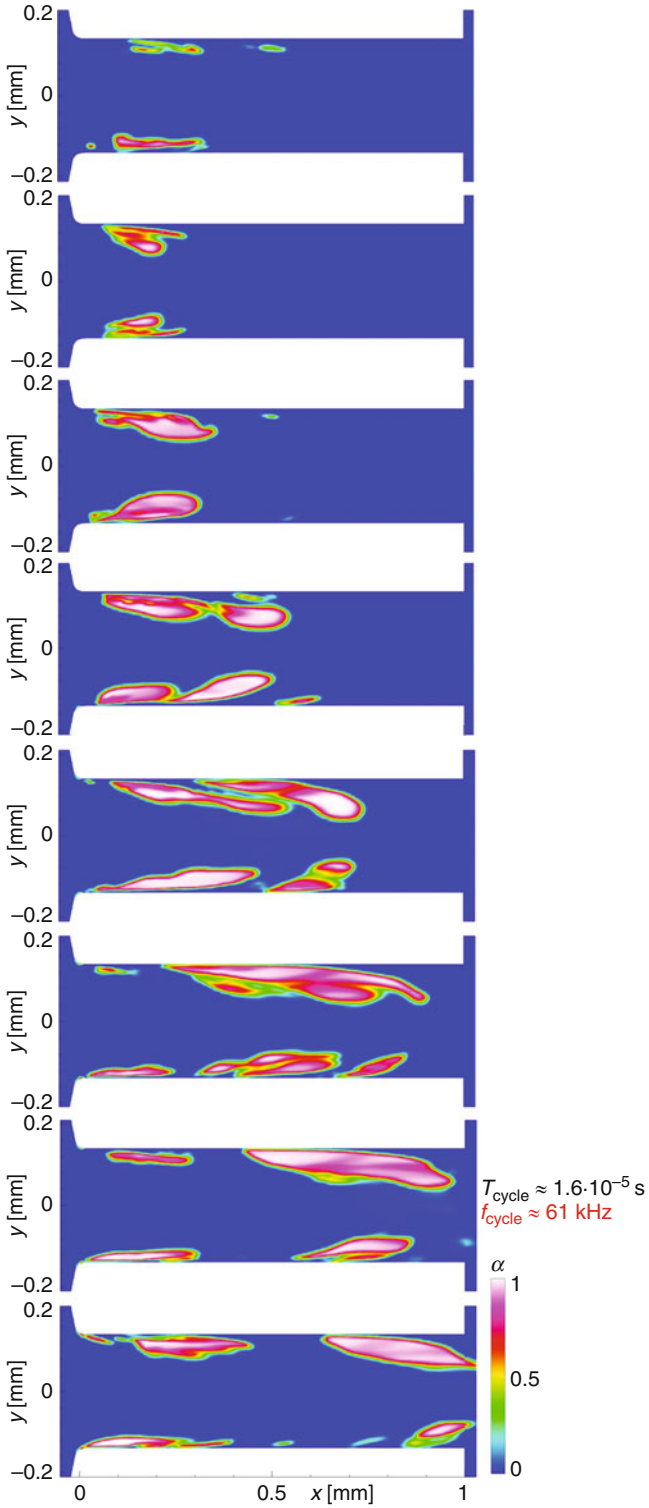
Because of the uncertainties and also because most of the liquids used in technical applications consist of large concentrations of natural impurities, heterogeneous modeling is dominant. Substantial tensile stress is avoided by appropriate values of the parameters $r_0 \approx 10^{-7}$–10^{-8} m and the number concentration $n_0 \approx 10^6$–10^9 m^{-3}. Inclusion of the surface tension is important for nuclei radii $\leq 10^{-6}$ m, and it tends to decrease the cavitation threshold beyond the thermodynamic vapor pressure. Because pre-existing microbubbles are never monodispersed, this means that activation of nuclei begins at larger scales.

Equilibrium phase transition

The closure of disperse models requires quantitative values of all model parameters. Because these models approach equilibrium in most of the practical applications, it is reasonable to avoid uncertain details of these models completely and to assume thermodynamic equilibrium throughout. Physically, this means that real systems consist of sufficient high concentrations of foreign nuclei that initiate phase transition at $S \approx 1$. The great advantage of such a thermodynamic model is the fact that it avoids all additional free parameters that are usually used for "artificial" fitting of experiment and numerical data. The system of conservation equations is closed by the equations of state in the different regimes, and the accuracy of the equilibrium model depends only on thermodynamic data. For water, IAPWS [87] provides an exceptional detailed and accurate database.

4.4 Hydrodynamic and Wave Dynamic Phenomena

Unsteady compressible flows in thermodynamic equilibrium are controlled by two separate time scales. The first is determined by the convective transport of the fluid, the flow velocity w that is rather low in liquid flows, typically O (1 m)–O (10 m). The second is determined by the speed of sound c of the fluid that controls the propagation of shocks and expansion waves and varies in a wide range from O (10^3 m/s) to O(10^{-1} m/s), dependent on the local void fraction α. In high pressure injection systems, wave dynamics and convective transport control cavitation dynamics simultaneously. Understanding of the main driving mechanism for erosion without considering shock and wave dynamics is impossible. In hydraulics, the phenomenon of sudden pressure waves, e.g., caused by instantaneous closing of valves is known as *water hammer* or *Joukowski shock*.



M11. Fig. 27. One cycle of unsteady and asymmetric high frequency void fraction formation in cavitating flow trough 2-D plane injection nozzle; inviscid flow modeling, numerical simulation, $T_{cycle} = 1.6 \cdot 10^{-5}$ s, $f_{cycle} = 61$ kHz; water as test fluid, $T_{inlet} = 293$ K, $p_{inlet} = 80$ bar, $p_{out,mix} = 26$ bar; $\Delta t_{CFD} = 10^{-9}$ s, second-order accurate discretization in space and time.

Phenomena such as sonoluminescence are essentially based on wave dynamics without convection. The amplitude of pressure waves Δp depends on the acoustic impedance ρc, whereas the convective pressure variation depends on ρw:

Waves $\Delta p \approx \rho c \cdot \Delta w$

Convective flow $\Delta p \approx \rho w \cdot \Delta w$

$\rho_{vap} = 0.02$ kg/m^3 $C_{vap} = 400$ m/s $T_{vap} = 293$ K } ρc { **8.0** kg/m^{2}s **vapor**

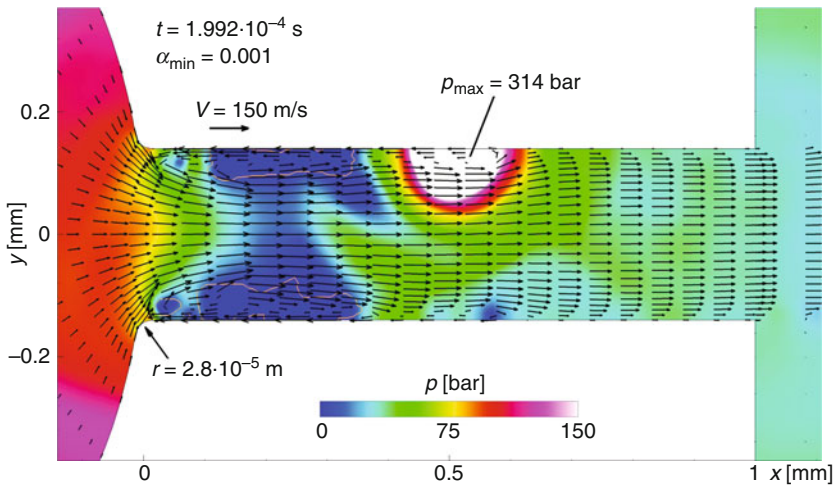
$\rho_{liq} = 10^3$ kg/m^3 $C_{liq} = 1500$ m/s $T_{liq} = 293$ K } ρc { **1.5·10^6** kg/m^{2}s **liquid**

	Δw [m/s]	Δp_{liq} [bar]	Δp_{vap} [bar]	
Waves	1	**15**	$8 \cdot 10^{-4}$	
	10	**150**	$8 \cdot 10^{-3}$	w = 15 m/s
Convective flow	1	$1.5 \cdot 10^{-1}$	$8 \cdot 10^{-6}$	
	10	1.5	$8 \cdot 10^{-5}$	

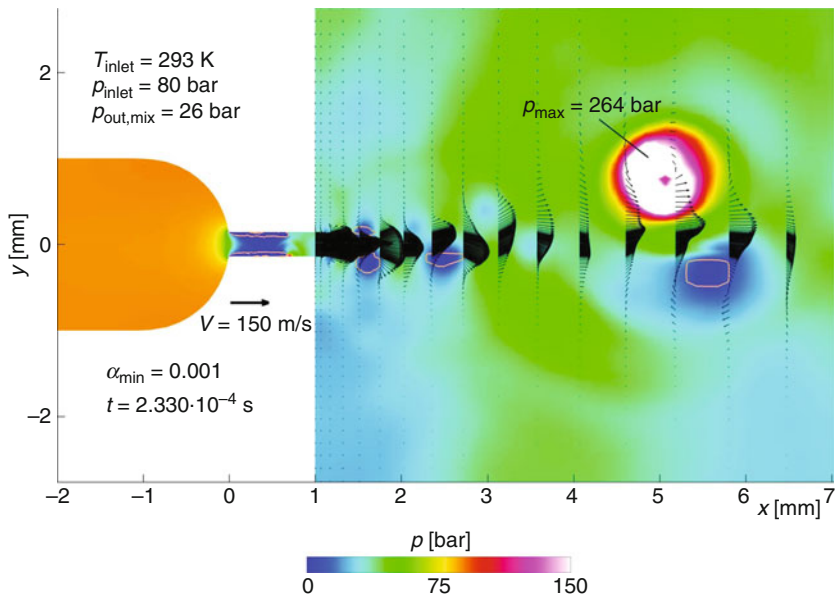
This comparison demonstrates the intensity of the wave impact on blade surfaces etc. in pure liquids even in case of low convective transport velocities of 1–10 m/s [88, 89, 91].

4.4.1 Collapse Dynamics and Erosion Mechanism

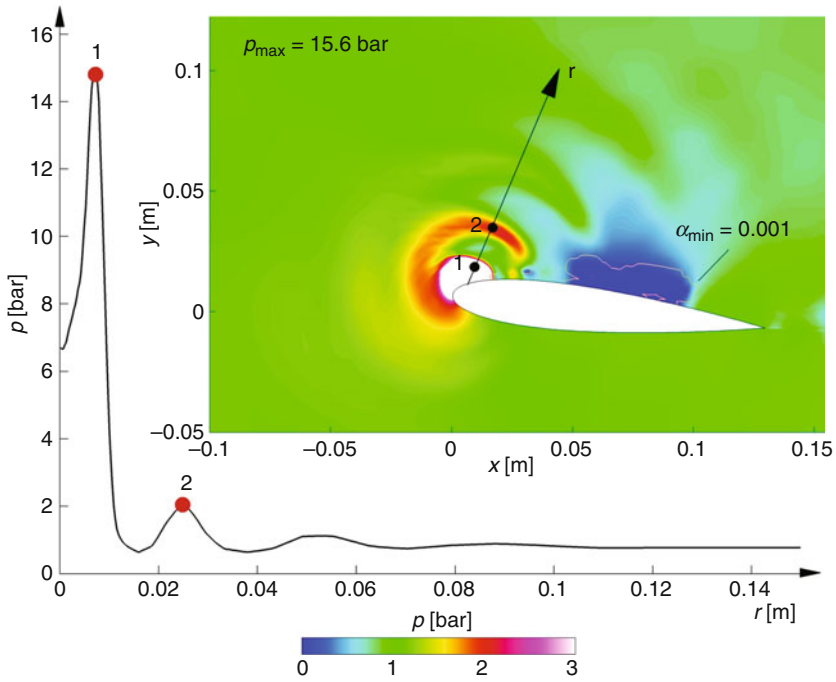
Figure 27 is an example of the unsteady void fraction evolution in a 2-D plane microchannel, scale and pressure difference are



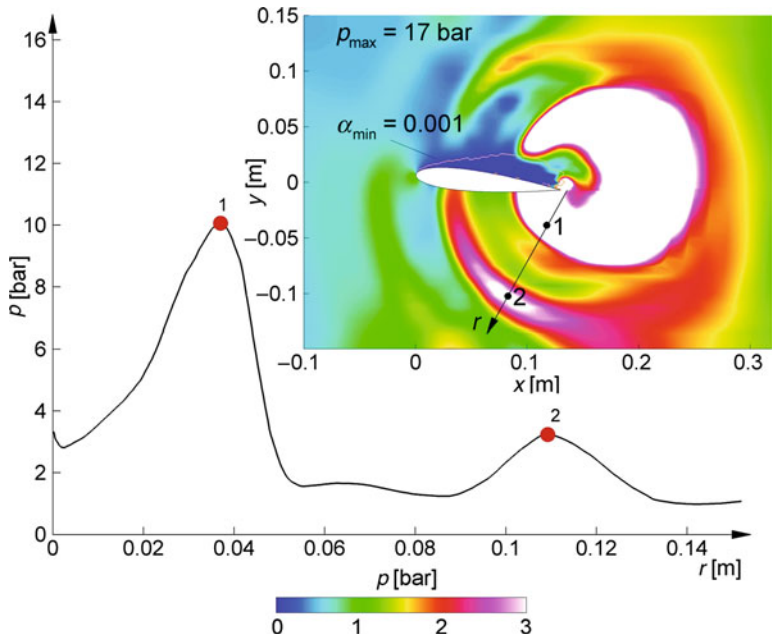
M11. Fig. 28. Instantaneous formation of a strong circular shock after violent vapor cloud collapse in the nozzle bore hole with maximum pressure $p_{max} = 314$ bar; $T_{inlet} = 293$ K, $p_{inlet} = 80$ bar, $p_{out,mix} = 26$ bar; $\Delta t_{CFD} = 10^{-9}$ s, second-order accurate discretization in space and time.



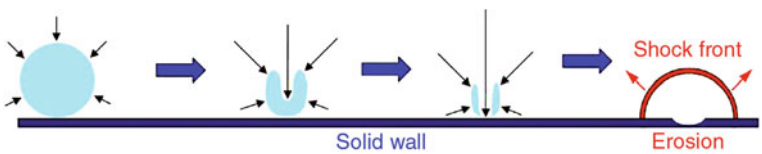
M11. Fig. 29. Instantaneous formation of a strong circular shock after violent cloud collapse in the cavitating shear layer of the outflow domain, maximum pressure $p_{max} = 264$ bar; $p_{in} = 80$ bar, $p_{out} = 26$ bar, $T_{in} = 293$ K; $\Delta t_{CFD} = 10^{-9}$ s, second-order accurate discretization in space and time.



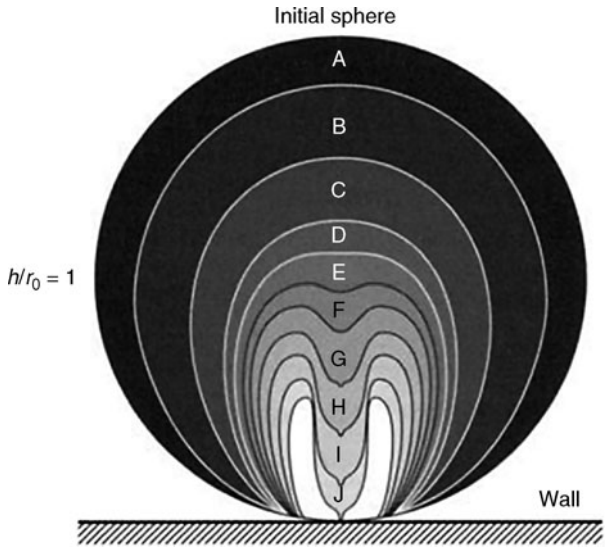
M11. Fig. 30. Radial pressure decay after collapse-induced shock formation at the leading edge of a 2-D hydrofoil 2-D plane NACA 0015 hydrofoil at 6° angle of attack; w_{inlet} = 12 m/s, T_{inlet} = 293 K, $p_{out,mix}$ = 0.74 bar, σ_{ref} = 1.0; $\Delta t_{CFD} = 10^{-7}$ s, second-order accurate discretization in space and time.



M11. Fig. 31. Radial pressure decay after collapse induced shock formation at the trailing edge of a 2-D hydrofoil 2-D plane NACA 0015 hydrofoil at 6° angle of attack; w_{inlet} = 12 m/s, T_{inlet} = 293 K, $p_{out,mix}$ = 0.74 bar, σ_{ref} = 1.0; $\Delta t_{CFD} = 10^{-7}$ s, second-order accurate discretization in space and time.



M11. Fig. 32. Sketch of the empirical idea of erosion mechanism driven by liquid jet impact during single vapor bubble collapse close to solid walls.



M11. Fig. 33. Asymmetric collapse of a liquid embedded vapor bubble close to solid surface, 10 instants in time; h/r_0 is the normalized distance of the bubble center from the wall, r_0 is the initial bubble radius, as given in the theory by Plesset and Chapman [112].

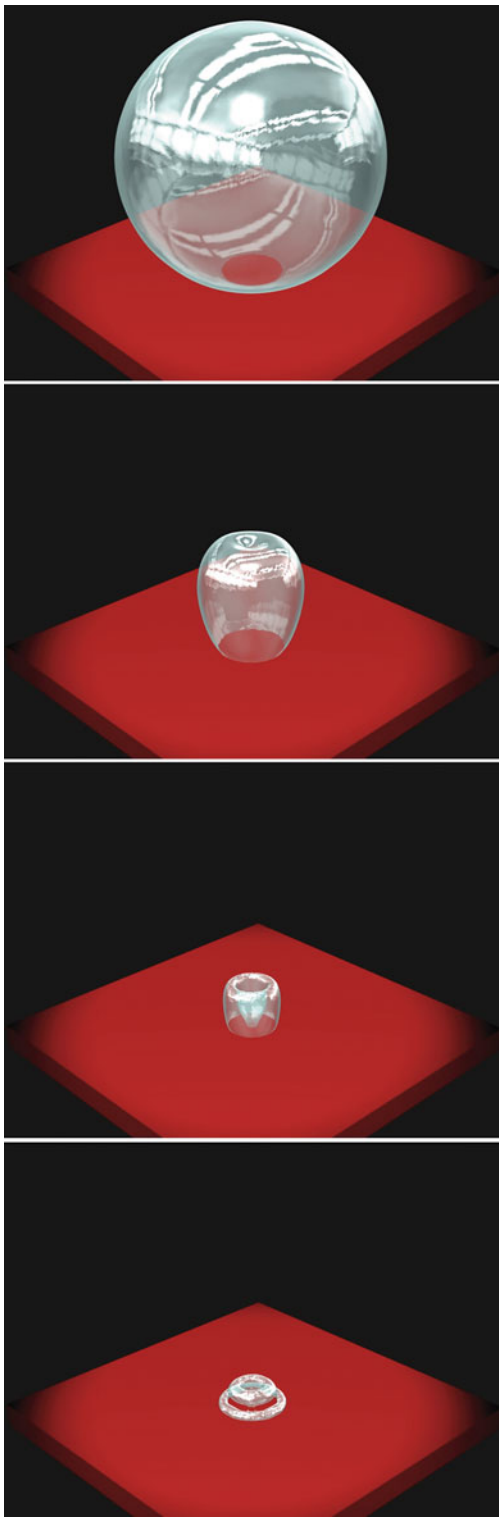
representative for injection nozzles. The strong expansion at the inlet initiates cavitation with local void fractions up to $\alpha \approx 1$. The instability of the flow is obvious, and the topology does not show any symmetry. Corresponding to the void formation, Figs. 28 and 29 show two instants with shocks inside the channel and outside. Both shocks evolve from local collapse events. The maximum intensity with 264 bar is about one order higher O (10^3 bar) as the average pressure outside of 26 bar. The real maximum intensity is at least one order higher, but the resolution of the numerical simulation is limited by the grid size. The interesting question in focus of this application is, how shocks interfere with the turbulence of the liquid jet, and can this interaction improve spray characteristics?

Figures 30 and 31 depict shocks emerging from the leading edge and from the trailing edge of a hydrofoil. In addition to their potential for erosion they produce instantaneous loads on the blade surface with strong variations of lift and drag [89–94].

The classical erosion model (Fig. 32) presumes the impact of a liquid jet during the bubble collapse as the main source of erosion. Fig. 33 shows the asymmetric deformation of an initially spherical bubble close to a wall, in detail [85]. The numerical simulation (Fig. 34) reproduces this analytical result accurately, and Fig. 35 demonstrates the exceptional strength of shocks emerging from the focus. In the violet region the pressure is about 4,000 bar. The last picture of Fig. 34 corresponds to the instantaneous shock evolution of Fig. 35.

4.5 CFD Techniques for Calculation of Cavitating Flows

Most of the CFD tools for simulation of cavitating flows are pressure based. Such methods are typical for incompressible flow



M11. Fig. 34. Numerical simulation of the asymmetric collapse of a liquid embedded vapor bubble close to solid surface, 4 instants in time, $t_0 = 0$ s, $t_1 = 1.59 \times 10^{-5}$ s, $t_2 = 1.71 \times 10^{-5}$ s, $t_3 = 1.76 \times 10^{-5}$ s, initial bubble radius $r_0 = 5 \times 10^{-4}$ m, collapse time $t_{collapse} = 1.74 \times 10^{-5}$ s, liquid pressure far from the bubble surface $p_{liq} = 10$ bar, pressure within the bubble $p_{vap} = 0.023$ bar; $\Delta t_{CFD} = 6{\cdot}10^{-9}$ s, second-order accurate discretization in space and time.

simulations. Extension to compressible flow applications is possible but not as effective and not as accurate as density-based methods that can resolve all scales of wave and shock dynamics effectively [95]. However, due to the physically determined small time steps CPU time requirements to perform such simulations are high and therefore not available in commercial codes.

It is interesting to note that the set of conservation equations for simulation of cavitating flows is quite similar to that for calculation of condensing flows [Eqs. (40–44)]. The transport equation for the mass fraction x reads

$$\frac{\partial(\rho x)}{\partial t} + \nabla \cdot (\rho x \vec{v}) = \rho \cdot \frac{\mathrm{d}x}{\mathrm{d}t} = F_{\text{source term, cavitation}}. \qquad (57)$$

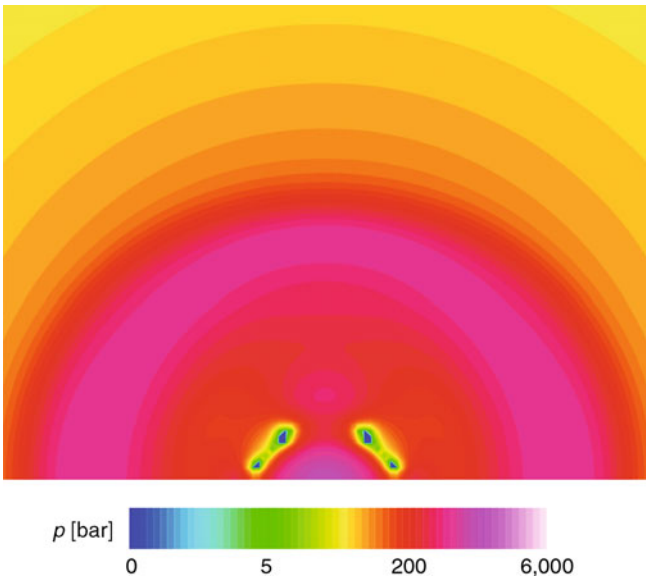
Assuming homogeneous nucleation in cavitating flows, which is rather unclear – how to determine accurately the homogeneous nucleation rate J_{hom} – would result in

$$\begin{aligned} \frac{\partial}{\partial t}(\rho x_{\text{hom}}) + \nabla(\rho x_{\text{hom}} \vec{v}) &= \frac{4}{3}\pi \rho_{\text{vap}} r_{\text{hom}}^{*3} J_{\text{hom}} \\ &\quad + \rho_{\text{vap}} \rho n_{\text{hom}} \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{4}{3}\pi \bar{r}_{\text{hom}}^{3}\right), \\ \frac{\partial}{\partial t}(\rho n_{\text{hom}}) + \nabla(\rho n_{\text{hom}} \vec{v}) &= J_{\text{hom}}. \end{aligned} \qquad (58)$$

Application of the dispersed two-phase model for the determination of vapor contents leads to the following source term

$$\frac{\partial}{\partial t}(\rho x_{\text{het}}) + \nabla(\rho x_{\text{het}} \vec{v}) = \rho_{\text{vap}} \frac{n_0}{1 + n_0 \frac{4}{3}\pi r_{\text{het}}^3} \cdot \frac{\mathrm{d}}{\mathrm{d}t}\left(\frac{4}{3}\pi r_{\text{het}}^3\right). \qquad (59)$$

Assuming equilibrium phase transition reduces this set of conservation equation substantially. Then the transport equations can immediately be replaced by the algebraic equation of state of the pure phases and of the two-phase mixture region.



M11. Fig. 35. Visualization of instantaneous static pressure rise behind shock in the meridian plane according to the last picture of Fig. 34, maximum pressure p_{max} = 4,000 bar at time instant $t_3 = 1.76 \times 10^{-5}$ s; $\Delta t_{\text{CFD}} = 6 \times 10^{-9}$ s, second-order accurate discretization in space and time.

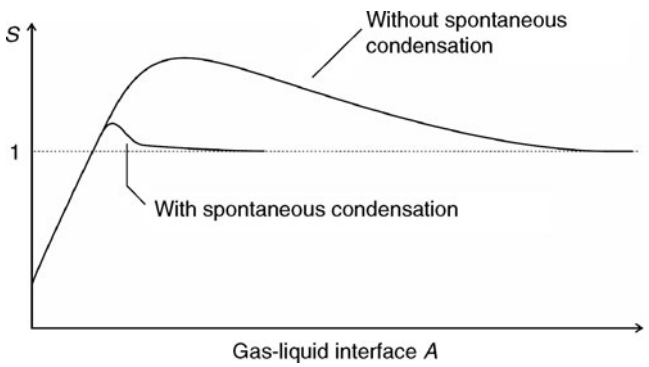
5 Aerosol Formation in Gas–Liquid Contact Devices

5.1 Phenomena and Scope

In gas–liquid contact devices such as absorbers, scrubbers, quench coolers, evaporators, and condensers, aerosols can be formed by spontaneous condensation or desublimation in supersaturated carrier gas–vapor flows. In contrast to the adiabatic expansion (Sect. 3) or cavitation (Sect. 4), supersaturation in gas–liquid contact devices may appear caused by a different mechanism: excluding chemical reactions in the gas phase, supersaturation can arise if the dew point line is intersected by the process trajectory, describing the change of state of the flowing gas due to simultaneous heat and mass transfer between both phases [3]. Figure 36 shows typical saturation curves along the interfacial area A of a gas–liquid contact device. Supersaturation in gas–liquid contact devices is a local phenomenon which vanishes again if the interfacial area tends versus infinite values. In this case, the thermodynamic equilibrium between both bulk phases is reached (S = 1). If nucleation and consequently, fog formation take place the saturation ratio of the gas phase decreases rapidly, and the growth of aerosol droplets is finished if values of S close to 1 are reached.

Supersaturation and fog formation especially may occur if high-strength inorganic acids such as HCl, HBr, HNO_3, and SO_3 (H_2SO_4) are absorbed in aqueous solutions, as well as if pure components or mixtures are condensed or evaporated in the presence of inert gases. The inert gas plays an important role: On the one hand, it causes a diffusion barrier which promotes supersaturation, and on the other hand, it serves as carrier medium for the aerosol droplets which are formed by nucleation and growth in the contact device.

The undesired aerosol formation in gas–liquid contact devices is a well-known phenomenon in the industry for more than 60 years. It has been described and explained in various publications [96, 97, 98], whereas the main emphasis



M11. Fig. 36. Typical curves of saturation versus interfacial area A of gas–liquid-contact devices for processes with and without nucleation.

is on condensation processes. Recent overviews on aerosol formation in absorption or wet scrubbing processes are given by Schaber [3, 34], Haep [99], Ulbrich et al. [100], Wix [31], and Brosig [101].

According to the scope of the VDI Heat Atlas, the following sections are focused to fog formation in condensation processes.

5.2 Modeling and Simulation of Aerosol Formation

Modeling of aerosol formation in an arbitrary contact device requires the description of the competing heat and mass transfer processes between gas and liquid phases on the one hand, and between gas and dispersed phases on the other hand. Both processes have rather different time scales, i.e., seconds for the first process and milliseconds for the latter process.

Since the physical situation in real industrial gas–liquid contact devices is far too complex for a detailed description including hydrodynamics, thermodynamics, and particle dynamics various simplified models have been described in the literature which are based on spatially one-dimensional flow of both phases in contact with one another. The interfacial area A has been chosen as an independent variable along which temperature and concentration profiles as well as saturation ratios of the bulk gas phase are calculated, using mainly a rigorous description of heat and mass transfer according to the film model. Homogeneous or heterogeneous nucleation and droplet growth are described by the methods discussed in Sect. 2. The simulation tools based on these models have been evaluated by experimental investigations, and it has been shown that the following basic assumptions are justified [31, 33, 99–102]:

(1) Spatially one-dimensional models including axial dispersion describe aerosol formation in packed columns sufficiently well. This is due to the fact that radial saturation profiles can be neglected in these devices.
(2) If heterogeneous nucleation takes place a monodisperse description of the growing aerosol droplets is a rather good approach for all contact devices.
(3) Processes with homogeneous nucleation require polydisperse modeling of the growing droplet fractions, especially in those cases when the nucleation event takes place within a larger interval of the saturation ratio S [31].

Aerosol formation may occur in a bulk gas phase as well as in a heat and mass transfer boundary layer. Concerning the total mass of aerosol droplets, the formation in a bulk gas phase is the dominating phenomenon. Nevertheless, some investigations show that aerosol formation in boundary layers may influence heat and mass transfer rates [103, 104].

Most of all investigations cited above are concerned with aerosol formation in absorption processes for the separation of hazardous gas components by means of packed columns. Although this topic is beyond the scope of the Heat Atlas, most of these findings can be transferred to condensation and evaporation processes discussed in the following section.

5.3 Fog Formation in Condensers and Evaporators

The essence of supersaturation and fog formation in condensation and evaporation in the presence of an inert gas can be demonstrated and explained with a simplified plug flow model suggested by Colburn and Edison [96] which allows to calculate the process path, i.e., the change of state of the gas phase during the process. A linear approach for heat and mass transfer together with a differential mass balance yields after integration and elimination of the interfacial area A the following equation:

$$p_{\mathrm{vap}} = \left(p_{\mathrm{vap},1} - p_{\mathrm{sat}}(T_{\mathrm{sf}})\right)\left[\frac{T - T_{\mathrm{sf}}}{T_1 - T_{\mathrm{sf}}}\right]^{L} + p_{\mathrm{sat}}(T_{\mathrm{sf}}) \qquad (60)$$

with

$$L = \frac{\alpha_{\mathrm{G}}}{\beta_{\mathrm{G}} c_{\mathrm{pG}} \rho_{\mathrm{G}}} = \mathrm{Le}^{0.6}. \qquad (61)$$

Le is the Lewis number $\mathrm{Le} = \lambda_{\mathrm{G}}/(\rho_{\mathrm{G}}\, c_{\mathrm{pG}}\, D)$, where D is the binary diffusion coefficient of the vapor component in the carrier gas.

Equation (60) is based on the following assumptions:

(1) The surface temperature of the condensing liquid film or the evaporating liquid can be considered constant along the gas–liquid interface.
(2) Heat and mass transfer can be described with simple linear transport equations, i.e., heat and mass transfer rates are low.
(3) The Lewis number is constant along the process path.

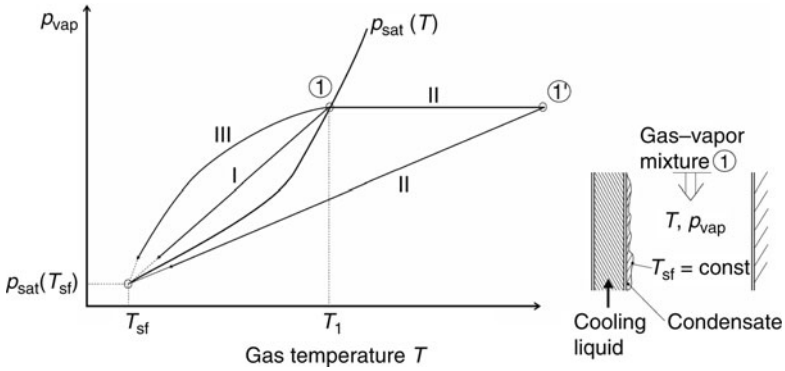
Figure 37 shows typical process paths according to Eq. (60). For infinite interfacial area A the process paths tend versus the film surface temperature T_{sf}. In this case, the thermodynamic equilibrium between gas and liquid phases is reached. For air–water mixtures the Lewis number is about 1, and the process paths are straight lines. If the Lewis number is >1 the process path is concave and higher saturation ratios are reached. For saturated gas–vapor mixtures, supersaturation arises directly after the condenser inlet. Supersaturation during condensation can be avoided if the gas–vapor mixture is superheated before it enters the condenser. It has also been established by experiments that supersaturation and aerosol formation initiated by heterogeneous nucleation can be avoided by superheating the gas–vapor mixture before condensation [27, 105].

Rigorous approaches for heat and mass transfer involving nonvanishing mass fluxes yield curved process paths as shown in Fig. 38 for condensation and evaporation processes [106].

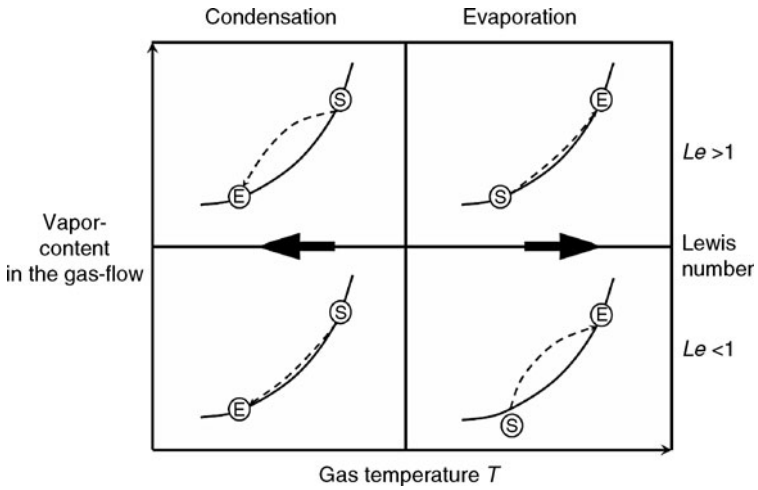
If the Lewis numbers are smaller than or equal to 1, for instance for air–water mixtures, only low supersaturation can be expected in condensation. In contrast to that, high supersaturation arises if the liquid is evaporated in the presence of an inert gas. For Lewis numbers considerably >1 the opposite behavior can be observed.

Experimental investigations confirm this behavior [106].

As pointed out in Sect. 5.2 spatially one-dimensional modeling of process paths is a reliable method to predict



M11. Fig. 37. Process paths for the condensation of gas–vapor mixtures at constant film surface temperature T_{sf} and low vapor loading in comparison to a saturation curve $p_{sat}(T)$. Curves I and II: Le = 1; Curve III: Le > 1.



M11. Fig. 38. Process paths (dashed lines) for evaporation and condensation processes in the presence of inert gases (S = start; E = end) in comparison to saturation curves. The process paths are calculated based on a spatially one-dimensional model with rigorous equations for heat and mass transfer as well as temperature- and concentration-dependent Lewis numbers.

supersaturation and aerosol formation in condensation or evaporation processes if packed columns are used as contact devices where radial profiles of concentration and saturation can be neglected. But most of all condensation processes take place in surface condensers, for instance in tube bundle condensers. For these apparatuses two- or three-dimensional simulations of concentration, temperature, and saturation profiles yield strong radial gradients. But the crucial fact whether or not the gas flow becomes supersaturated ($S > 1$) and fog is formed initiated by heterogeneous nucleation can be predicted based on a one-dimensional model describing the process path along the axis of an apparatus [105, 107]. Investigations of saturation profiles in laminar tube flows underline this finding [108]. It has been demonstrated by Manthey that the theory and experiment match very well if the operation parameters for fog formation (fog limit) initiated by heterogeneous nucleation have to be determined for mixtures with Lewis numbers close to 1 [105]. Obviously, if in a certain cross section the saturation ratio is below 1 but there are local saturation peaks ($S > 1$), and aerosol formation takes place in a narrow section, small-scale transport of droplets in subsaturated sections ($S < 1$) leads to re-evaporation.

For mixtures with higher Lewis numbers saturation peaks may occur in a surface condenser which exceed the critical saturation for homogeneous nucleation, even if the mean saturation ratio in a cross section of an apparatus is far below the critical saturation S_{crit} for homogeneous nucleation [109]. For this case it has been shown by Mall-Gleißle that fog formation initiated by homogeneous nucleation already may occur if the saturation ratio predicted by a one-dimensional plug flow model exceeds $S = 1$ [106].

Summary of the findings describing the following recommendations to estimate the fog formation potential in condensation and evaporation in the presence of inert gases can be given:

(1) The Lewis number of the gas–vapor mixture is the decisive parameter governing the formation of a supersaturated gas phase.
(2) Spatially one-dimensional modeling of condensers and evaporators is sufficient for estimating the maximum saturation which is relevant to decide whether fog formation occurs.

(3) High temperature differences between gas phase and cooling medium favor fog formation.
(4) Superheating of gas–vapor mixtures before condensation decreases supersaturation and consequently, the tendency to fog formation.

6 Symbols

c	speed of sound (m/s)
d	diameter (m)
F_i	ith functional relation ($i = 1,\ldots, 4$)
f	frequency (s^{-1})
g	condensate mass (kg)
g/g_{max}	condensate mass fraction/wetness (–)
J	nucleation rate ($m^{-3}\ s^{-1}$)
$k = 1.380662 \times 10^{-23}$ J/K	Boltzmann constant
K	frequency factor ($m^{-3}\ s^{-1}$)
$\mathrm{Kn} = \Lambda/d$	Knudsen number (–)
L	latent heat (J kg^{-1})
m_1	mass of a molecule (monomer) (kg)
M	Mach number (–)
$N_A = 6.022045 \times 10^{23}\ mol^{-1}$	Avogadro constant
n	number concentration (m^{-3})
n_{het}	heterogeneous nuclei concentration (m^{-3})
n_{hom}	homogeneous nuclei concentration (kg^{-1})
O	surface of a cluster /nucleus (m^2)
p	pressure (bar)
$p_{i,sat}$	partial saturation vapor pressure of component i in a mixture (bar)
$p_{0i,sat}$	pure component saturation vapor pressure in a mixture (bar)
p_{sat}	total saturation vapor pressure (bar)
q	heat addition (J kg^{-1})
Re	Reynolds number (–)
r^*	critical nuclei radius, radius of curvature at the nozzle throat (m)
S	saturation ratio (–)
St	Strouhal number (–)
T_{cycle}	time interval of one cycle (s)
Tu	degree of turbulence (–)
w	velocity (m s^{-1})
$\vec{v}$	velocity vector (m s^{-1})
x	vapor mass fraction (–)
y^*	half nozzle height at the nozzle throat (m)
Z	Zeldovich factor (–)

Greek letters

α	Mach angle (°)
α	void fraction, vapor volume fraction (–)
α_C	accommodation coefficient (–)
β, δ	angle (°)
Λ	mean free path (m)
γ	heat capacity ratio (–)
Φ	relative humidity (–)
μ_i	chemical potential of a component i in a mixture (J/mol)
μ	chemical potential of a pure component (J/mol)
σ	surface tension (N m^{-1})
σ_{ref}	cavitation number at reference state (–)
Θ	nonisothermal factor (–)
τ_c, τ_f	characteristic time scales (s)

Subscripts

0	reservoir conditions
1, 2	conditions at position 1, 2
c	condensation onset
cycle	value of one cycle
G, gas	gaseous value
het	heterogeneous
hom	homogeneous
inlet	inlet value
L, liq	liquid value
max	maximum value
min	minimum value
out, mix	outlet value
r	curved surface with radius r
ref	reference value
rot	rotational velocity
sat	equilibrium saturation state
sf	liquid film surface property
vap	vapor value
∞	flat interface r = ∞, bulk value

Superscripts

a	exponent of similarity law
–	reduced value, averaged value
*	value of critical nucleus, value at $M = 1$

M2 Heat Transfer to Walls with Welded Coils

Wolfgang Heidemann
Universität Stuttgart, Stuttgart, Germany

1 Introduction

In process and chemical engineering apparatuses like stirrer vessels, tanks, or autoclaves are often equipped with welded on coils at the outer surface. These coils are used for the heating and cooling of the respective vessel contents. For that purpose a heat carrier fluid flows through the pipes. Figure 1 shows the cross section of three typical stirrer vessel wall constructions. Compared to double-walled vessels, vessels with welded on coils allow smaller wall thicknesses and hence, are more economic. Furthermore, a good heat transfer inside of the coil is possible even though high viscous heating or cooling fluids are applied.

2 Theory

The calculation of the overall heat transfer from inside of the vessel to the heat carrier fluid requires – in case of known heat transfer coefficients α_t and α_w – the knowledge of the thermal resistance of the vessel wall. Komoßa [1] presented a method which implies the following simplifying assumptions:

- Since the wall thickness of the apparatuses to be observed is small compared to the diameter, a planar problem results.
- The heat transport is in steady state.
- Heat losses from the outer surface of the coil to the ambient are neglected.

Figures 3–5 show simple symmetrical subzones of the whole wall constructions depicted in Fig. 1. The symmetrical subzones according to Figs. 4 and 5 may be composed of three basic bodies with simple layout as follows:

- A part of the vessel wall
- The welded seam
- One half of the tube, stretched to a rectangular strip for simplicity

The thermal resistance of a vessel wall with welded on coils (see Fig. 1) results from adding up the single thermal resistances of the series-connected basic bodies.

2.1 Thermal Resistance of Rectangular Bodies

Considering a one-dimensional heat transfer, the thermal resistance of a rectangular body according to Fig. 2a can be calculated from $R_{th} = s/(\lambda \cdot A)$ with λ, s, A as thermal conductivity, thickness, and surface, respectively.

Since one half of the tube, stretched to a rectangular strip, as well as the part of the vessel wall (see Figs. 3–5) transfers heat only in a limited region X ($< l$), a two-dimensional heat flow results in reality. Using a numerical method presented by Heidemann [2], the thermal resistance for two-dimensional heat flow in a rectangular body according to Fig. 2b was numerically investigated for different boundary conditions. The variation from the thermal resistance R_{th} for the one-dimensional case is considered by introducing two correction factors ε and χ

$$R_{th} = \frac{1}{\varepsilon \cdot \chi} \cdot \frac{s}{\lambda \cdot A}. \tag{1}$$

The following polynomial functions are recommended for the calculation of the correction factors

$$\varepsilon = \sum_{i=0}^{3} \sum_{j=0}^{2} a_{ij} \cdot \left(\frac{s}{l}\right)^j \cdot \left(\frac{X}{l}\right)^i \tag{2a}$$

$$\chi = \sum_{i=0}^{2} \sum_{j=0}^{3} b_{ij} \cdot \left(\frac{s}{l}\right)^j \cdot \left(\frac{1}{1 + \frac{\lambda}{\alpha \cdot s}}\right)^i \tag{2b}$$

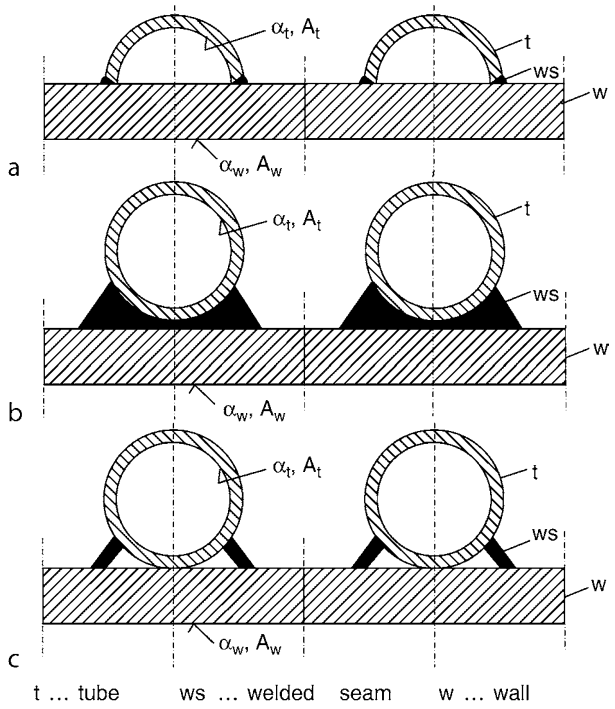
with a_{ij} and b_{ij} as polynomial coefficients, listed in Tables 1 and 3 as well as in Tables 2 and 4 for different wall constructions. Alternatively the correction factors can be taken out of the charts in Figs. 6 and 8 (for ε) and Figs. 7 and 9 (for χ), respectively.

2.2 Multilayered Vessel Walls

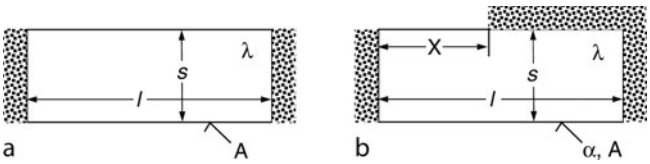
In practical applications vessel walls often consist of the basic wall material and an additional layer at the inside, for example,

- A protection layer made of tin, lead, or enamel
- A fouling layer resulting from pollutions of the vessel content

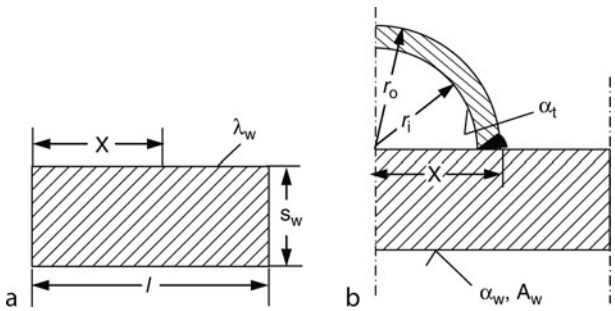
VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_51,



M2. Fig. 1. Cross section of vessel walls with welded on pipe coils at the outside. (**a**) Welded on half pipe, (**b**) welded on full pipe with intermediate layer, (**c**) welded on full pipe without intermediate layer.



M2. Fig. 2. Heat conduction in rectangular bodies. (**a**) One-dimensional, (**b**) two-dimensional.



M2. Fig. 3. Cross section of welded on half pipe. (**a**) Part of the vessel wall, (**b**) symmetrical part.

In this case a fictitious wall layer thickness is introduced as follows

$$s_w = s'_w + s_{al}\frac{\lambda_w}{\lambda_{al}} \text{ with } \lambda_{al} < \lambda_w \qquad (3)$$

In Eq. (3) s'_w, λ_w, s_{al}, and λ_{al} denotes the wall thickness of the basic wall material, the thermal conductivity of the basic wall material, the thickness of the additional layer, and the thermal conductivity of the additional layer.

2.3 Thermal Conductivity of Weld Seams

If the welding material is similar to the basic wall material, the thermal conductivity of the basic wall material can approximately also be used for the weld seam.

3 Overall Heat Transfer Coefficient

3.1 Welded on Half Pipe

The overall heat transfer coefficient k related to the heat transfer area at the inside of the wall A_w (see Fig. 3) results from adding up the single thermal resistances

$$\frac{1}{k} = \frac{1}{\alpha_w} + \frac{1}{\varepsilon \cdot \chi}\cdot\frac{s_w}{\lambda_w} + \frac{1}{\alpha_t}\cdot\frac{1}{X} \qquad (4)$$

with $X = r_o$

$$\varepsilon = \varepsilon\left(\frac{X}{l}, \frac{s_w}{l}\right) \text{ from Fig. 6 or Eq. (2a) with Table 1}$$

$$\text{and } \chi = \chi\left(\frac{X}{l}, \frac{s_w}{l}, \frac{\lambda_w}{\alpha_w \cdot s_w}\right) \text{ from Fig. 7 or Eq. (2b) with Table 2}$$

Example 1

On a vessel wall made of stainless steel (λ_w = 15 W/(m K), s_w = 8 mm), a coiled half pipe (d_o = 32 mm, d_i = 28 mm) is welded with clearances of $2l$ = 100 mm. At the inside of the vessel wall a 0.1 mm thick fouling layer (λ_{al} = 0.75 W/(m K)) occurs. The heat transfer coefficients at the vessel wall and inside the coil are α_w = 1,300 W/(m^{2}K) and α_t = 2,000 W/(m^{2}K), respectively. Sought is the value of the overall heat transfer coefficient.

The fictitious wall thickness is obtained from Eq. (3)

$$s_w = 0.008\text{ m} + (0.0001 \cdot 15/0.75)\text{ m} = 0.01\text{ m}.$$

One receives

$$X = d_0/2 = 0.016\text{ m},\ l = 0.1\,\text{m}/2 = 0.05\,\text{m}$$

as well as

$$\frac{X}{l} = 0.016/0.05 = 0.32;\ \frac{s_w}{l} = 0.001/0.05 = 0.2;$$

$$\frac{\lambda_w}{\alpha_w \cdot s_w} = 15/(1,300 \cdot 0.01) = 1.154$$

Thus results in

ε = 0.39, for example, from Fig. 6 and χ = 0.76, for example, from Fig. 7.

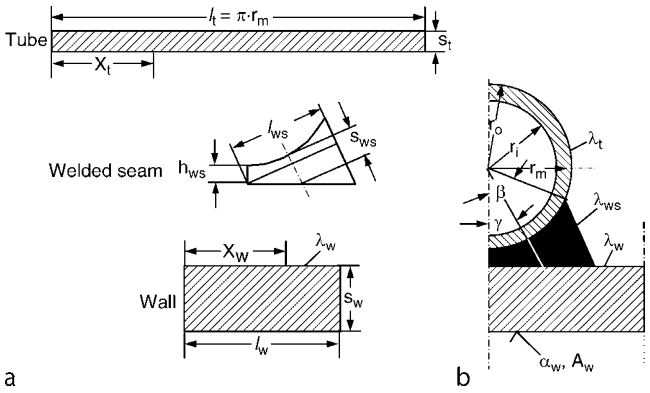
From Eq. (4) follows

$$\frac{1}{k} = \left(\frac{1}{1,300} + \frac{1}{0.39 \cdot 0.76}\cdot\frac{0.01}{15} + \frac{1}{2,000}\cdot\frac{0.05}{0.016}\right)\frac{\text{m}^2\text{K}}{\text{W}}$$

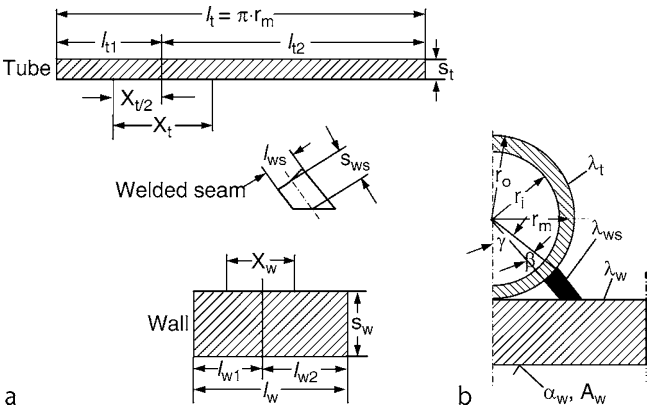
$$= 0.0045809\frac{\text{m}^2\text{K}}{\text{W}}$$

$$k = 218.3 \frac{\mathrm{W}}{\mathrm{m^2 K}}$$

The comparison of the result with the exact (numerical) solution ($k_{num} = 229.2\,\mathrm{W/(m^2K)}$) shows an error of about 4.8% which is acceptable for most of the technical applications.



M2. Fig. 4. Cross section of welded on full pipe with intermediate layer. (**a**) Simplified parts, (**b**) Symmetrical geometry.



M2. Fig. 5. Cross section of welded on full pipe. (**a**) Simplified parts, (**b**) Symmetrical geometry.

3.2 Welded on Full Pipe with Intermediate Layer

$$\frac{1}{k} = \frac{1}{\alpha_w} + A_w(R_{th,w} + R_{th,ws} + R_{th,t}) + \frac{1}{\alpha_1} \cdot \frac{1_w}{\pi \cdot r_i} \tag{5}$$

In Eq. (5) is

- $R_{th,w} \cdot A_w = \dfrac{1}{\varepsilon \cdot \chi} \cdot \dfrac{s_w}{\lambda_w}$ (5a)

  with $\varepsilon = \varepsilon\left(\frac{X_w}{l_w}, \frac{s_w}{l_w}\right)$ from Fig. 8 or Eq. (2a) with Table 3

  $\chi = \chi\left(\frac{X_w}{l_w}, \frac{s_w}{l_w}, \frac{\lambda_w}{\alpha_w \cdot s_w}\right)$ from Fig. 9 or Eq. (2b) with Table 4,

- $R_{th,ws} \cdot A_w = \dfrac{s_{ws}}{\lambda_{ws}} \cdot \dfrac{l_w}{l_{ws}}$ (5b)

  with $s_{ws} = \frac{X_w}{2 \cdot \sin\gamma} - r_o$, $\gamma = \arctan\frac{X_w}{2 \cdot (r_o + h_{ws})}$, $l_{ws} \approx 2(r_0 + h_{ws})\,\sin\gamma$

- $R_{th,t} \cdot A_w = \dfrac{1}{\varepsilon \cdot \chi} \cdot \dfrac{s_t}{\lambda_t} \cdot \dfrac{l_w}{l_t}$ (5c)

  with $\varepsilon = \varepsilon\left(\frac{X_t}{l_t}, \frac{s_t}{l_t}\right)$ from Fig. 8 or Eq. (2a) with Table 3

  $\chi = \chi\left(\frac{X_t}{l_t}, \frac{s_t}{l_t}, \frac{\lambda_t}{\alpha_t \cdot s_t}\right)$ from Fig. 9 or Eq. (2b) with Table 4,

  and $\frac{X_t}{l_t} = \frac{\beta}{180°}$.

Example 2

A coiled full pipe with intermediate layer is welded on a vessel wall. At the inside of the vessel wall a 0.1 mm thick fouling layer ($\lambda_{al} = 0.75$ W/(m K)) occurs. The heat transfer coefficients at the vessel wall and inside the coil are $\alpha_w = \alpha_t = 500$ W/(m^{2}K), respectively. Sought is the value of the overall heat transfer coefficient. The following data are given:

Thermal conductivity of vessel material $\lambda_w = 15$ W/(m K)
Vessel wall thickness $s_w = 10$ mm
Breadth of welded seam $X_w = 24$ mm
Length of the symmetrical part of the vessel wall $l_w = 50$ mm
Thermal conductivity of welded seam $\lambda_{ws} = 14.6$ W/(m K)
Height of welded seam $h_{ws} = 6$ mm
Thermal conductivity of tube material $\lambda_t = 16.7$ W/(m K)
Outer radius of tube $r_o = 24$ mm

Tube thickness $s_t = 4$ mm

Outline angle $\beta = 44°$

One calculates for the vessel wall

$$\frac{X_w}{l_w} = \frac{0.024}{0.05} = 0.48,\ \frac{s_w}{l_w} = \frac{0.01}{0.05} = 0.2,\ \frac{\lambda_w}{\alpha_w \cdot s_w} = \frac{15}{500 \cdot 0.01} = 3$$

Thus results in $\varepsilon = 0.571$, for example, from Eq. (2a) and Table 3 as well as $\chi = 0.747$ from Eq. (2b) and Table 4b. From Eq. (5a) follows

- For the vessel wall $R_{th,w} \cdot A_w = \frac{1}{0.571 \cdot 0.747} \cdot \frac{0.01}{15} \frac{m^2K}{W}$ $= 0.001561 \frac{m^2K}{W}$.
- For the welded seam $\gamma = \arctan\left(\frac{0.024}{2(0.024+0.006)}\right) = 21.8°$, $s_{ws} = \frac{0.024\,m}{2 \cdot \sin(21.8°)} - 0.024\,m = 0.0083\,m$ $l_{ws} = 2(0.024 + 0.006\,m) \cdot \sin(21.8°) = 0.0223\,m$

and from Eq. (5b) $R_{th,ws} \cdot A_w = \frac{0.0083}{14.6} \cdot \frac{0.05}{0.0223} \frac{m^2K}{W} = 0.001275 \frac{m^2K}{W}$.

One receives for the tube

$$\frac{X_t}{l_t} = \frac{44°}{180°} = 0.244,\ \frac{s_t}{l_t} = \frac{0.004}{\pi \cdot \left(0.024 - \frac{0.004}{2}\right)} = 0.0578,$$

$$\frac{\lambda_t}{\alpha_t \cdot s_t} = \frac{16.7}{500 \cdot 0.004} = 8.35.$$

With the values $\varepsilon = 0.266$ from Eq. (2a) with Table 3 and $\chi = 0.22$ from Eq. (2b) with Table 4a it follows for the tube

$$R_{th,t} \cdot A_w = \frac{1}{0.266 \cdot 0.22} \cdot \frac{0.004}{16.7} \cdot \frac{0.05}{\pi \cdot 0.022} \frac{m^2K}{W}$$

$$= 0.002961 \frac{m^2K}{W}.$$

From Eq. (5) it results

$$\frac{1}{k} = \left(\frac{1}{500} + 0.001563 + 0.001275 + 0.002961 + \frac{1}{500} \cdot \frac{0.05}{\pi \cdot 0.02}\right) \frac{m^2K}{W}$$

$$= 0.00939 \frac{m^2K}{W}$$

$$k = 106.5 \frac{W}{m^2K}.$$

3.3 Welded on Full Pipe

According to Fig. 5a the vessel wall as well as the stretched part of the tube is subdivided into two separate parts with individual lengths l_{w1}, l_{w2} and l_{t1}, l_{t2} respectively. The overall heat transfer coefficient results from the single serial and parallel connected thermal resistances

$$\frac{1}{k} = \sum_{i=1}^{2} \frac{1}{\alpha_w} \frac{l_w}{l_{w,i}} + A_w\left(R_{th,w,i} + R_{th,ws} + R_{th,t,i}\right) + \frac{1}{\alpha_t} \cdot \frac{l_w}{l_{t,i}}. \quad (6)$$

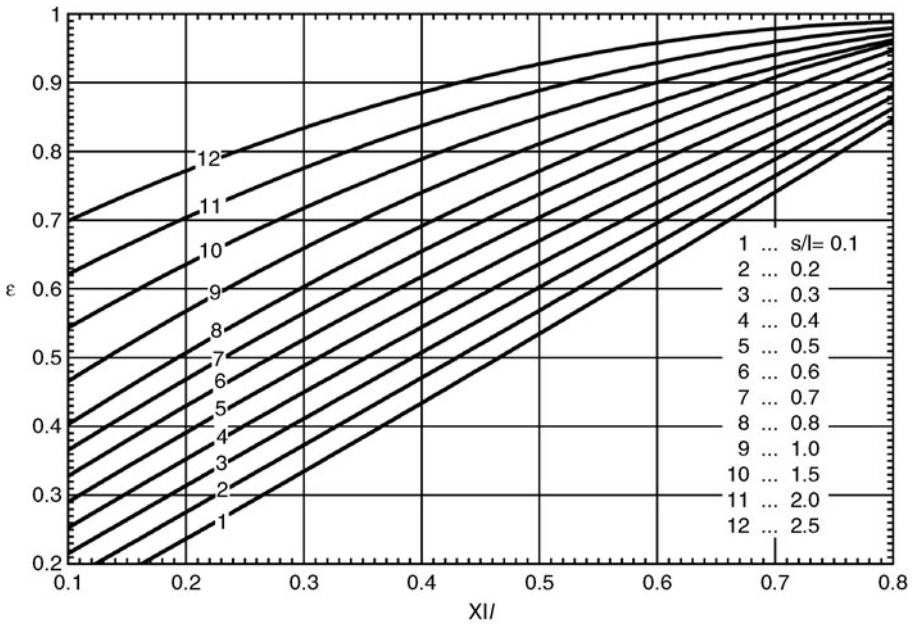
In Eq. (6) is

- $R_{th,w,i} \cdot A_w = \frac{1}{\varepsilon \cdot \chi} \cdot \frac{s_w}{\lambda_w} \cdot \frac{l_w}{l_{w,i}}$ $i = 1, 2$ (6a)

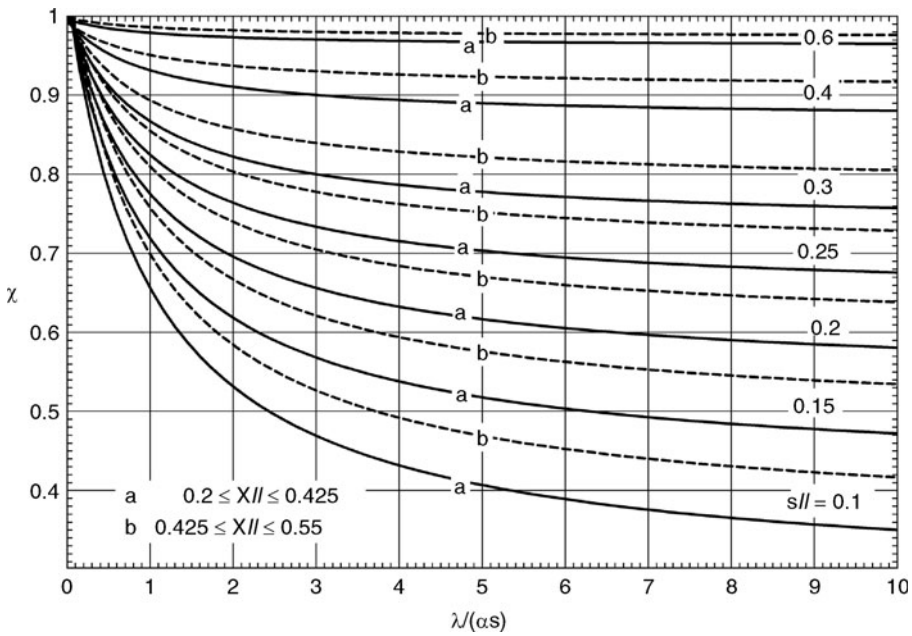
  with for $i = 1$

  $\varepsilon = \varepsilon\left(\frac{X_w}{2 \cdot l_{w,1}}, \frac{s_w}{l_{w1}}\right)$ from Fig. 8 or Eq. (2a) with Table 3

  $\chi = \chi\left(\frac{X_w}{2 \cdot l_{w,1}}, \frac{s_w}{l_{w,1}}, \frac{\lambda_w}{\alpha_w \cdot s_w}\right)$ from Fig. 9 or Eq. (2b) with Table 4, for $i = 2$



M2. Fig. 6. Correction factor ε for welded on half pipe (see Fig. 3).



M2. Fig. 7. Correction factor χ for welded on half pipe (see Fig. 3).

$\varepsilon = \varepsilon\left(\frac{X_w}{2\cdot l_{w,2}}, \frac{s_w}{l_{w2}}\right)$ from Fig. 8 or Eq. (2a) with Table 3

$\chi = \chi\left(\frac{X_w}{2\cdot l_{w,2}}, \frac{s_w}{l_{w,2}}, \frac{\lambda_w}{\alpha_w \cdot s_w}\right)$ from Fig. 9 or Eq. (2b) with Table 4,

- $$R_{th,ws} \cdot A_w = \frac{s_{ws}}{\lambda_{ws}} \cdot \frac{2 \cdot l_w}{l_{ws}} \qquad (6b)$$
- $$R_{th,t,i} \cdot A_w = \frac{1}{\varepsilon \cdot \chi} \cdot \frac{s_t}{\lambda_t} \cdot \frac{l_w}{l_{t,i}} \; i = 1, 2 \qquad (6c)$$

with for $i = 1$

$\varepsilon = \varepsilon\left(\frac{X_t}{2\cdot l_{t,1}}, \frac{s_t}{l_{t,1}}\right)$ from Fig. 8 or Eq. (2a) with Table 3

$\chi = \chi\left(\frac{X_t}{2\cdot l_{t,1}}, \frac{s_t}{l_{t,1}}, \frac{\lambda_t}{\alpha_t \cdot s_t}\right)$ from Fig. 9 or Eq. (2b) with Table 4,

for $i = 2$

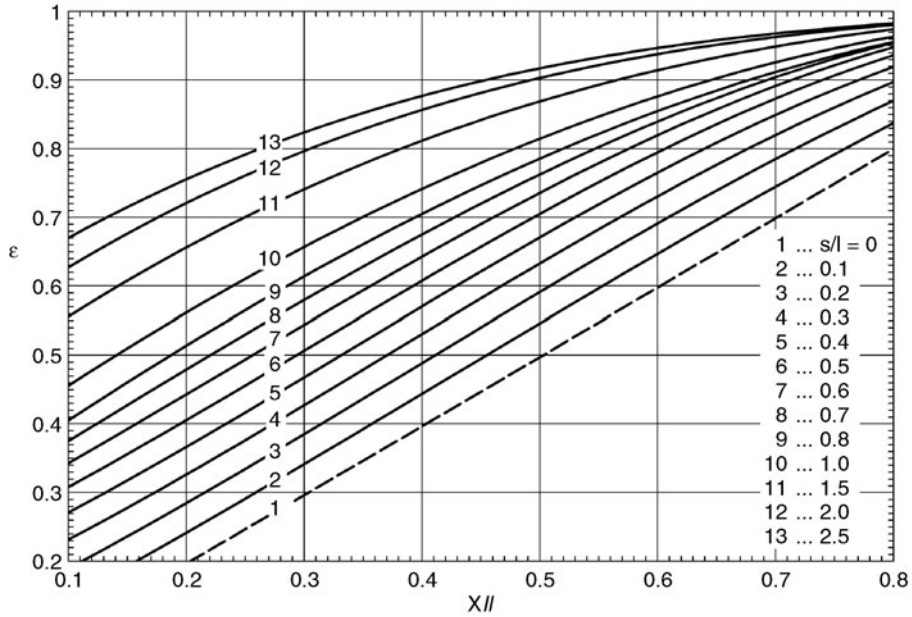
$\varepsilon = \varepsilon\left(\frac{X_t}{2\cdot l_{t,2}}, \frac{s_t}{l_{t,2}}\right)$ from Fig. 8 or Eq. (2a) with Table 3

$\chi = \chi\left(\frac{X_t}{2\cdot l_{t,2}}, \frac{s_t}{l_{t,2}}, \frac{\lambda_t}{\alpha_t \cdot s_t}\right)$ from Fig. 9 or Eq. (2b) with Table 4,

and $\frac{X_t}{l_t} = \frac{\beta}{180°}$, $\frac{l_{t,1}+0.5\cdot X_t}{l_t} = \frac{\gamma}{180°}$.

Example 3

On a 10-mm-thick vessel wall a coiled full pipe (d_o = 48 mm, s_t = 4 mm) is welded with clearances of $2l_w$ = 100 mm in such a way, that 75% of the outer tube surface is in contact with the ambience. The welded seam has a thickness of s_{ws} = 6 mm and a



M2. Fig. 8. Correction factor ε for welded on full pipes (see Figs. 4 and 5).

length of $l_{ws} = 5$ mm. Furthermore, the following data are given: $l_{w,2} = 32.5$ mm, $X_w = 6$ mm, $\beta = 13°$. The heat transfer coefficients at the vessel wall and inside the coil are $\alpha_w = 1{,}000$ W/(m^{2}K) and $\alpha_t = 2{,}500$ W/(m^{2}K), respectively. The thermal conductivities of the tube, the welded seam, and the wall material correspond to example 2. Sought is the value of the overall heat transfer coefficient.

One calculates for the vessel wall

$$l_w = \frac{0.1\,\text{m}}{2} = 0.05\,\text{m},\ l_{w,1} = (0.05 - 0.0325)\,\text{m} = 0.0175\,\text{m},$$
$$\frac{\lambda_w}{\alpha_w \cdot s_w} = \frac{15}{1{,}000 \cdot 0.01} = 1.5$$

For part 1 of the wall ($i = 1$) one calculates

$$\frac{X_w}{2 \cdot l_{w,1}} = \frac{0.006}{2 \cdot 0.0175} = 0.171,\ \frac{s_w}{l_{w,1}} = \frac{0.01}{0.0175} = 0.571.$$

Thus results in $\varepsilon = 0.403$ from Eq. (2a) and Table 3 as well as $\chi = 0.971$ from Eq. (2b) and Table 4b.

Equation (6a) yields the thermal resistance

$$R_{th,w,1} \cdot A_w = \frac{1}{0.403 \cdot 0.971} \cdot \frac{0.01}{15}\frac{\text{m}^2\text{K}}{\text{W}} \cdot \frac{0.05}{0.0175} = 0.004867\,\frac{\text{m}^2\text{K}}{\text{W}}.$$

For part 2 of the wall ($i = 2$) one receives

$$\frac{X_w}{2 \cdot l_{w,2}} = \frac{0.006}{2 \cdot 0.0325} = 0.092,\ \frac{s_w}{l_{w,2}} = \frac{0.01}{0.0325} = 0.307$$

and calculates

$\varepsilon = 0.227$ from Eq. (2a) and Table 3

as well as $\chi = 0.863$ from Eq. (2b) and Table 4b.

From Eq. (6a) it results

$$R_{th,w,2} \cdot A_w = \frac{1}{0.227 \cdot 0.863} \cdot \frac{0.01}{15}\frac{\text{m}^2\text{K}}{\text{W}} \cdot \frac{0.05}{0.0325} = 0.005235\,\frac{\text{m}^2\text{K}}{\text{W}}.$$

One calculates for the welded seam from Eq. (6b)

$$R_{th,ws} \cdot A_w = \frac{0.006}{14.65} \cdot \frac{2 \cdot 0.05}{0.005}\frac{\text{m}^2\text{K}}{\text{W}} = 0.008191\,\frac{\text{m}^2\text{K}}{\text{W}}.$$

One receives for the tube

$$X_t = \frac{13°}{180°} \cdot \pi \cdot 0.022\,\text{m} = 0.005\,\text{m}, \gamma = \frac{(100 - 75)}{100} \cdot 180° = 45°$$
$$l_{t,1} = \frac{\gamma}{180°} \cdot l_t - \frac{X_t}{2} = 0.25 \cdot \pi \cdot 0.022 - 0.0025\,\text{m} = 0.0147\,\text{m},$$

$$l_{t,2} = \pi \cdot 0.022 - 0.0147\,\text{m} = 0.0544\,\text{m}, \frac{\lambda_t}{\alpha_t \cdot s_t} = \frac{16.74}{2{,}500 \cdot 0.004} = 1.674.$$

For part 1 of the tube ($i = 1$) one calculates

$$\frac{X_t}{2 \cdot l_{t,1}} = \frac{0.005}{2 \cdot 0.0147} = 0.17, \frac{s_t}{l_{t,1}} = \frac{0.004}{0.0147} = 0.272.$$

and obtains $\varepsilon = 0.285$ from Eq. (2a) and Table 3 as well as $\chi = 0.803$ from Eq. (2b) and Table 4b.

From Eq. (6a) it results

$$R_{th,t,1} \cdot A_w = \frac{1}{0.285 \cdot 0.803} \cdot \frac{0.004}{16.74} \cdot \frac{0.05}{0.0147}\frac{\text{m}^2\text{K}}{\text{W}} = 0.003551\,\frac{\text{m}^2\text{K}}{\text{W}}.$$

For part 2 of the tube ($i = 2$) one calculates

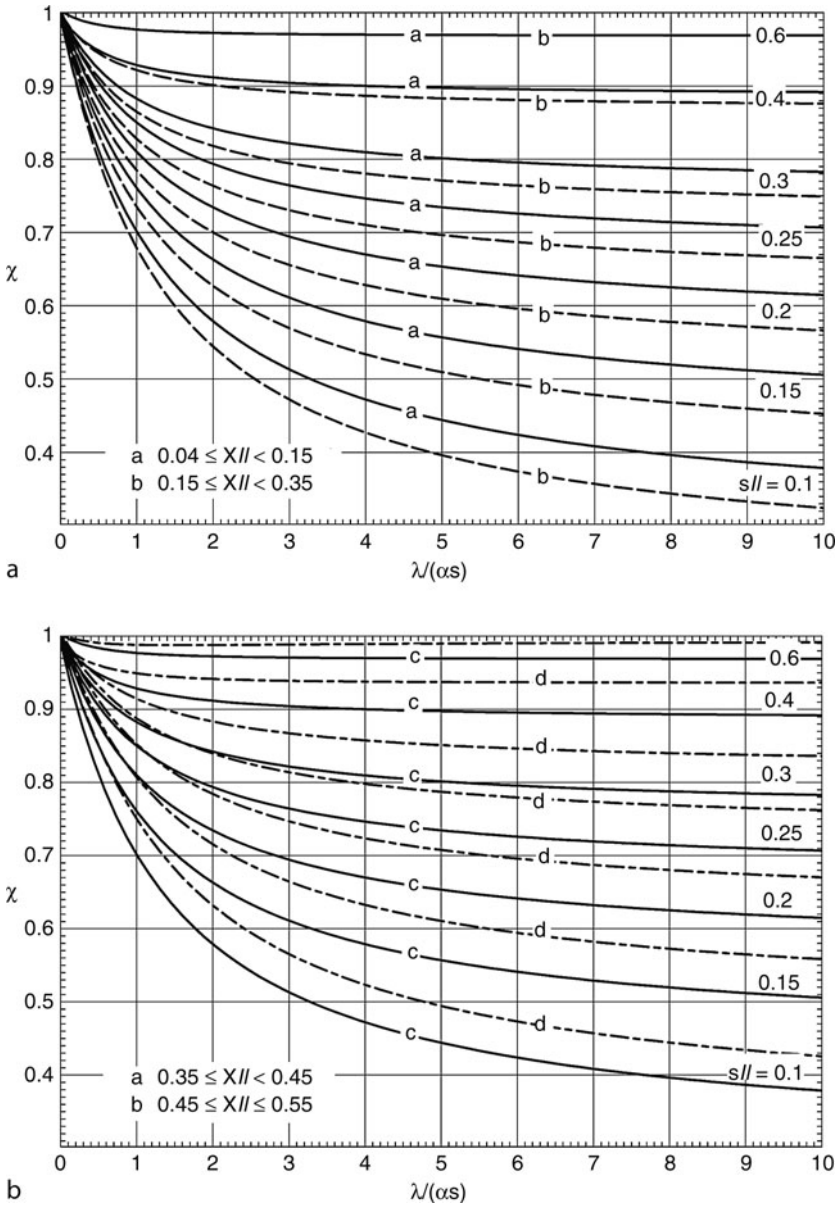
$$\frac{X_t}{2 \cdot l_{t,2}} = \frac{0.005}{2 \cdot 0.0544} = 0.046, \frac{s_t}{l_{t,2}} = \frac{0.004}{0.0544} = 0.0735.$$

and obtains $\varepsilon = 0.082$ from Eq. (2a) and Table 3, $\chi = 0.562$ from Eq. (2b) and Table 4b.

From Eq. (6a) it results

$$R_{th,t,2} \cdot A_w = \frac{1}{0.082 \cdot 0.562} \cdot \frac{0.004}{16.74} \cdot \frac{0.05}{0.0544}\frac{\text{m}^2\text{K}}{\text{W}} = 0.004765\,\frac{\text{m}^2\text{K}}{\text{W}}.$$

and from Eq. (6) one obtains



M2. Fig. 9. (**a**) Correction factor χ for welded on full pipes (see Figs. 4 and 5). (**b**) Correction factor χ for welded on full pipes (see Figs. 4 and 5).

$$k = \left[\frac{1}{\left(\frac{0.05}{1{,}000 \cdot 0.0175} + 0.004867 + 0.008191 + 0.003551 + \frac{1}{2{,}500} \cdot \frac{0.05}{0.0147}\right)}\right] \frac{\mathrm{W}}{\mathrm{m^2K}} + \left[\frac{1}{\left(\frac{0.05}{1{,}000 \cdot 0.0325} + 0.005235 + 0.008191 + 0.004765 + \frac{1}{2{,}500} \cdot \frac{0.05}{0.0544}\right)}\right] \frac{\mathrm{W}}{\mathrm{m^2K}}$$
$$= 97.8 \frac{\mathrm{W}}{\mathrm{m^2K}}$$

M3 Heat Transfer to Falling Films at Vertical Surfaces

Günter Schnabel
BIDECO GmbH, Biberach (Riss), Germany

1 General: Definitions

In falling-film equipment, a thin film of liquid generally flows downward under gravity on the inner surfaces of vertical tube bundles. Heat is transferred in order to

- raise the temperature of the liquid and/or
- evaporate some of the liquid.

The heating medium is mostly steam that condenses on the outer surfaces of the tubes. Occasionally, the falling film is cooled by heat removal. Features of falling-film equipment are

- high heat transfer coefficients
- short residence times
- short liquid holdup
- low pressure drops.

This chapter presents simple power-law equations for the determination of heat transfer during heating, cooling, and evaporation of falling films. They have been derived from verified compilations of measured values [1]. Three dimensionless numbers suffice for the description of heat transfer, viz.,

- the Nusselt number $\equiv \frac{\alpha}{\lambda}\left(\frac{\nu^2}{g}\right)^{1/3}$
- the Reynolds number $\mathrm{Re} \equiv \frac{\dot{m}}{\eta}$
- the Prandtl number $\mathrm{Pr} \equiv \frac{\nu}{a}$.

The term (ν^2/g) has the dimension of a length. It is used instead of the film thickness s, because s itself depends on Re. The wetting rate $\dot{m}$ is the mass flow rate of liquid per unit length of circumference, i.e., $\dot{m} = \dot{M}/\pi d$. Among the dimensionless numbers the following correlation exists:

$$\mathrm{Re} = \mathrm{Nu}^* \mathrm{Ph}^* \mathrm{Ga}^{1/3}/\mathrm{Pr}$$

with

$$\mathrm{Ph} = c_\mathrm{p}{}^* \Delta\vartheta/\Delta h_\mathrm{v}$$
$$\mathrm{Ga}^{1/3} = L/(\nu^2/g)^{1/3}$$

In nonboiling falling films, all the properties (λ, ν, η, and a) are determined at the average of the inlet and the outlet temperatures, i.e., at $\vartheta = (\vartheta_\mathrm{i} + \vartheta_\mathrm{o})/2$; and in boiling films, at the boiling point $\vartheta = \vartheta_\mathrm{sat}(p)$.

2 Film Thickness

A knowledge of the film thickness s is required for the determination of the liquid holdup. It can be obtained from the Nusselt theory [2] if the film is smooth and laminar, i.e.,

$$s_\mathrm{lam} = \left(\frac{3\,\nu^2}{g}\right)^{1/3} \mathrm{Re}^{1/3}; \quad \mathrm{Re} < 400. \tag{1}$$

Kapitza [3] recommended that allowance for surface waves in laminar falling films be made by inserting a numerical value of 2.4 instead of 3 in Eq. (1). Brauer [4] determined the following relationship for turbulent falling films from optical measurements:

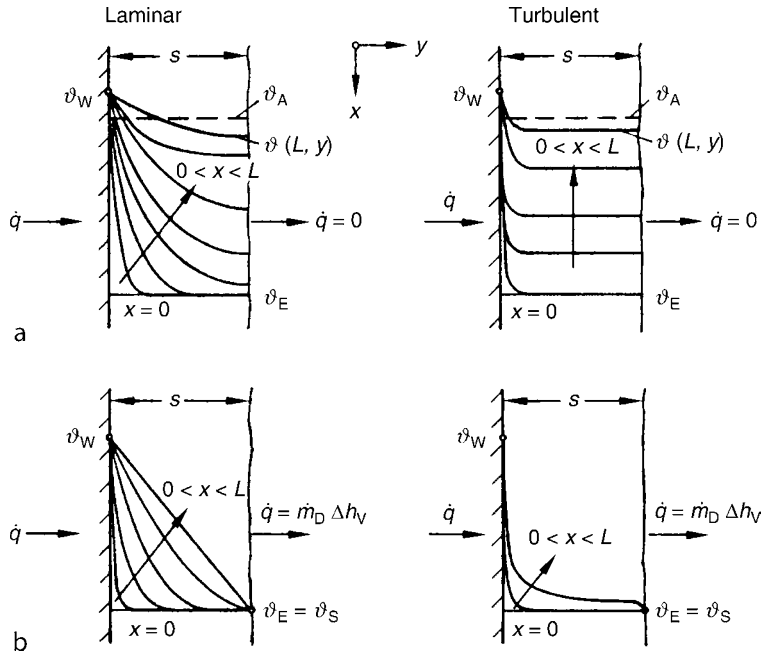
$$s_\mathrm{turb} = 0.302\left(\frac{3\,\nu^2}{g}\right)^{1/3} \mathrm{Re}^{8/15}; \quad \mathrm{Re} > 400. \tag{2}$$

Equation (2) agrees well with the results obtained from semi-empirical correlations derived from general laws on velocity distribution [5–7].

3 Heat Transfer

Various boundary conditions apply to the free surfaces of nonboiling and boiling falling films. Thus, the temperature profile formed in the liquid film during heating or cooling differs from that formed during evaporation. Temperature fields in falling films that have been hydrodynamically developed at a constant wall temperature are shown graphically in Fig. 1. In a *nonboiling* falling film, the temperature profile $\vartheta(x, y)$ changes steadily,

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_52,



M3. Fig. 1. Temperature fields in hydrodynamically developed falling films. (**a**) Nonboiling, laminar, and turbulent falling films without evaporation at the free surface; (**b**) boiling, laminar, and turbulent falling films during evaporation at the free surface.

commencing at $x = 0$, from the inlet ϑ_i to the outlet ϑ_o temperature, as is illustrated in Fig. 1a. The outlet temperature is the calorific mean of the film temperature distribution, i.e.,

$$\vartheta_o = \frac{\int_0^s \varrho c u \vartheta \, dy}{\int_0^s \varrho c u \, dy}.$$

If the flow path x is short, the bulk of the liquid is not affected by the change in temperature. This length is referred to as the zone of thermal development. Initially, the temperature profile assumes the character of a boundary layer. It is parabolic at a point downstream, where flow is thermally developed. If heat is not removed, there is a horizontal tangent to the film at this point.

Temperature fields in *boiling* falling films are shown in Fig. 1b. If the wall temperature ϑ_w is not too high, no vapor bubbles are formed at the wall. When the flow path is short, the falling film is initially superheated near the wall, but evaporation does not occur. It is not until the flow path becomes longer and the temperature gradient penetrates to the surface that evaporation commences. Then, if flow is laminar, heat is transmitted, in accordance with the *Nusselt* condensation theory [2], by a linear temperature gradient to the surface where it is consumed in phase conversion. If film flow is turbulent, the temperature in the bulk is largely equalized. Steeper temperature gradients occur only in the immediate vicinity of the wall and at the surface. The boiling point at the phase boundary is that corresponding to the ambient pressure.

The definition of the heat transfer coefficient α in the heating or cooling of falling films differs from that in evaporation. Consequently, the two cases must be treated separately. A distinction must also be drawn between thermally developing and thermally developed flows. Another factor of some (minor) significance is the manner in which the heat is applied, i.e., whether $\dot{q}$ = constant or ϑ_w = constant.

3.1 Heat Transfer at Nonboiling Falling Films

The coefficient of local heat transfer is defined by

$$\alpha_x \equiv \frac{\dot{q}}{\vartheta_w - \vartheta_x}. \tag{3}$$

The rate of heat flow $\dot{Q}$ at a constant wall temperature over a path of length L is calculated from the average coefficient of surface heat transfer, which is defined by

$$\bar{\alpha} \equiv \frac{\dot{Q}}{A \Delta \vartheta_{log}} = \frac{\dot{m} c_p}{L} \ln \frac{\vartheta_w - \vartheta_i}{\vartheta_w - \vartheta_o}. \tag{4}$$

Conversely, if ϑ_w and α are known, Eq. (4) can be taken to determine the requisite length of tube L.

The average heat transfer coefficient in heating or cooling is obtained from the equations for $\overline{Nu}$, which are as follows in the $x = 0$ to $x = L$ range [1]:

- for laminar, hydrodynamically and thermally developed flow,

$$\overline{Nu} = C_\infty Re^{-1/3}, \tag{5}$$

  where $C_\infty = 1.30$ for ϑ_w = constant and $C_\infty = 1.43$ for $\dot{q}$ = constant;
- in the zone of thermally developing flow,

$$\overline{Nu} = \overline{C}_0 \sqrt[3]{Re^{1/3} \, Pr \left(\frac{\upsilon^2}{g}\right)^{1/3}} \Big/ L, \tag{6}$$

where $\overline{C}_0 = 0.912$ for ϑ_w = constant and $\overline{C}_0 = 1.10$ for $\dot{q}$ = constant;

- in the zone of transition to turbulent flow,

$$\overline{Nu} = 0.0425\,Re^{1/5}\,Pr^{0.344}; \tag{7}$$

- for turbulent flow,

$$\overline{Nu} = 0.0136\,Re^{2/5}\,Pr^{0.344}. \tag{8}$$

The highest value of $\overline{Nu}$ obtained from Eqs. (5–8) is taken to calculate the average heat transfer coefficient α.

The viscosity depends strongly on temperature, and its effect on heat transfer can be taken into account by multiplying the right-hand sides of Eqs. (5–8) by the Bays and McAdams [8] correction factor $(\eta/\eta_w)^{0.25}$, in which η is the dynamic viscosity at the average film temperature and η_w is that at the wall temperature. This factor is valid for both heating and cooling.

The average Nusselt number $\overline{Nu}$ has been plotted against the Reynolds number Re under the boundary condition of ϑ_w = constant in Fig. 2. The parameters are the Prandtl number Pr and the term $Pr(v^2/g)^{1/3}/L$ for the zone of thermal development, which is of significance only for very viscous materials. In the cases of this nature, however, high Reynolds numbers are hardly ever encountered. For this reason, the curves that characterize the zone of thermal development are shown in dashed lines for $Re > 10$ and are not continued beyond $Re > 100$. Again, the higher value should be applied.

Example 1

A predominantly aqueous liquid, e.g., milk or fruit juice, flows downward at a rate of 58.8 kg/h in a vertical, stainless steel tube (d_i = 23 mm; d_o = 25 mm). It is to be sterilized at elevated pressure by brief heating from $\vartheta_i = 25°C$ to $\vartheta_o = 125°C$. Steam condenses at a temperature of $\vartheta_s = 130°C$ on the outer surface of the tube. What is the length L of tube required?

If the area of the outer surface $A = \pi d_o L$ is taken as the reference, the following relationship can be obtained from Chap. C2:

$$\dot{Q} = kA\,\Delta\vartheta_m = k\pi d_o L\,\Delta\vartheta_m,$$

where

$$k = \left(\frac{1}{\bar{\alpha}_c} + \frac{d_o \ln\frac{d_o}{d_i}}{2\lambda} + \frac{d_o}{d_i\bar{\alpha}}\right)^{-1}.$$

The heat balance is

$$\dot{Q} = \dot{M}\,c_p(\vartheta_o - \vartheta_i).$$

It follows that

$$\frac{k\pi\,d_o\,L}{\dot{M}\,c_p} = \ln\frac{\vartheta_s - \vartheta_i}{\vartheta_s - \vartheta_o}.$$

(a) Determination of the heat transfer coefficient on the film side:

The reference temperature for the properties is $\vartheta_m = (25 + 125)/2°C = 75°C$. The values for the properties, which are approximately the same as those for water itself, are obtained by linear interpolation from Chap. D2. Thus,

$$\eta = 379.7 \cdot 10^{-6}\,kg/m; \quad \lambda = 663 \cdot 10^{-3}\,W/(m\,K);$$
$$v = 0.3895 \cdot 10^{-6}\,m^2/s; \quad Pr = 2.40.$$

The Reynolds number determined from these figures is

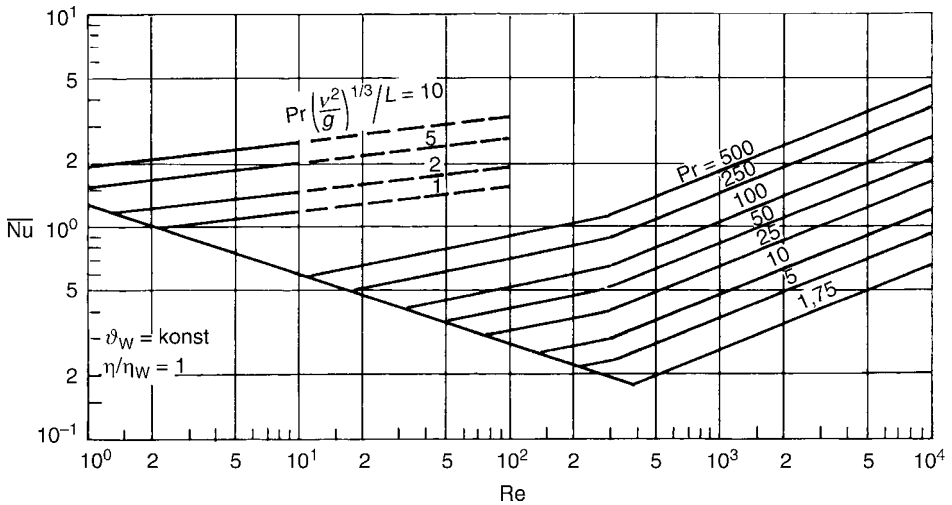
$$Re = \frac{58 \cdot 8}{3,600\pi \cdot 23 \cdot 10^{-3} \cdot 379.7 \cdot 10^{-6}} = 59.5.$$

The Nusselt number is derived from Eqs. (5–8) or from Fig. 2. Thus

$$\overline{Nu} = \begin{cases} 0.154 \text{ from Eq. (5)}, \\ 0.073 \text{ from Eq. (6)}, \\ 0.206 \text{ from Eq. (7)}, \\ 0.237 \text{ from Eq. (8)}. \end{cases}$$

$Nu_{max} = 0.237.$

Hence $\alpha = \overline{Nu}_{max}\,v \Big/ \left(v^2/g\right)^{1/3} = 6,299\,W/(m^2\,K).$



M3. Fig. 2. Average Nusselt number as a function of Re with Pr and $Pr(v^2/g)^{1/3}/L$ as parameters for nonboiling falling films.

In the determination of $\overline{\mathrm{Nu}}$ from Eq. (6), it was assumed that $L = 1$. Here, the calculation is performed in full for the sake of illustration, but it could have been dispensed with since $\mathrm{Re} \gg 10$ (see diagram).

(b) Determination of the heat transfer coefficient on the condensate side:

The heat balance is

$$\dot{M}_c \Delta h_v = \dot{M} c_p (\vartheta_o - \vartheta_i).$$

Hence the condensate flow rate at the lower end of the tube is

$$\dot{M}_c = \frac{\dot{M} c_p (\vartheta_o - \vartheta_i)}{\Delta h_{v,(130°C)}} = 0.00317\,\mathrm{kg/s}.$$

If the condensate temperature is assumed to be 125°C as an initial estimate, the Reynolds number for the condensate film will be

$$\mathrm{Re}_c = \frac{\dot{M}_c}{\pi d_o \eta_{125°C}} = \frac{0.00317}{25 \cdot 10^{-3} \pi \cdot 222.4 \cdot 10^{-6}} = 182.$$

Inserting $\mathrm{Re}_c = 182$ in Eqs. (24) and (25) in Chap. J1 gives the following value for the average Nusselt number:

$$\mathrm{Nu}_c = 0.9245 f_{waves} \mathrm{Re}_c^{-1/3} = 0.188.$$

Therefore, the average heat transfer coefficient on the condensate side is $\alpha_c = 6{,}752\ \mathrm{W/(m^2\,K)}$.

(c) Determination of L

Since $\lambda = 17\ \mathrm{W/(m\,K)}$ for stainless steel,

$$k = \left\{ \frac{1}{6{,}752} + \frac{25 \cdot 10^{-3} \ln 25/23}{2 \cdot 17} + \frac{25}{23 \cdot 6307} \right\}^{-1} = 2{,}619\,\mathrm{W/(m^2\,K)}.$$

Finally, $L = 1.0$ m. Therefore, the average wall temperature on the condensate side is

$$\bar{\vartheta}_{w,c} = \vartheta_s - \frac{\dot{M} c_p (\vartheta_o - \vartheta_i)}{\alpha_c \pi d_o L} = 117.3°C;$$

and the average condensate temperature is

$$\vartheta = \left(\vartheta_s - \bar{\vartheta}_{w,c}\right)/2 = 123.6°C.$$

This figure agrees quite well with the initial assumption.

A more accurate figure for the heat transfer coefficient on the condensate side and thus for the requisite length L involves a differential approach, because the wall temperature is not constant and the values for the properties also change considerably along the length of the path. If Eq. (37) in Chap. J1 is applied to the condensate side, the more accurate figure of $L = 1.16$ would be obtained.

Example 2

The kinematic viscosity at 50°C of an aqueous polymer solution is 500 times greater than that of water, but the other properties correspond to those of water at a temperature of 50°C. The solution flows downward in a tube of 1 m length at a mass flux of $\dot{m} = 0.544\ \mathrm{kg/(m\,s)}$. What is the average Nusselt number $\overline{\mathrm{Nu}}$?

The properties, as listed in Chap. D2, are

$$\mathrm{Pr} = 3.57 \cdot 500 = 1{,}785,$$
$$\nu = 0.554 \cdot 10^{-6} \cdot 500 = 2.770 \cdot 10^{-4}\,\mathrm{m^2/s},$$
$$\varrho = 988\,\mathrm{kg/m^3},$$
$$\eta = \nu\varrho = 0.2736\,\mathrm{kg/m\,s}.$$

Therefore, $\mathrm{Re} = 2$ and $\mathrm{Pr}(\nu^2/g)^{1/3}/L = 3.5$.

The following are obtained from Eqs. (5–8):

$$\overline{\mathrm{Nu}} = \begin{cases} 1.03 \text{ from Eq. (5)} \\ 1.50 \text{ from Eq. (6)} \\ 0.64 \text{ from Eq. (7)} \\ 0.24 \text{ from Eq. (8)} \end{cases} = 1.50 \text{ max},$$

$$\mathrm{Nu}_{max} = 1.50.$$

Hence heat transfer still takes place in the zone of thermal development. However, as the example demonstrates, this case arises only under extreme conditions. After all, the thickness of the film, as determined from Eq. (1), is $s = 3.6$ mm under the aforementioned conditions.

3.2 Heat Transfer During Falling-film Evaporation

The local heat transfer coefficient is defined by

$$\alpha_x = \frac{\dot{q}}{\vartheta_w - \vartheta_{sat}}. \tag{9}$$

In thermally developed flow, the entire amount of heat applied is consumed in vaporization. However, the evaporation rate in practice is usually small compared to the rate of downward liquid flow. Consequently, the film thickness and thus the heat transfer coefficient are practically constant, i.e., $\alpha \approx \alpha_x$. The heat transfer coefficient can be obtained from the evaporation rate, i.e.,

$$\alpha \approx \alpha_x = \frac{\dot{M}_v \Delta h_v}{A(\vartheta_w - \vartheta_{sat})}. \tag{10}$$

Conversely, the evaporation rate $\dot{M}_v$ can be calculated from Eq. (10) if the wall temperature ϑ_w is given and the heat transfer coefficient α is known.

If the heating rate is not too high, the liquid evaporates exclusively at the free surface of the falling film. Vapor bubbles are not yet formed on the heated surface at this stage. Since there have been comparatively few studies on nucleate boiling in falling films, the transition from convective to nucleate boiling cannot be uniquely defined. Nevertheless, as long as the difference $\Delta\vartheta$ between the temperature of the heated wall and the boiling point of the falling film does not exceed 6 K, the heating rate $\dot{q}$ has practically no effect on heat transfer to both water and refrigerants [9, 10], although nucleation does occur at smaller temperature differences.

3.2.1 Heat Transfer in Convective Boiling

The heat transfer equations for boiling at the surface of the film, i.e., convective boiling, are [1]

$$\mathrm{Nu} = \sqrt{\mathrm{Nu}_{\mathrm{lam}}^2 + \mathrm{Nu}_{\mathrm{turb}}^2}, \tag{11}$$

$$\mathrm{Nu}_{\mathrm{lam}} = 0.9\mathrm{Re}^{-1/3}, \tag{11a}$$

$$\mathrm{Nu}_{\mathrm{turb}} = 0.00622\mathrm{Re}^{0.4}\,\mathrm{Pr}^{0.65}; \quad \mathrm{Pr} < 50. \tag{11b}$$

Equation (11b) has not yet been verified by measurements for $\mathrm{Pr} > 7$, but has been found to agree well with measurements for turbulent film condensation [9]. This fact can be readily appreciated in view of the similarity that exists between the hydrodynamic relationships and the thermal boundary conditions. Consequently, a good approximation can be achieved by applying the effect of the Prandtl number on heat transfer during film condensation to that during falling-film evaporation. Thus, the validity of Eq. (11b) can be extended to $\mathrm{Pr} < 50$, as can be verified by comparing the results that it yields with those obtained from Eq. (39) in Chap. J1.

Equation (11) has also proved to be useful in the determination of heat transfer during the falling-film evaporation of water at pressures down to $p \approx 0.05$ bar ($\vartheta \approx 32°\mathrm{C}$) [9].

Equation (11) presupposes that the vapor produced exerts only a moderate shear stress on the falling film. The increase in heat transfer at higher vapor velocities has not yet been studied. A good approximation can undoubtedly be obtained by applying the effect of the gas velocity on heat transfer during condensation to that during evaporation, because – as has already been stated – falling-film evaporation and film condensation are subject to very similar laws. The following values serve as a guide in assessing the improvement in heat transfer that can be achieved in the evaporation of water:

Re_v	7,500	15,000	25,000
$\mathrm{Nu}_{\tau\varrho 0}/\mathrm{Nu}_{\tau=0}$	1.03	1.1	1.2

A more accurate calculation is presented in Chap. J1.

A thermal development zone in which the temperature profile is initially formed also exists in boiling falling films. Evaporation does not commence until the temperature field has reached the surface of the film. Aqueous films reach this stage after they have traversed a path of a few centimeters length. If the liquid is very viscous, a check should be made to determine whether the value for Nu calculated from the following form of Eq. (6) is higher than that obtained from Eq. (11):

$$\mathrm{Nu} = C_0 \sqrt[3]{\mathrm{Re}^{1/3}\,\mathrm{Pr}\left(\frac{\nu^2}{g}\right)^{1/3}} \Big/ L, \tag{6a}$$

where $C_0 = 0.608$ for ϑ_w = constant and $C_0 = 0.733$ for $\dot{q}$ = constant. If this is the case, evaporation will not be initiated along the path of length L.

Results obtained from Eqs. (11) and (6a) are presented graphically in Fig. 3, in which the parameters are the Prandtl number and $\mathrm{Pr}(\nu^2/g)^{1/3}/L$.

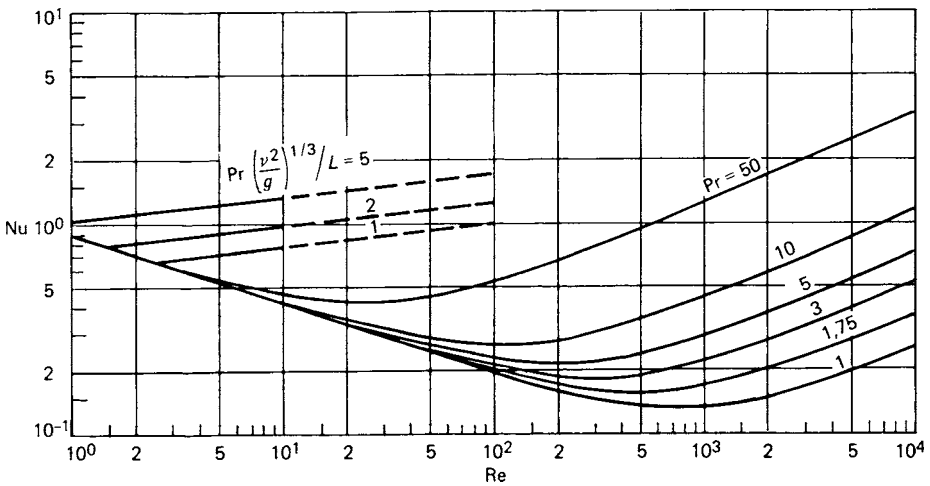
It has been demonstrated [9, 11] that heat transfer in falling-film evaporation can be greatly improved if tubes with longitudinal sinusoidal grooves are used instead of smooth tubes. The overall heat transfer coefficient has been increased by a factor as high as 2.5 in this case.

3.2.2 Heat Transfer in Nucleate Boiling

Significant factors in nucleate boiling are the heat flux $\dot{q}$, the roughness of the walls, the material from which the walls have been constructed, and the properties of the flowing medium itself. Heat transfer in all forms of boiling increases with the heat flux $\dot{q}$, but nucleate boiling is less desirable than the other forms, because it incurs the risk of fouling or damaged product. Fujita [12] measured heat transfer coefficients during nucleate boiling of water films on stainless steel tubes, and the value of α in $\mathrm{W/(m^2\,K)}$ that he thus determined at $\dot{q} > 1.6 \cdot 10^5\ \mathrm{W/m^2}$ was

$$\alpha = 1.24\,\dot{q}^{0.741}. \tag{12}$$

Hence α is independent of the Reynolds number for a falling film in pronounced nucleate boiling. Equation (12) yields results that are practically identical to those obtained by Bressler [13]. As opposed to this, Haase [14] determined a transition to nucleate boiling at smaller temperature differences. Therefore,



M3. Fig. 3. Nusselt number as a function of Re with Pr and $\mathrm{Pr}\,(\nu^2/g)^{1/3}/L$ as parameters in falling-film evaporation (convective boiling).

the application of Eq. (12) ought to ensure that the values of α are not overestimated in the nucleate boiling range if large temperature differences exist. Values of α calculated from Eqs. (11) and (12) are shown in Fig. 4 as a function of the heat flux $\dot{q}$ of a water film that evaporates at 100°C. A gradual transition from convective to nucleate boiling was assumed in compiling the diagram, because it was unknown whether more accurate studies exist.

In accordance with the definition, the curves for constant temperature difference $\Delta\vartheta$ in Fig. 4 are inclined at an angle of 45°. They can be adopted for the determination of the heat transfer coefficient. For instance, a value of α = 6,500 W/(m^2 K) can be read off against a temperature difference of $\Delta\vartheta$ = 15 K (between the heated wall and the falling film) and a Reynolds number of Re = 1,000 or 200; the associated heat flux is $\dot{q} = 9.5 \cdot 10^4$ W/m^2.

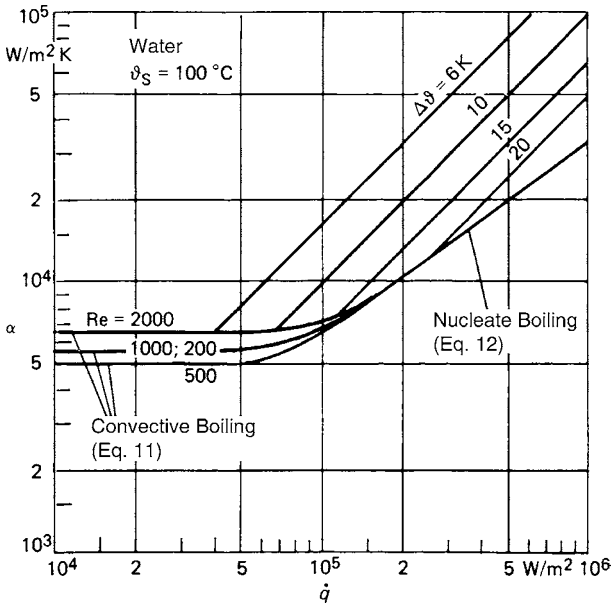
Struve drew up corresponding diagrams for the evaporation of Refrigerant R 11 falling films on brass tubes [10].

Example 3

An aqueous solution with a boiling point of 100°C is to be concentrated in a circulating falling-film evaporator. The film runs down the inner surfaces of the tubes, and the outer surfaces are heated by the condensation of saturated steam at a temperature of ϑ_c = 110°C. Fresh solution is fed to the evaporator at a rate of $\dot{M}_1$ = 2.0 kg/s. The tube bundle consists of 100 stainless steel tubes of 4 m length (λ = 17 W/(m K); d_i = 47 mm; d_o = 50 mm).

(a) The Reynolds number of the falling film must be Re $\geq$ 1,000 in order to ensure that all the tubes are thoroughly wetted. What must be the rate $\dot{M}_{rec}$ at which the liquid has to be recirculated in order to obtain Re = 1,000?

(b) To what extent can the solution be concentrated, i.e., at what rate $\dot{M}_2$ must the concentrate be continuously removed and what is the $\dot{M}_2/\dot{M}_1$ ratio?



M3. Fig. 4. Heat transfer coefficient α as a function of $\dot{q}$, Re, and $\Delta\vartheta$ during nucleate and convective boiling of water films at 100°C.

The properties (for water as an approximation) can be obtained from Chap. D2. Thus,

$$\eta = 282.2 \cdot 10^{-6}\ \text{kg/m s}; \quad \text{Pr} = 1.756;$$
$$\nu = 0.294 \cdot 10^{-6}\ \text{m}^2/\text{s}; \quad \Delta h_v = 2257.3\ \text{kJ/kg};$$
$$\lambda = 0.677\ \text{W/(m K)}.$$

(a) Re $= \dot{m}/\eta = \dot{M}/z\pi d_i\eta =$ 1,000, where $\dot{M} = \dot{M}_1 + \dot{M}_{rec}$.

Hence the mass flow rate of recirculated liquid is

$$\dot{M}_{rec} = \text{Re}(z\pi d_i\eta) - \dot{M}_1$$
$$= 1{,}000(100\pi \cdot 47 \cdot 10^{-3} \cdot 282.2 \cdot 10^{-6}) - 2.0$$
$$= 2.17\ \text{kg/s}.$$

(b) The mass flow rate of liquid to be removed is

$\dot{M}_2 = \dot{M}_1 - \dot{M}_v$, where $\dot{M}_v = \dot{Q}/\Delta h_v$ and $\dot{Q} = kA(\vartheta_c - \vartheta_v)$. As in Example 1,

$$k = \left\{ \frac{1}{\bar{\alpha}_c} + \frac{d_o \ln \frac{d_o}{d_i}}{2\lambda} + \frac{d_o}{d_i \alpha_v} \right\}^{-1}. \tag{13}$$

Inserting Re = 1,000 and Pr = 1.756 in Eq. (11) gives a Nusselt number of Nu = 0.168. A value of α_v = 5,506 W/(m^2 K) is then obtained from the figures for the properties.

In order to determine the heat transfer coefficient on the condensate side, the corresponding temperature difference $\Delta\vartheta_c$ must be estimated and approximate calculations must be made as is indicated in Table 1.

Hence the temperature difference is obtained by the second approximation. Consequently,

$$\dot{Q} = 1.389 \cdot 10^6\ \text{W}; \quad \dot{M}_2 = 1.377\ \text{kg/s};$$
$$\dot{M}_v = 0.623\ \text{kg/s}; \quad \dot{M}_2/\dot{M}_1 = 0.6886.$$

Additional Check:
Since the temperature difference on the vaporization side is $\Delta\vartheta$ = 4 K, nucleate boiling does not occur. The Reynolds number for the vapor at the tube outlet is

$$\text{Re}_v = \frac{4\dot{M}_v}{z\varrho_v\pi d_i \nu_v} = \frac{4 \cdot 0.623}{100 \cdot 0.826\pi \cdot 47 \cdot 10^{-3} \cdot 15.28 \cdot 10^{-6}}$$
$$= 13{,}372.$$

Therefore, the heat transfer coefficient α_v ought to be, on an average, about 5% higher.

M3. Table 1. Determination of temperature on the condensate side

	First approximation	Second approximation
$\Delta\vartheta_c = \vartheta_c - \vartheta_{w,c}$	5 K	3.75 K
Thus ϑ_{cm} from Subchap. J1.1 and $(\text{Ph}^*\text{Ga}^{1/3}/\text{Pr})$	107.5°C	108°C
	1,179	884.6
$\text{Nu} = 0,9245^*\text{Re}^{-1/3}$ $= 0,9428(\text{Ph}^*\text{Ga}^{1/3}/\text{Pr})^{1/4}$	0.161	0.173
$\bar{\alpha}_c$	5,538 W/(m^2 K)	5,951 W/(m^2 K)
k from Eq. (13)	2,151.6 W/(m^2 K)	2,211 W/(m^2 K)
Check: $\Delta\vartheta_c = k/\alpha_c\Delta\vartheta_c$	3.88	3.72

4 Film Breakdown

Heated surfaces over which a falling film descends must be completely wetted. If the liquid film is interrupted, heat transfer will be greatly improved as a result of contact between the vapor and the wall. The following mechanisms lead to breakdown of the film.

(a) Dry spots may be formed as a consequence of inadequate supply of liquid. The governing factors are the wetting angle and the surface tension. A comprehensive review of the relevant mathematical models has been compiled by Ganić and Mastanaiah [15].
(b) Surface tension gradients caused by temperature and concentration gradients may give rise to channeling by the Marangoni effect, which is most likely to occur in mixtures.
(c) Vapor bubbles formed on the wall may cause the liquid to be entrained in the bulk of the vapor stream. As a consequence, the mass flux of liquid in the film is reduced, and dry spots may be formed.
(d) The wall temperature must always remain below a certain critical value in order to ensure that the surface is not covered by vapor as a result of the Leidenfrost effect. Normally, this effect is insignificant in falling-film evaporators, owing to their low temperature differences.

An experimental and theoretical study of these phenomena by Fujita and Ueda [16, 17] was restricted to water. Mechanisms (a) and (b) mainly occur in subcooled films that do not evaporate. They are difficult to describe, because the main parameters, i.e., the contact angle and the local surface tension gradients, do not permit easy measurement. Values relating to the breakdown of subcooled water films can be obtained from Fig. 5. Pure saturated liquids permit more effective wetting, because they do not allow significant surface tension gradients to occur in the film. Film breakdown is primarily caused by nucleation, i.e., mechanism (c).

In the experiments, permanently dry spots were formed at the lower end of the tube for $\dot{\Gamma} \leq 0.01 - 0.02\,\mathrm{kg/ms}$ (cf. Fig. 6) corresponding to a Reynolds number $\dot{\Gamma}/\mu$ of 140–180. A criterion for dryout is

$$B_F = \dot{\Gamma}\,\lambda/(\dot{q}\,L). \tag{14}$$

Dryout can be avoided in the evaporation of water if

$$B_F > 1.5. \tag{15}$$

Mixtures of ethylene or propylene glycol with water do not dry out unless B_F falls below a value of 5–35.

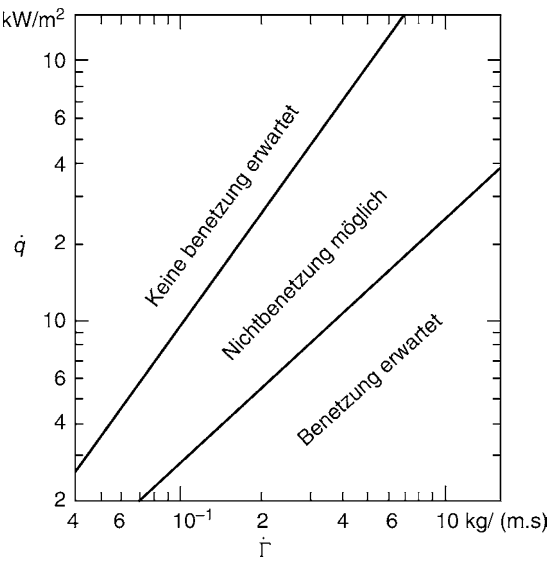
A simple equation for estimating the temperature difference required for the Leidenfrost effect has been derived from the measurements by Cichelli and Bonilla [19, 20], i.e.,

$$\begin{aligned}\Delta T_L &= T\mathrm{w}_L - T_{sat} \\ &= 0.555\left[52(1-p^*) + 0.04/p^{*2}\right],\end{aligned} \tag{16}$$

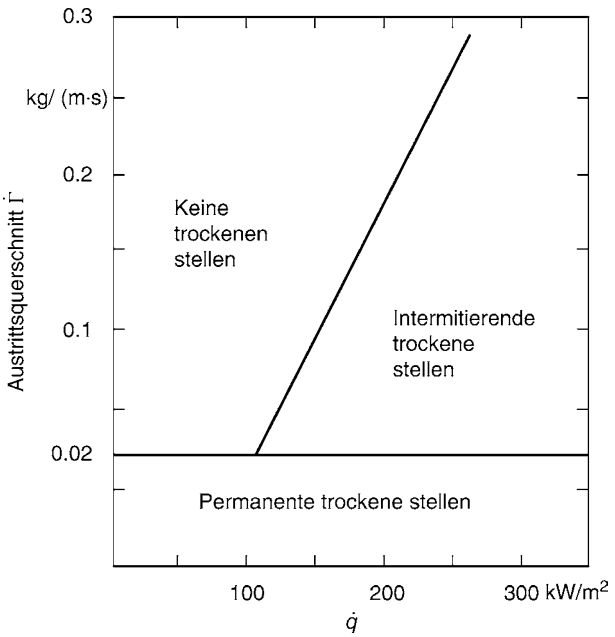
where $T\mathrm{w}_L$ is the wall temperature at which the Leidenfrost effect occurs and $p^* = p/p_c$.
For safety reasons, the actual wall temperature should be less than

$$\Delta T = T_w - T_{sat} = 0.6\Delta T_L \tag{17}$$

In the food and pharmaceutical industry, vessels are very often cleaned by rinsing the inner surface with caustic solution, e.g., 1 N NaOH, at 60–80°C. This process is called cleaning-in-place (CIP). It requires a completely wetted surface. A good practical number for that purpose is a specific flow rate of 0.5 l/(m s).



M3. Fig. 5. Breakdown on subcooled films in water; subcooling 20–50°C [17, 18].



M3. Fig. 6. Breakdown of saturated water films at 99.5°C [17]; rising vapor current and downward falling film on a tube of 46-mm outer diameter and 1,000 mm length.

M4 Heat Transfer to Non-Newtonian Fluids

Manfred H. Wagner
Technische Universität Berlin, Berlin, Germany

1 Introduction

The flow of many liquids, for example, solutions, polymer melts, and concentrated dispersions, may differ considerably from Newtonian fluids. Knowledge of the rheology of non-Newtonian fluids is essential in the design of processing machinery and pipelines. However, the multiplicity of rheological systems and the complexity of the behavior of the fluids render it impossible to quote laws of general validity that describe the flow and rheological characteristics under any given condition. Recourse must therefore be taken to a description of the rheological behavior under the conditions that relate to those in practice. A case in question is the flow through pipes of non-Newtonian fluids, many of which are very viscous. It concerns hydrodynamically developed laminar flow and is the subject to which the analytical methods discussed here have been restricted.

The subjects dealt with are pressure drop (under nonisothermal conditions) and heat transfer during flow through circular tubes and rectilinear slits. Relationships for tubes of different geometries are considered in [1]. Heat transfer in turbulent flow is discussed in [2–4]. The following assumptions are made in deriving the relationships discussed in this contribution:

1. The flow is laminar and completely hydrodynamically developed.
2. The liquid adheres to the wall.
3. Thermal conductivity λ, specific heat c_p, and the density ρ of the liquid remain constant.
4. The temperature of the tube wall δ_w remains constant during heat transfer.
5. The rise in temperature due to viscous dissipation can be neglected. The maximum mean dissipative rise in temperature undser adiabatic boundary conditions $\Delta\delta_{ad}$ is

$$\Delta\delta_{ad} = \frac{\Delta p}{\rho c_P} \tag{1}$$

Dissipation can be ignored if $\beta\ \Delta\delta_{ad} < 0.1$, where β is the temperature coefficient for the liquid (cf. Eq. (13)). No reliable analytical correlations are known for heat transfer in a flow with considerable dissipation, particularly since the conventional definition of an average Nusselt number is pointless in this case [5]. A review on various studies of the subject is presented in [6].

2 Definition of Heat Transfer Coefficient

The average heat transfer coefficient α over a length l of tube is defined by

$$\dot{q} = \alpha\,\Delta\delta_{log} \tag{2}$$

$\Delta\delta_{log}$ is the logarithmic temperature difference and is given by

$$\Delta\delta_{log} = \frac{(\delta_w - \delta_i) - (\delta_w - \delta_o)}{\ln\left(\frac{(\delta_w-\delta_i)}{(\delta_w-\delta_o)}\right)} \tag{3}$$

where δ_i is the inlet temperature (which is constant over the entire cross-section at the inlet), δ_o is the average outlet temperature of the liquid, and δ_w is the constant wall temperature. The average Nusselt number is given by Eq. (4); and the Graetz number, by Eq. (5):

$$\mathrm{Nu} = \frac{\alpha d}{\lambda} \tag{4}$$

$$\mathrm{Gz} = \frac{wd^2}{al}\mathrm{Re.Pr}\frac{d}{l} = \mathrm{Pe}\frac{d}{l} \tag{5}$$

where w is the average flow velocity in the axial direction, d is the inner diameter of the tube or the slit width, and a is the diffusivity.

The average outlet temperature is obtained from a simple heat balance, that is,

$$\frac{\delta_w - \delta_o}{\delta_w - \delta_i} = e^{-4\frac{\mathrm{Nu}}{\mathrm{Gz}}} \tag{6}$$

3 Scalar Flow Rule for Steady-state Stratified Flow

The term "non-Newtonian fluids" embraces nonlinear/purely viscous and viscoelastic liquids. Quantitative rheological laws

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_53,

generally define a functional relationship between the stress in the material and the complete prior history of strain. For steady-state stratified flow, for example, hydrodynamically developed duct flow, these laws can be reduced to a scalar flow rule, that is, to a (in general nonlinear) relationship between the velocity gradient, namely the shear rate $\dot{\gamma}$ and the shear stress τ.

The scalar flow rule can be determined by use of capillary, Couette, cone-and-plate, and other rheometers that allow realization of steady-state stratified flow [7]. The flow curve $\dot{\gamma}(\tau)$ and the viscosity function $\eta(\dot{\gamma}) = \tau(\dot{\gamma})/\dot{\gamma}$ for non-Newtonian liquids are nonlinear; but, if plotted on a log–log scale, sections of them can be described by the *Ostwald-de-Waele* power-law equations:

$$\dot{\gamma} = \Phi\tau^m \tag{7}$$

$$\eta = \frac{\tau}{\dot{\gamma}} = \Phi^{-\frac{1}{m}}\dot{\gamma}^{\frac{1}{m}-1} \tag{8}$$

The flow index $m = 1$ corresponds to Newtonian flow. Polymer solutions and melts display pseudo-plasticity, that is, the rate of shear increases over-proportionally with the shear stress, and the flow index is typically in a range of $1 < m < 5$. Shear thickening, that is, an index of $m < 1$, is observed in some dispersions. Equations. (7) and (8) may also be expressed in the following forms [5]:

$$\tau = K\dot{\gamma}^n \tag{9}$$

$$\eta = \frac{\tau}{\dot{\gamma}} = K\dot{\gamma}^{n-1} \tag{10}$$

The following relationship exists between the fluidity Φ and the consistency factor K:

$$K = \Phi^{-\frac{1}{m}} \tag{11}$$

The following applies for the flow index:

$$n = \frac{1}{m} \tag{12}$$

The index m is largely independent of temperature, but an exponential relationship exists for the fluidity Φ through the temperature shift factor a_T, which is given by

$$a_T = e^{-\beta(\delta-\delta_{ref})} \tag{13}$$

The exponential relationship concerned is

$$\Phi = \Phi(\delta) = \frac{\Phi(\delta_{ref})}{a_T} = \frac{\Phi_{ref}}{a_T} \tag{14}$$

Departure from isothermal conditions is described by a temperature weighting factor θ, which is defined by

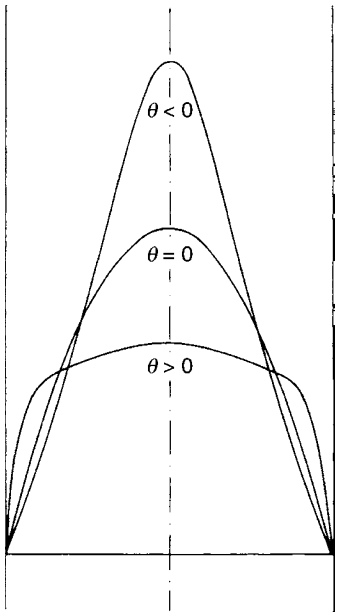
$$\theta = \frac{\beta}{m}(\delta_w - \delta_i) \tag{15}$$

or, by use of Eqs. (13) and (14):

$$\theta = \frac{1}{m}\ln\left(\frac{\Phi_w}{\Phi_i}\right) \tag{16}$$

Alternatively, the dual relationship to Eq. (7) may be used, that is,

$$\tau = K(\delta_{ref})\dot{\gamma}^n = K_{ref}\dot{\gamma}^n \tag{17}$$



M4. Fig. 1. Velocity distribution during pipe flow: Temperature-independent viscosity ($\theta = 0$), heating ($\theta > 0$), and cooling ($\theta < 0$).

In this case, θ is given by

$$\theta = \ln\left(\frac{K_i}{K_w}\right) \tag{18}$$

A qualitative interpretation of the effect of θ on the pressure drop and heat transfer is presented in Fig. 1. If the viscosity of the liquid does not change with temperature ($\theta = 0$, since $\beta = 0$), the velocity and temperature fields are decoupled. The index m entails that the velocity field can be represented by a parabola of the order $m + 1$, and is independent of the direction of heat flow. If a real liquid is heated ($\theta > 0$), the viscosity decreases in the vicinity of the wall. As a result, the velocity gradient increases near the wall and decreases in the center of the duct, and the velocity field tends towards that for plug flow. By virtue of the higher shear rate at the wall, heat transfer is enhanced, and the pressure drop as compared to isothermal pipe flow at a temperature δ_i is reduced. As thermal development proceeds, the pressure gradient finally attains the value of isothermal flow at a temperature δ_w, and the velocity field again corresponds to a parabola of the order $m + 1$. The same applies *mutatis mutandis* to the cooling of a real liquid ($\theta < 0$). Since the viscosity is higher in the vicinity of the wall, the rate of shear at the wall decreases. As a consequence, the pressure drop as compared to isothermal pipe flow at a temperature δ_i, is increased, and heat transfer is reduced. In the light of these considerations, Kwant [8–11] made a detailed study of heat transfer to non-Newtonian liquids and presented his results in the form of simple regressions. The following discussion is largely in line with his ideas on the subject.

4 Pressure Drop and Heat Transfer for Fluids with Temperature-Independent Viscosity

Although Eq. (7) or Eq. (9) fits only certain sections of the experimentally determined flow curve, it allows the pressure

drop to be predicted with sufficient accuracy for engineering purposes, because the pressure drop largely depends on the rate of shear near the wall. The pressure drop in a length l of duct can be calculated from the Hagen-Poiseuille law, that is,

For the pipe with circular cross-section:

$$\frac{\Delta p}{l} = \frac{4}{d}\left[\frac{2(m+3)}{\Phi}\frac{w}{d}\right]^{\frac{1}{m}} \tag{19}$$

For the rectilinear slit:

$$\frac{\Delta p}{l} = \frac{2}{d}\left[\frac{2(m+2)}{\Phi}\frac{w}{d}\right]^{\frac{1}{m}} \tag{20}$$

If the viscosity does not change with temperature, the average Nusselt number for non-Newtonian liquids with flow indices of $1 \le m \le 10$ can be calculated from the following approximate relationships [9, 11]:

Pipe with circular cross-section

$$\mathrm{Gz} < 30\text{: } \mathrm{Nu}_0 = 3.66m^{0.13} + 0.050\,\mathrm{Gz}\,(\text{accuracy} \pm 2\%) \tag{21}$$

$$\mathrm{Gz} > 30\text{: } \mathrm{Nu}_0 = 1.018(m+3)^{1/3}\mathrm{Gz}^{1/3}\,(\text{accuracy} \pm 5\%); \tag{22}$$

Rectilinear slit

$$\mathrm{Gz} < 100\text{: } \mathrm{Nu}_0 = 3.77m^{0.13} + 0.0053\,\mathrm{Gz}\,(\text{accuracy} \pm 3\%), \tag{23}$$

$$\mathrm{Gz} > 100\text{: } \mathrm{Nu}_0 = 1.018(m+2)^{1/3} + \mathrm{Gz}^{1/3}\,(\text{accuracy} \pm 5\%). \tag{24}$$

More accurate Nusselt numbers derived by numerical analysis are given by Kwant [8].

5 Pressure Drop for Fluids with Temperature-Dependent Viscosity

The reference state that will be used in the case of temperature-dependent viscosity is isothermal pipe flow **after** complete thermal development, that is, at temperature δ_w. The relative pressure drop φ is defined as the ratio of the pressure drop in nonisothermal pipe flow Δp_θ to that in the corresponding isothermal pipe flow Δp_0 according to Eqs. (19) or (20) for a fluid characterized by fluidity $\Phi(\delta_w) = \Phi_w$, that is,

$$\varphi = \frac{\Delta p_\theta}{\Delta p_0} \tag{25}$$

Likewise, the relative shear rate at the wall Γ is the ratio of the shear rate in nonisothermal pipe flow $\dot{\gamma}_\theta$ to that in the corresponding isothermal pipe flow $\dot{\gamma}_0$ after complete thermal development, that is,

$$\Gamma = \frac{\dot{\gamma}_\theta}{\dot{\gamma}_0} \tag{26}$$

The following approximate relationships exist for φ [9, 11]:

Pipe with circular cross-section

$$\varphi = (0.6\mathrm{Gz})^{A'\theta}$$
$$(\text{limits of validity: } 2.5 < \mathrm{Gz} < 1,000; 1 \le m \le 5), \tag{27}$$

Heating ($\theta > 0$)

$$A' = \frac{2A}{m+1} \tag{28}$$

M4. Table 1. A (regression coefficient) for circular tubes as a function of θ and m

m \ θ	1	1.33	2	3	5
1	0.105	0.115	0.129	0.140	0.141
2	0.100	0.107	0.105	0.094	0.090
3	0.095	0.101	0.086	0.066	0.062

M4. Table 2. A (regression coefficient) for rectilinear gaps as a function of θ and m

m \ θ	1	1.33	2	3	5
1	0.105	0.109	0.123	0.134	0.132
2	0.100	0.102	0.100	0.088	0.070
3	0.095	0.096	0.082	0.061	0.049

A is a weak function of θ and m (cf. Table 1). As a first approximation, $A \approx 0.1$

Cooling ($\theta < 0$)

$$A' = 0.125 \quad \text{for } -2.5 < \theta < 0, \tag{29}$$

$$A' = 0.135 \quad \text{for } \theta < -2.5; \tag{30}$$

Rectilinear slit

$$\varphi = (1.8\mathrm{Gz})^{A'\theta} \tag{31}$$

(limits of validity: $1.1 > \mathrm{Gz} > 1,000; 1 \le m \le 5$),

Heating ($\theta > 0$):

$$A' = \frac{2A}{m+1} \tag{32}$$

A is a week function of θ and m (cf. Table 2). As a first approximation, $A \approx 0.1$.

Cooling ($\theta < 0$):

$$A' = 0.110 \quad \text{for } -2.0 < \theta < 0, \tag{33}$$

$$A' = 0.116 \quad \text{for } \theta < -2.0 \tag{34}$$

The relative shear rate Γ_o at the outlet is given by

$$\Gamma_o = [(1 - A'\theta)\varphi]^m \tag{35}$$

6 Heat Transfer for Fluids with Temperature-Dependent Viscosity

The following relationships exist between the Nusselt number Nu_θ and the relative shear rate Γ_o at the outlet, as defined by Eq. (35):

Pipe with circular cross-section

$$\frac{\mathrm{Nu}_\theta}{\mathrm{Nu}_0} = 1 + 0.271\,\ln\Gamma_o + 0.023(\ln\Gamma_o)^2 \tag{36}$$

Rectilinear gap

$$\frac{\mathrm{Nu}_\theta}{\mathrm{Nu}_0} = 1 + 0.238\,\ln\Gamma_o + 0.0224(\ln\Gamma_o)^2 \tag{37}$$

Example

An aqueous polymer solution flows through a circular tube with

Tube diameter	$d = 0.01$ m
Length of tube	$l = 10$ m
Average flow velocity	$w = 2$ m/s
Inlet temperature	$\delta_i = 20°C$
Pipe wall temperature	$\delta_w = 80°C$
Fluidity	$\Phi(\delta_i) = \Phi_i = 3{\cdot}10^{-2}$ Pa^{-m}s^{-1}
Fluidity	$\Phi(\delta_w) = \Phi_w = 1.5$ Pa^{-m}s^{-1}
Flow index	$m = 2.0$
Diffusivity	$a = 1.56{\cdot}10^{-7}$ m^2/s
Specific heat capacity	$c_p = 4.2{\cdot}10^3$ J/kgK
Density	$\rho = 10^3$ kg/m^3.

The first step is to calculate the pressure drop Δp_0 and the Nusselt number Nu_0 on the assumption of temperature-independent viscosity or fluidity $\Phi(\delta_w) = \Phi_w$ Applying Eq. (19) gives

$$\Delta p_0 = \frac{4l}{d}\left[\frac{2(m+3)}{\Phi_w}\frac{w}{d}\right]^{\frac{1}{m}} = \frac{4\cdot 10}{0.01}\left[\frac{2(2+3)}{1.5}\frac{2}{0.01}\right]^{\frac{1}{2}}$$
$$= 1.46\cdot 10^5 \mathrm{N/m^2} = 1.46\,\mathrm{bar}.$$

The Graetz number, as determined from Eq. (5), is

$$Gz = \frac{wd^2}{al} = \frac{2\cdot 0.01^2}{1.56\cdot 10^{-7}\cdot 10} = 128.2.$$

Applying Eq. (22) for the Nusselt number gives

$$Nu_0 = 1.018(2+3)^{1/3}Gz^{1/3} = 8.78.$$

The outlet temperature δ_o is obtained from Eq. (6), that is,

$$\delta_o = \delta_w - (\delta_w - \delta_i)\ exp(-4\frac{Nu_0}{Gz})$$
$$= 80°C - (60K)\exp\left(-4\frac{8.78}{128.2}\right) = 34.4°C$$

The next step is to determine the changes caused by a temperature-dependent viscosity or fluidity. The temperature weighing factor θ is obtained from Eq. (16), that is,

$$\theta = \frac{1}{m}\ln\left(\frac{\Phi_w}{\Phi_i}\right) = \frac{1}{2}\ln\left(\frac{1.5}{3\cdot 10^{-2}}\right) = 1.956.$$

Linear interpolation in Table 1 gives $A = 0.106$ for $\theta = 1.956$ and $m = 2$. Inserting in Eq. (27) for the relative pressure drop φ gives

$$\varphi = \frac{\Delta p_\theta}{\Delta p_0} = (0.6Gz)^{A'\theta} = (0.6Gz)^{\frac{2A}{m+1}\theta}$$
$$= (0.6\cdot 128.2)^{\frac{2\cdot 0.106}{2+1}1.956} = (0.6\cdot 128.2)^{0.138} = 1.823.$$

The actual pressure drop is therefore

$$\Delta p_\theta = \varphi\Delta p_0 = 1.823\cdot 1.46 = 2.66\,\mathrm{bar}.$$

The pressure drop Δp_θ is 82% higher than the pressure drop in isothermal pipe flow at temperature δ_w and fluidity Φ_w.

Obviously, the pressure drop Δp_θ is much less than the pressure drop Δp for isothermal pipe flow at temperature δ_i and fluidity Φ_i, which is obtained from Eq. (19) as

$$\Delta p = \frac{4l}{d}\left[\frac{2(m+3)}{\Phi_i}\frac{w}{d}\right]^{\frac{1}{m}} = \left[\frac{\Phi_w}{\Phi_i}\right]^{\frac{1}{m}}\Delta p_0 = e^\theta\Delta p_0$$
$$= 7.07\cdot 1.46\,\mathrm{bar} = 10.32\,\mathrm{bar}.$$

The relative shear rate Γ_o at the outlet is obtained from Eq. (35):

$$\Gamma_o = [(1 - A'\theta)\varphi]^m = [(1 - 0.138)1.823]^2 = 2.468.$$

The Nusselt number can then be calculated from Eq. (36), that is,

$$Nu_\theta = Nu_0[1 + 0.271\cdot\ln\Gamma_0 + 0.023(\ln\Gamma_0)^2]$$
$$= 8.78\left[1 + 0.271\cdot\ln 2.468 + 0.023(\ln 2.468)^2\right]$$
$$= 8.78\cdot 1.264 = 11.09$$

The actual Nusselt number Nu is therefore 26% higher than the value obtained on assuming that the viscosity does not depend on temperature. Accordingly, the actual temperature at the outlet, as determined from Eq. (6), is

$$\delta_{o,\theta} = \delta_w - (\delta_w - \delta_i)\ \exp\left(-4\frac{Nu_0}{Gz}\right)$$
$$= 80°C - (60K)\exp\left(-4\frac{11.09}{128.2}\right) = 37.6°C.$$

The effect of dissipation can be estimated from Eq. (1). Under adiabatic boundary conditions, the maximum rise in temperature caused by dissipation is

$$\Delta\delta_{ad} = \frac{\Delta p_0}{\rho c_p} = \frac{2.66\cdot 10^5}{10^3\cdot 4.2\cdot 10^3} = 0.06K.$$

Dissipation can therefore be neglected in this example.

7 Symbols

a	Diffusivity (m^2/s)
A	Regression coefficient (Tables 1 and 2)
A'	Regression coefficient (Eqs. 28–30) and (32–34))
a_T	Temperature shift factor
c_p	Specific heat capacity (J/kg K)
d	Inner pipe diameter; gap width (m)
Gz	Greatz number (Eq. (5))
K	Consistency factor (Pas^n)
K_i	Consistency factor at temperature δ_i(Pas^n)
K_w	Consistency factor at temperature δ_w (Pas^n)
K_{ref}	Consistency factor at reference temperature δ_{ref} (Pas^n)
l	Length of pipe (m)
m	Flow index
n	Flow index (Eq. (12))
Nu	Nusselt number
Nu_θ	Nusselt number that allows for the dependence of viscosity on temperature
Nu_0	Nusselt number based on the assumption that the viscosity does not change with temperature
Δp N/mm^2	Pressure drop
Δp_θ N/mm^2	Pressure drop that allows for the dependence of viscosity on temperature
Δp_0 N/mm^2	Pressure drop in isothermal pipe flow at temperature δ_w for a fluid characterized by fluidity $\Phi(\delta_w) = \Phi_w$

Pe	Péclet number ($\mathrm{Pe} = \frac{wd}{a}$)
Pr	Prandtl number ($\mathrm{Pr} = \eta_r c_p/\lambda$)
q	Heat flux ($\mathrm{W/m^2}$)
Re	Reynolds number ($\mathrm{Re} = \rho\ wd/\eta_r$)
w	Mean axial flow velocity (m/s)
α	Heat transfer coefficient ($\mathrm{W/m^2K}$)
β	Temperature coefficient ($\mathrm{K^{-1}}$)
$\dot{\gamma}$	Rate of shear ($\mathrm{s^{-1}}$)
$\dot{\gamma}_\theta$	Shear rate at wall with due allowance for the dependence of viscosity on temperature ($\mathrm{s^{-1}}$)
$\dot{\gamma}_0$	Shear rate at wall in isothermal pipe flow at temperature δ_w for a fluid characterized by fluidity $\Phi(\delta_w) = \Phi_w(\mathrm{s^{-1}})$
Γ	Relative shear rate
Γ_o	Relative shear rate at outlet
φ	Relative pressure drop
Φ	Fluidity ($\mathrm{Pa^{-m}s^{-1}}$)
Φ_i	Fluidity at temperature δ_i ($\mathrm{Pa^{-m}s^{-1}}$)
Φ_w	Fluidity at temperature δ_w($\mathrm{Pa^{-m}s^{-1}}$)
Φ_{ref}	Fluidity at the reference temperature δ_{ref} ($\mathrm{Pa^{-m}s^{-1}}$)
λ	Thermal conductivity (W/mK)
η_r	Representative kinematic viscosity ($\mathrm{Pas\ m^{-2}}$)
ρ	Density ($\mathrm{kg/m^3}$)
τ	Shear stress ($\mathrm{N/m^2}$)
θ	Temperature weighting factor (Eq. (15))
δ	Temperature (°C)
δ_i	Inlet temperature (°C)
δ_o	Mean outlet temperature (°C)
δ_w	Temperature of pipe wall (°C)
δ_{ref}	Reference temperature (°C)
$\Delta\delta_{ad}$	Rise in temperature due to dissipation under adiabatic boundary conditions (K)
$\Delta\delta_{log}$	Logarithmic temperature difference (Eq. (3)) (K)

M5 Heat Transfer in Fluidized Beds

Holger Martin
Karlsruher Institute für Technologie (KIT), Karlsruhe, Germany

1 Range of Existence of Fluidization and Bed Expansion

In order to fluidize a particulate solid by an upward-flowing gas or liquid, the fluid velocity u (i.e., the volumetric flow-rate divided by the total cross-section) must be in the range between the minimum fluidization velocity, u_{mf}, and the terminal velocity, u_t:

$$u_{mf} < u < u_t. \tag{1}$$

The two limits in Eq. (1) define the range of existence of a fluidized bed. The limiting velocities are obtained from force (or momentum) balances as

$$\frac{u_{mf}\,d}{\nu} \equiv \mathrm{Re}_{mf} = \mathrm{Re}_{mf}(\mathrm{Ar}, \psi_{mf}), \tag{2}$$

$$\frac{u_t\,d}{\nu} \equiv \mathrm{Re}_t = \mathrm{Re}_t(\mathrm{Ar}), \tag{3}$$

where ψ_{mf} is the bed voidage at minimum fluidization (practically often between 0.4 and 0.7) and Ar is the Archimedes number $\mathrm{Ar} \equiv g d^3 \rho(\rho_P - \rho)/\eta^2$. For spherical monosized particles Eq. (2) becomes

$$\mathrm{Re}_{mf} = 42.9(1-\psi_{mf})\left(\sqrt{1 + \frac{\psi_{mf}^3}{(1-\psi_{mf})^2}\frac{\mathrm{Ar}}{3{,}214}} - 1\right), \tag{2a}$$

while (Eq. 3), for homogeneous fluidization, becomes

$$\mathrm{Re}_t = 18\left(\sqrt{1 + \frac{1}{9}\sqrt{\mathrm{Ar}}} - 1\right)^2, \quad \mathrm{Ar} < 2 \cdot 10^{10} \tag{3a}$$

equal to the terminal velocity of a single particle.

For heterogeneous, bubbling fluidization, the velocity may be greater than the single-particle values from Eq. (3a). According to Reh [1], this can be approximated by

$$\mathrm{Re}_{t(\mathrm{hetero})} \approx \sqrt{\frac{4}{3}\mathrm{Ar}} \quad \text{if } \mathrm{Re}_{t(\mathrm{hetero})} > \mathrm{Re}_t. \tag{3b}$$

Bed expansion, for homogeneous fluidization can be approximately calculated from

$$\frac{u}{u_t} = \frac{\mathrm{Re}}{\mathrm{Re}_t} = \psi^n \quad \text{with} \quad n = \frac{\ln\left(\frac{\mathrm{Re}_{mf}}{\mathrm{Re}_t}\right)}{\ln\ \psi_{mf}}. \tag{4}$$

By local measurements in fluidized beds, Bakker and Heertjes [2] have found that the gas volume fraction, ψ, within the range of the initial bed height ($z < L_{mf}$), is more or less independent of z for any given gas velocity, while it increases exponentially with z (up to 1) for $z > L_{mf}$. In the lower range ($z < L_{mf}$) the average gas volume fraction increases linearly with gas velocity. For this range a linear bed expansion equation, therefore, should approximately describe the otherwise quite complex situation.

$$\psi \approx \psi_{mf} + (1-\psi_{mf})\frac{u-u_{mf}}{u_t-u_{mf}}. \tag{4a}$$

2 Fluid-to-Particle Heat Transfer in Fluidized Beds

2.1 Definition of the Heat Transfer Coefficient

The heat transfer coefficient, α, between fluid and particles in a fluidized bed is defined as

$$\alpha \equiv \frac{\dot{Q}_{(f-P)}}{A(T_f - T_{P,O})_{av}}, \tag{5}$$

where $\dot{Q}_{(f-P)}$ is the total heat flow transmitted from the fluid to the particle surface, A. The average temperature difference, $(T_f - T_{P,O})_{av}$, between the fluid and the particle surface is the

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_54,

logarithmic mean temperature difference if $T_{P,O}$ is constant and the fluid passes through the particles in plug flow (no backmixing)

$$(T_f - T_{P,O})_{av} = \frac{T_{f,in} - T_{f,out}}{\ln\left(\frac{T_{f,in} - T_{P,O}}{T_{f,out} - T_{P,O}}\right)} = \Delta T_{ln}, \tag{5a}$$

for total backmixing in the fluid flow ("ideal stirred tank") the average temperature difference becomes:

$$(T_f - T_{P,O})_{av} = T_{f,out} - T_{P,O} = \Delta T_{out}. \tag{5b}$$

2.2 Calculation of Heat Transfer Coefficients

Figure 1 shows Nusselt numbers $Nu = \alpha\, d/\lambda$ versus Reynolds number $Re = u\, d/\nu$ for a fixed bed with $\psi = 0.4$ (upper, dotted curve) and for a single sphere in cross flow (full, lower curve with $\psi = 1$), calculated for $Pr = \eta c_P/\lambda = 0.7$ from the equations given by Gnielinski [3]:

$$Nu_{\text{fixed bed}} = [1 + 1.5(1 - \psi)] \cdot Nu_{\text{single sphere}}(Re_\psi, Pr), \tag{6}$$

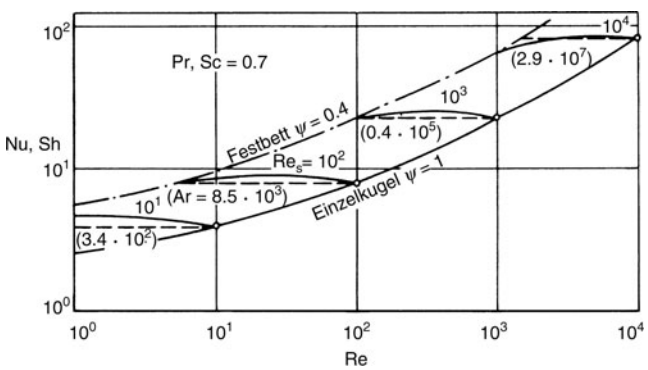
$$Nu_{\text{single sphere}}(Re_\psi, Pr) = 2 + \sqrt{Nu_{lam}^2 + Nu_{turb}^2}, \tag{6a}$$

$$Nu_{lam}(Re_\psi, Pr) = 0.664\sqrt[3]{Pr}\sqrt{Re_\psi}, \tag{6b}$$

$$Nu_{turb}(Re_\psi, Pr) = \frac{0.037 Re_\psi^{0.8}\, Pr}{1 + 2.443 Re_\psi^{-0.1}(Pr^{2/3} - 1)}, \tag{6c}$$

$$Re_\psi = \frac{Re}{\psi} = \frac{u\, d}{\psi \nu}. \tag{6d}$$

If the particles are fixed in space, as in a packed bed, the void fraction, ψ, can be varied independently from the fluid velocity (or the Reynolds number). In a fluidized bed, however, bed expansion and fluid flow rate are coupled by an expansion relationship, such as given by Eq. (4). Replacing the void fraction, ψ, in Eq. (6) by the function $\psi(Re, Ar, \psi_{mf})$, following from Eq. (4) with Eqs. (2) and (3), results in the slightly upward bent curves showing a flat maximum at intermediate Reynolds numbers, as shown in Fig. 1 for fixed values of Ar, or Re_t, from Eq. (3a).



M5. Fig. 1. Nusselt number versus Reynolds number for Pr = 0.7 with Re_t (terminal-velocity Reynolds number) or Archimedes number, (Ar), respectively, as parameters.

For glass spheres or sand particles ($\rho_P \approx 2{,}500$ kg/m^3) fluidized by air at room temperature and normal pressure, the values of the terminal-velocity Reynolds number, Re_t, and the corresponding values of the Archimedes number, Ar, from Eq. (3a), as given in Fig. 1, belong to particle sizes of about 150 µm ($Re_t = 10$) up to about 7 mm ($Re_t = 10^4$).

Some of the known experimental results, especially those obtained from mass transfer experiments with liquid-fluidized beds [4, 5], in fact show a variation of Nu(Re) with a flat maximum, as resulting from the coupling of the fixed bed Eq. (6) with the bed expansion Eq. (4). Experimental uncertainty, however, is usually greater than the difference between these flatly curved and the straight, broken lines shown in Fig. 1, which are drawn through the end points of the curves, lying on the lower limiting curve for the single sphere.

It is therefore recommended to calculate the fluid-to-particle heat transfer coefficient within the range of existence of the fluidized bed from the simple relationship

$$Nu_{\text{fluidized bed}} \approx Nu_{\text{single sphere}}(Re_t, Pr). \tag{7}$$

That means, to use $\psi = 1$, and $Re_\psi = Re_t$ (Ar) from Eq. (3a) in Eq. (6).

Within the range of existence of the fluidized bed, $Re_{mf} < Re < Re_t$, the fluid-to particle heat transfer only depends on the acceleration of gravity, g, on the particle diameter, d, the particle density, ρ_P, and the physical properties of the fluid (ρ, c_P, η, λ), but not on the fluid velocity u.

2.3 Influence of Maldistribution and Backmixing

Many authors [6–10] have reported about heat (or mass) transfer coefficients which are lower than those for a single sphere in cross flow (lower curve in Fig. 1) for low Péclet numbers, Pe = RePr (or ReSc, respectively, for mass transfer).

These anomalously low heat (and mass) transfer coefficients, leading to Nusselt, or Sherwood numbers much lower than the theoretical Nu_{min} (= Sh_{min}) = 2 for a single sphere, today are usually regarded not as "true" heat transfer coefficients, but as "apparent" coefficients, which are not due to heat transfer alone, but contain effects which have not been taken into account in their evaluation from the experiments. Backmixing and maldistribution of flow lead to drastic reductions in the driving temperature difference as compared to the logarithmic mean in Eq. (5a), for example.

In the range of sufficiently large Péclet numbers (say Pe > 500) the corresponding numbers of transfer units, NTUs,

$$NTU = \frac{\alpha A}{c_P \dot{M}} = \frac{Nu}{Pe}\frac{A}{f}, \tag{8}$$

where A/f is the ratio of transfer surface area to cross-sectional area for the flow, are typically relatively small. Under these conditions, small maldistribution, or backmixing effects are nearly

negligible. For low Péclet numbers – and correspondingly high NTUs – even small maldistribution or backmixing effects suffice to shift the "apparent" heat (and mass) transfer coefficients by orders of magnitudes below the single-sphere values [10].

Various models have been developed to describe the effects of maldistribution and backmixing [6, 7, 9]. One of the simplest and practically most easily applicable of these models is the so-called "bypass model." In this model the total mass flow rate of fluid, $\dot{M}$, is subdivided in a main stream, free of backmixing, $(1-\upsilon)\dot{M}$, and a bypass flow, $\upsilon\dot{M}$. It is furthermore assumed that the bypass flow does not take part in heat transfer ($\mathrm{NTU}_{\mathrm{bypass}} \approx 0$, "model of the inactive bypass"). The outlet temperature of the fluid under these assumptions is the mixing value of the outlet temperature of the main stream and that of the bypass (which for inactive bypass remains equal to the inlet temperature):

$$\frac{T_{\mathrm{f,out}} - T_{\mathrm{P,O}}}{T_{\mathrm{f,in}} - T_{\mathrm{P,O}}} = (1-\upsilon)\exp(-\mathrm{NTU_m}) + \upsilon,$$
$$\upsilon = \dot{M}_{\mathrm{bypass}}/\dot{M}, \quad \mathrm{NTU_m} = \frac{\mathrm{Nu}}{(1-\upsilon)\mathrm{Re}\,\mathrm{Pr}}\frac{A}{f}. \tag{9}$$

Here, the ("true")Nusselt number is to be calculated from Eq. (7) or Eq. (6). Calculating the heat transfer coefficients from measured inlet and outlet temperatures under the assumption of plug flow (from Eqs. (5) and (5a)), "apparent" Nusselt numbers are obtained as

$$\mathrm{Nu_{app}} = -\mathrm{Re}\,\mathrm{Pr}\frac{f}{A}\cdot\ln[(1-\upsilon)\exp(-\mathrm{NTU_m}) + \upsilon]. \tag{10}$$

With $A/f = 6(1-\psi_{\mathrm{mf}})L_{\mathrm{mf}}/d$ and a bypass ratio of 5% ($\upsilon = 0.05$), $\psi_{\mathrm{mf}} = 0.5$, $L_{\mathrm{mf}}/d = 10$ (L_{mf} is the bed height at minimum fluidization), Pr = 0.7, and Re = $\mathrm{Re_t}$, Nu, and $\mathrm{Nu_{app}}$ are found as:

$\mathrm{Re_t}$	1	10	100	1,000	10,000
Nu	2.59	3.88	8.09	22.6	80.4
$\mathrm{Nu_{app}}$	0.07	0.699	6.06	21.8	79.6

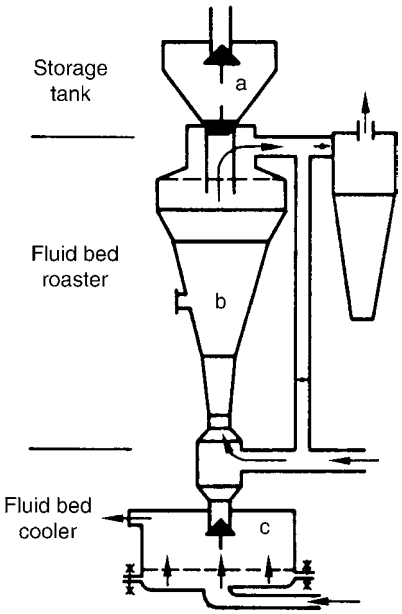
Most experimental data in the low-Péclet-number range can be explained sufficiently well with the simple bypass model and an appropriate constant value of υ [11]. For a first approximation it is recommended to start with υ = 0.05.

Example 1

As an example the batchwise process of cooling roasted coffee beans in a fluid bed cooler is shown in Fig. 2. A batch of coffee beans is roasted for 150 s in a venturi-type fluidized bed apparatus. During this time the previous charge is to be cooled with ambient air in the cylindrical fluidized bed under the roaster. It is checked whether the 150 s would suffice to cool the coffee beans from their initial temperature $T_{\mathrm{P,I}} = 300°\mathrm{C}$ to a temperature below 35°C. The following data are given to solve this problem:

Particles (subscript "P"): coffee beans

Initial temperature	$T_{\mathrm{P,I}} = 300°\mathrm{C}$
Density	$\rho_{\mathrm{P}} = 630\ \mathrm{kg/m^3}$
Specific heat capacity	$c_{\mathrm{P}} = 1.70\ \mathrm{kJ/(kg\ K)}$
Conductivity	$\lambda_{\mathrm{P}} = 0.10\ \mathrm{W/(m\ K)}$
Solid mass per cross-section	$M_{\mathrm{P}}/f = m_{\mathrm{P}} = 60\ \mathrm{kg/m^2}$
Mean diameter	$d = 6\ \mathrm{mm}$



M5. Fig. 2. Roasting and cooling of coffee beans in a fluidized bed (Example 1).

Fluid (no subscript for properties): air at $p = 1$ bar

Temperature at the inlet	$T_{\mathrm{f,in}} = 20°\mathrm{C}$
Mass flux	$\dot{m} = 3\ \mathrm{kg/(m^2\ s)}$
Density	$\rho = 1\ \mathrm{kg/m^3}$
Specific heat capacity	$c = 1.0\ \mathrm{kJ/(kg\ K)}$
Conductivity	$\lambda = 0.029\ \mathrm{W/(m\ K)}$
Kinematic viscosity	$\nu = 20 \cdot 10^{-6}\ \mathrm{m^2/s}$

It can be assumed that the solid particles are well mixed, so that T_{P} only depends on time, but not on the position in the bed. If the local change of enthalpy of the gas is neglected against that of the solid, one gets

$$m_{\mathrm{P}} c_{\mathrm{P}} \frac{\mathrm{d}\bar{T}_{\mathrm{P}}}{\mathrm{d}t} = \dot{m}c\left(T_{\mathrm{f,in}} - T_{\mathrm{f,out}}(t)\right) \tag{11}$$

and from Eq. (9)

$$\varepsilon \equiv \frac{T_{\mathrm{f,in}} - T_{\mathrm{f,out}}}{T_{\mathrm{f,in}} - \bar{T}_{\mathrm{P}}} = (1-\upsilon)(1-e^{-\mathrm{NTU_m}}). \tag{12}$$

From these two equations, for the two unknowns $T_{\mathrm{P}}(t)$ and $T_{\mathrm{f,out}}(t)$, one obtains after elimination of $T_{\mathrm{f,out}}(t)$ and integration over t,

$$\Theta_{\mathrm{P}} = \frac{\bar{T}_{\mathrm{P}}(t) - T_{\mathrm{f,in}}}{T_{\mathrm{P,I}} - T_{\mathrm{f,in}}-} = \exp(-\varepsilon\tau^*) \tag{13}$$

with the efficiency of the fluid bed heat exchanger

$$\varepsilon = (1-\upsilon)(1-e^{-\mathrm{NTU_m}}), \tag{14}$$

the dimensionless time

$$\tau^* \equiv \frac{\dot{m}c}{m_{\mathrm{P}} c_{\mathrm{P}}} t, \tag{15}$$

and the NTUs

$$\mathrm{NTU_m} = \frac{6k\,m_\mathrm{P}}{\rho_\mathrm{P} d(1-\upsilon)(\dot{m}c)_\mathrm{f}} \cdot t. \qquad (16)$$

The outside heat transfer coefficient in Eq. (9) had to be replaced here by an overall heat transfer coefficient k, because the surface temperature of the particles $T_{\mathrm{P,O}}$ is not known, but only the caloric average temperature $\bar{T}_\mathrm{P}$. This overall coefficient, k, also includes the internal conduction resistance (see Chap. E2):

$$\frac{1}{k} = \frac{1}{\alpha_\mathrm{o}} + \frac{1}{\alpha_\mathrm{i}} \qquad (17)$$

The outside heat transfer coefficient is calculated from Eqs. (7) and (6).

The Archimedes number is

$$\mathrm{Ar} = \frac{gd^3}{\nu^2}\frac{\rho_\mathrm{P}-\rho}{\rho} = 3.34 \cdot 10^6.$$

From this, Eq. (2a), with $\psi_\mathrm{mf} = 0.4$, gives $\mathrm{Re_{mf}} = 326$, and Eq. (3a) yields $\mathrm{Re_t} = 3{,}180$.

From the actual flow rate, Re is found: $\mathrm{Re} = \dot{m}d/(\rho\nu) = 900$ (so the velocity is actually within the range of fluidization), and $\mathrm{Pr} = 0.69$; $\mathrm{Nu_{lam}} = 33.1$; $\mathrm{Nu_{turb}} = 21.3$; $\mathrm{Nu} = 41.32$ and $\alpha_\mathrm{o} = \lambda/d$, $\mathrm{Nu} = 200\ \mathrm{W/(K\,m^2)}$.

Calculation of the internal heat transfer coefficient from Chap. E2–Sect. 3.1.1.

With the dimensionless time $\tau = \kappa t/(d/2)^2 = 1.56$; $\mathrm{Nu_i} = 3.41$; $\alpha_\mathrm{i} = \lambda/(d/2)$, $\mathrm{Nu_i} = 114\ \mathrm{W/(K\,m^2)}$.

From this one finds $k = 72.6\ \mathrm{W/(m^2\,K)}$; $\tau^* = 4.41$ (Eq. (15)); $\mathrm{NTU_m} = 2.305/(1-\upsilon)$ and with varying values of the bypass ratio υ:

υ	0.00	0.05	0.10	0.20	0.30
ε	0.900	0.866	0.831	0.755	0.674
$\bar{T}_\mathrm{P}/°\mathrm{C}$	25.3	26.1	27.2	30.0	34.3

From this calculation one can find out that the time of 150 s probably suffices to cool the coffee beans to a temperature below 35°C, even if the bypass ratio is chosen to be as high as 30%.

Alternatively total backmixing of the air in the fluidized bed can be assumed, see Eq. (5b). In this case the efficiency is $\varepsilon = \mathrm{NTU}/(1+\mathrm{NTU}) = 2.305/3.305 = 0.697$, and the particle temperature after 150 s turns out to be $\bar{T}_\mathrm{P} = 32.9°\mathrm{C}$ (so total backmixing has roughly the same effect as an inactive bypass of about 25% in this case).

3 Heat Transfer from Immersed Surfaces to Gas-Fluidized Beds of Solid Particles

3.1 Definition of the Heat Transfer Coefficient

The heat transfer coefficient, α, between gas-fluidized beds of solid particles and the surfaces of immersed heating or cooling equipment (such as plates, tubes, or tube bundles) is defined as

$$\alpha \equiv \frac{\dot{Q}_{(\mathrm{O-B})}}{A_\mathrm{O}(T_\mathrm{O} - T_\mathrm{B})}, \qquad (18)$$

where $\dot{Q}_{(\mathrm{O-B})}$ is the heat flow transmitted from the surface area A (subscript: O) of the heat exchanger elements immersed in the fluidized bed (subscript: B). T_O is the surface temperature of these immersed elements, and T_B is the bed temperature, which may be assumed to be more or less uniformly distributed sufficiently far away from the exchanger elements.

Because of the great surface area of the solid particles and the intensive mixing in fluidized beds one usually does not have to distinguish between gas and solid temperatures. In most cases one can also assume that the bed temperature T_B in a fluidized bed is independent of the position ("ideal stirred tank").

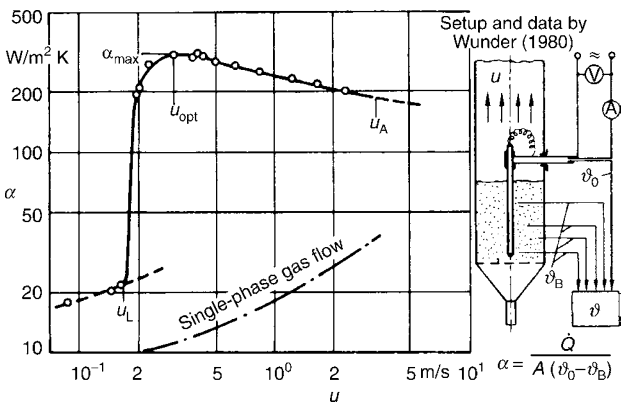
3.2 Calculation of Heat Transfer Coefficients

Figure 3 shows the heat transfer coefficients, α, between a vertical cylindrical heater and an air-fluidized bed of glass spheres (of 400 µm diameter) as a function of fluid velocity, u, as measured by Wunder [12].

In contrast to the monotonous increase of heat transfer coefficients with gas velocity for a single-phase gas flow (without the particles), shown as the dotted curve in Fig. 3, in the fluidized bed a steep rise of heat transfer coefficients is observed immediately after the minimum fluidization. The values increase up to a maximum, α_max, at a certain gas velocity, u_opt (and a corresponding gas volume fraction, ψ_opt), while they decrease with even higher gas velocities (and correspondingly increasing bed height). The very steep increase immediately following the minimum fluidization conditions obviously is caused by the free motion of particles and the "particle-convective" net energy transport from the heater surface to the bulk of the bed.

Apart from this particle convective transport, heat is also transferred directly to the gas ("gas convection"), and – especially so for higher temperatures – also by radiation between the heater surface and the particles. Treating these mechanisms approximatively as independent and parallel, the total heat transfer coefficient can be written as the sum of three parts [13].

$$\alpha = \underbrace{\alpha_\mathrm{P}}_{\text{particle convection}} + \underbrace{\alpha_\mathrm{G}}_{\text{gas convection}} + \underbrace{\alpha_\mathrm{R}}_{\text{radiation}}. \qquad (19)$$



M5. Fig. 3. Heat transfer coefficient between immersed surface and fluidized bed versus gas velocity.

With $Nu_P = \alpha_P\, d/\lambda$, $Nu_G = \alpha_G\, d/\lambda$, and $Nu_R = \alpha_R\, d/\lambda$ (the conductivity, λ, is that of the gas in all cases!) the particle convective part, Nu_P, is obtained first, from:

$$Nu_P = (1-\psi)\, Z\, (1-\exp(-N)) \tag{20}$$

with Z and N from:

$$Z = \frac{1}{6}\frac{(\rho c)_P}{\lambda}\sqrt{\frac{g d^3(\psi-\psi_{mf})}{5(1-\psi_{mf})(1-\psi)}},\quad N = Nu_{WP}/(C_K Z), \tag{21}$$

$$\frac{1}{Nu_{WP}} = \frac{1}{Nu_{WP,max}} + \frac{\lambda/\lambda_P}{4\left(1+\sqrt{\frac{3C_K}{2\pi}\frac{\lambda}{\lambda_P}Z}\right)}, \tag{21a}$$

$$Nu_{WP,max} = 4\left(\left(1+\frac{2\ell}{d}\right)\ln\left(1+\frac{d}{2\ell}\right)-1\right), \tag{21b}$$

$$\ell = 2\Lambda\left(\frac{2}{\gamma}-1\right), \tag{21c}$$

$$\Lambda = \sqrt{\frac{2\pi\tilde{R}T}{\tilde{M}}}\frac{\lambda}{p(2c_p-\tilde{R}/\tilde{M})}, \tag{22}$$

$$\lg\left(\frac{1}{\gamma}-1\right) = 0.6 - \left(\frac{1{,}000\,K}{T}+1\right)\Big/ C_A. \tag{23}$$

The value of constant C_K from the comparison with experimental data is

$$C_K = 2.6. \tag{24}$$

$Nu_{WP,max}$ is the Nusselt number containing the maximum heat transfer coefficient between wall and particle according to Schlünder [14]. It results from the limiting heat transfer resistance by conduction through the gaseous gap between a plane wall and a spherical particle at short contact times, and only depends on the ratio $2\ell/d$, of the modified mean free path of the gas molecules and the particle radius $d/2$. This is also called a Knudsen number in the literature. This modified mean free path is defined by Eq. (21c), where Λ is the effective mean free path, and γ is the accommodation coefficient. The mean free path, Λ, is calculated as a function of gas properties from Eq. (22), based on the kinetic theory of gases.

The accommodation coefficient, γ, a measure of the incompleteness of energy transfer during a molecule–wall collision, depends, primarily, upon the kind of gas, and on temperature. According to Reiter et al. [15] the temperature dependence of γ can be approximated empirically by Eq. (23). The constant C_A can be calculated from a measured value $\gamma_0 = \gamma(T_0)$. For the noble gases the following values are found

Gas	He	Ne	Ar	Kr	Xe
C_A	50	6	3	2.5	2.25
γ(25°C)	0.235	0.573	0.876	0.933	0.956

For some other gases the following values are recommended (see also [16]):

Gas	H_2	H_2O	Air	CO_2
C_A	∞	3.62	2.8	2.8
γ(25°C)	0.20	0.80	0.90	0.90

The gas convective part, Nu_G, is calculated according to Baskakov [17] from the empirical Eq. (25)

$$Nu_G = 0.009\ Pr^{1/3}\ Ar^{1/2} \tag{25}$$

while the radiative part follows from a linearized form of the Stefan–Boltzmann equation:

$$Nu_R \cong 4\varepsilon\sigma\, T_m^3\, (d/\lambda). \tag{26}$$

In Eq. (26), ε is an effective emissivity ($0 < \varepsilon < 1$), which primarily depends on the surface properties of the immersed surfaces (the surface of the particles in a fluidized bed is very close to a black body). The Stefan–Boltzmann constant has the value: $\sigma = 5.67 \cdot 10^{-8}$ W/(m^{2}K^4). The maximum heat transfer coefficient α_{max} can be found from Eqs. (19–26), for the gas volume fraction $\psi = \psi_{opt}$. This value can be obtained from Eq. (20) with $\partial Nu_P/\partial\psi = 0$:

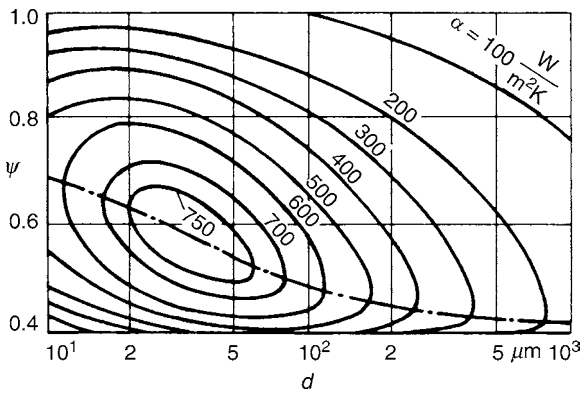
$$\frac{\psi_{opt}-\psi_{mf}}{1-\psi_{mf}} = \frac{1}{2}\left(1-\frac{N(\psi_{opt})}{e^{N(\psi_{opt})}-1}\right). \tag{27}$$

This equation has to be solved iteratively. For large particles, that is, small values of N, ψ_{opt} is close to the minimum fluidization voidage, ψ_{mf}. For small particles, and correspondingly large values of N, the optimal bed voidage comes closer to the center of the range of existence of the fluidized bed:

$$\lim_{N\to 0}\ \psi_{opt} = \psi_{mf}, \tag{27a}$$

$$\lim_{N\to\infty}\ \psi_{opt} = \frac{1}{2}(1-\psi_{mf}). \tag{27b}$$

Figure 4 shows a contour line plot of the heat transfer coefficient for glass or sand particles fluidized by air at 25°C and 1 bar over



M5. Fig. 4. Heat transfer coefficient between immersed surface and fluidized bed: Influence of particle diameter, d, and gas volume fraction, ψ (bed expansion, voidage). Air, 25°C, 1 bar; sand or glass particles. Dotted line: $\psi = \psi_{opt}$.

a particle diameter, d, and bed voidage, ψ, plane, as calculated from Eqs. (19–26).

3.3 Influence of Particle Properties, Gas Properties, and Operation Parameters

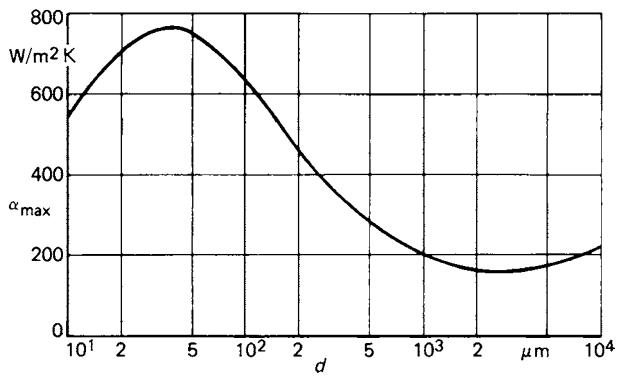
Following Eqs. (19–26), the heat transfer coefficient between gas-fluidized beds of solid particles and immersed surfaces depends upon a number of quantities, which may be classified into the three groups: particle properties, gas properties, and operation parameters.

3.3.1 Particle Properties

Five quantities, the diameter, d, the void fraction at minimum fluidization, ψ_{mf}, the volumetric heat capacity, $(\rho c)_P$, the density, ρ_P, and the conductivity, λ_P, of the particles play some role in the model Eqs. (19–26). Mainly three of them, d, ψ_{mf}, $(\rho c)_P$, are primary parameters in the particle convective part Eqs. (20–24). The conductivity of the particles, λ_P, only plays a part in the particle convective heat transfer, if the conductivities of the solid and the gas are in the same order of magnitude, as for example for polystyrene foam particles and air. In most practical cases, the transient internal conductive resistance in the particles (the second term on the right-hand side of Eq. (21a)) can be neglected against the first one. The particle density, ρ_P, additionally plays a role for the gas convective part, Eq. (25), in the Archimedes number.

Figure 5 shows the variation of the maximum heat transfer coefficient, α_{max}, as a function of the particle diameter, d. The curve is calculated with the properties of air at $p = 1$ bar, $T = 25°C$, and glass (or sand) particles ($\rho_P = 2{,}500$ kg/m^3, $c_P = 750$ J/(kg K)) with a void fraction at minimum fluidization of $\psi_{mf} = 0.4$. The radiative part was neglected.

It can be seen from Figs. 4 and 5 that there is an absolute maximum of the heat transfer coefficient at a certain particle size, in this case at $d = 38$ µm. For smaller particles the finite heat capacity of the solids is a limiting factor; the fine particles in contact with the heater wall rapidly reach the surface temperature. For larger particles the conductive resistance in the gaseous gap plays a limiting role, α_{max} decreases up to a minimum at $d = 3$ mm. The increase for even greater diameters is due to the gas convective part α_G from Eq. (25) ($\alpha_G \propto \sqrt{d}$).



M5. Fig. 5. Maximum heat transfer coefficient between immersed surface and fluidized bed versus particle diameter. Air, 25°C, 1 bar; sand or glass particles.

With decreasing solids fraction, $(1 - \psi_{mf})$, the particle convective part becomes smaller. The volumetric heat capacity of the particles $(\rho c)_P$ affects the particle convective heat transfer especially for smaller particles; in the limiting case $N \to \infty$ from Eqs. (20) and (27) one gets

$$\lim_{N\to\infty} \alpha_{P,max} = \frac{1}{6}(\rho c)_P \sqrt{\frac{gd(1-\psi_{mf})}{20}} \tag{28}$$

that is, $\alpha_{P,max}$ is directly proportional to the volumetric heat capacity and to the square root of the solid fraction at minimum fluidization. For sufficiently large particles, however, the heat capacity plays a vanishing role. For $N \to 0$ from Eqs. (20) and (27) one finds

$$\lim_{N\to 0} \alpha_{P,max} = \frac{\lambda}{d}(1-\psi_{mf})\frac{Nu_{WP}}{C_K}. \tag{29}$$

The conductivity of the particles, λ_P, only plays a role if the internal conduction resistance in (Eq. 21a), the second term on the right side, comes in the order of magnitude of the first one:

$$\frac{\alpha_{WP,max}}{\alpha_{WP}} = 1 + \frac{\lambda}{\lambda_P}\cdot\frac{Nu_{WP,max}/4}{1+\sqrt{\frac{3C_K}{2\pi}\frac{\lambda}{\lambda_P}Z}}. \tag{30}$$

In many practical cases, the ratio (λ/λ_P) is very small, even for relatively poor conductors, such as sand, fluidized with air it is typically about (0.03/2), that is only 1.5%.

The internal resistance of the particles, however, is not negligible if the particles are porous solids, such as polystyrene foam, with conductivities in the same order of magnitude as that of gases.

3.3.2 Gas Properties

The relevant properties of the fluidizing gas are the conductivity, λ, and the modified mean free path of the molecules, ℓ (or its ratio to the particle radius, $2\ell/d$). Only these two gas properties affect the particle convective component. From an empirical equation the maximum heat transfer coefficients are found to be roughly proportional to $\lambda^{0.6}$, which is better explained by the model Eqs. (19–24) with the two properties, λ and ℓ.

Density, ρ, heat capacity (at constant pressure), c_P, and viscosity, η, play an additional role in the gas convective component only.

3.3.3 Operation Parameters

The operation parameters are gas flow rate, pressure, temperature, and shape, size and arrangement of the heater (or cooler) surfaces. The gas flow rate is coupled to particle size and density by the range of existence of fluidization ($u_{mf} < u < u_t$). Within this range the bed voidage, ψ, changes from ψ_{mf} to 1. At a certain gas velocity, u_{opt}, the maximum heat transfer

coefficient, α_{max}, is reached. From Eqs. (19–27) the function $\alpha(\psi)$ can be obtained for the whole range ($\psi_{mf} < \psi < 1$), so $\alpha_{max} = \alpha(\psi_{opt})$ can be calculated without any knowledge of the actual bed expansion behavior. These maximum values are in reasonable agreement with many experimental values [13, 18].

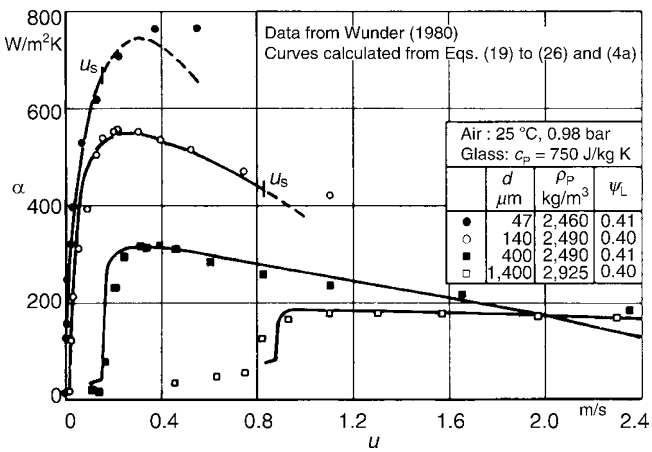
The question what is the value of the average gas velocity required to reach the bed voidage in the zone of the bed, where the heater (or cooler) elements are positioned, however, can only be answered, if the bed expansion behavior of the actual equipment is known, from experiments [19].

For a first approximation it is recommended to use the simple linear expansion relationship from Eq. (4a), combined with $\alpha(\psi)$ from Eqs. (19–27), to obtain heat transfer coefficients as a function of gas velocity (as long as the heater surfaces are placed within the range $z < L_{mf}$ of the initial bed height L_{mf}. In Eq. (4a) u_{mf} is to be calculated from Eq. (2a), and u_t from Eq. (3a) or from Eq. (3b) if the latter gives greater values. Figure 6 shows the curves for $\alpha(u)$ as calculated in this way for four different particle sizes, from $d = 47$–$1{,}400$ µm (=1.4 mm), as compared with experimental data by Wunder [12].

The pressure has some effects on α_P via the mean free path ($\ell \propto 1/p$), and has much stronger effects, on α_G via the gas density ($\rho \propto p$). The gas convective part increases approximatively proportional to the square root of the pressure $\alpha_G \propto \sqrt{p}$, while the effect on the particle convective part is much smaller. Higher pressure can improve the heat transfer primarily for larger particles.

Higher temperatures also have an effect via the physical properties. Conductivity, viscosity, and mean free path increase with temperature, while the density decreases with increasing temperature. The contribution of radiation, see Eq. (26), increases with the third power of the average absolute temperature. For $T_m = 1{,}000$ K (= 727°C) one already obtains $\alpha_R = \varepsilon\ 227$ W/(K m^2).

The shape, size, and position of the heater (or cooler) surfaces are not required for the calculation from Eqs. (19–26). The comparison with experimental data [20] has shown that these equations are applicable for single cylindrical heaters or coolers, immersed vertically or horizontally [21] in the bed center. Even experiments with spherical probes, with coils of tubes, or tube bundles have been found to agree relatively well with the model predictions.



M5. Fig. 6. Heat transfer coefficient immersed surface-to-fluidized bed versus gas velocity.

Example 2

To determine the size of the heater surfaces for an allothermal fluid-bed coal gasification process the heat transfer coefficient between these surfaces (tubes, tube bundles) and the pressurized-steam-fluidized bed of coal particles is needed. The steam enters the bed at 800°C at a pressure of 40 bars.

Particle properties: coal:

$\rho_P = 1{,}400$ kg/m^3, $c_P = 1{,}500$ J/(kg K), $d = 50$–500 µm, $\psi_{mf} = 0.5$.

Gas properties: steam (water) at 800°C and 40 bar:

$\eta = 40.5 \cdot 10^{-6}$ Pa s	$\widetilde{M} = 18$ kg/kmol
$c_P = 2.38 \cdot 10^3$ J/(kg K)	$C_A = 3.62$; $\gamma = 0.462$ (Gl. (23))
$\lambda = 0.110$ W/(m K)	$\Lambda = 11.29$ nm (Gl. (22))
$\rho = 8.14$ kg/m^3	$\ell = 75.20$ nm (Gl. (21))

The effective emissivity of the heater surface and the fluid-bed is assumed to be $\varepsilon = 0.9$.

Eq. (26) thus gives a radiative heat transfer coefficient of $\alpha_R = 247$ W/(m^2 K).

From Eqs. (19–27) one finds:

d	50	100	200	500	µm	Eq.
α_G	54.9	77.6	109.8	173.6	W/(m^2 K)	(25)
ψ_{opt}	0.726	0.667	0.607	0.552	–	(27)
$\alpha_{P,max}$	1,189	1,390	1,289	866.1	W/(m^2 K)	(20)
α_{max}	1,491	1,715	1,646	1,287	W/(m^2 K)	(19)

Under the conditions used here, a heat transfer coefficient of $\alpha_{max} \approx 1{,}670$ W/(m^2 K) was found experimentally for a particle size fraction of $d < 500$ µm in a pilot plant [22].

The absolute maximum, appearing at a particle size of about 40 µm for air (25°C, 1 bar) (see Fig. 5), in this case is shifted to a particle size of about 150 µm. This is confirmed by the results of [22]: For a smaller size fraction, $d < 100$ µm, lower maximum heat transfer coefficients of $\alpha_{max} \approx 1{,}390$ W/(m^2 K) have been observed.

3.4 Limits of Application

The set of Eqs. (19–27) to calculate the heat transfer coefficients between immersed surfaces and gas-fluidized beds of granular solids have been compared within wide ranges of all the relevant parameters with experimental data from a number of different sources, see [13, 18, 20, 23]. In the range of very fine powders ($d < 40$ µm), where these equations predict lower heat transfer coefficients with decreasing particle size (see Fig. 5), very few experimental data are available, which do not allow a definitely clear conclusion. Other calculation methods from the literature [7, 8, 24, 25], which in other ranges lead to more or less similar results, predict a different behavior in this fine powder range, for example, a further increase of heat transfer with decreasing particle size [7, 8], or constant limiting maximum value [24, 25], which agrees more or less with the absolute maximum

obtained from our equations (about 750 W/(m^2 K) for air-fluidized beds of sand or glass particles at normal conditions). In this fine-powder range experiments are difficult, as fine powders are not easily fluidized, because the adhesion forces between the particles are in the same order of magnitude as the fluid-particle forces.

The equations given in Sect. 3 from Chap. M5 are not applicable to liquid-fluidized beds. For these cases, some purely empirical equations, based on an evaluation of a great amount of data are given in the next subchapter.

4 Heat Transfer from Immersed Surfaces or Container Walls to Liquid-fluidized Beds

4.1 Calculation of Heat Transfer Coefficients

For liquid-fluidized beds of solid particles the heat transfer coefficient between immersed surfaces and the bed – as defined for gas-fluidized beds in Eq. (18) – can be calculated, according to Haid et al. [26], from:

$$\mathrm{Nu} = c\mathrm{Re}^{a}\ \mathrm{Pr}^{b}(1-\psi)^{1-a}\psi^{-1}, \qquad c = 0.0734, \quad a = 0.75, \quad b = 0.63. \tag{31}$$

The three constants have been fitted by non-linear regression to all available data [27] for heat transfer to liquid fluidized beds. The exponents of the terms $(1-\psi)^{1-a}$ and ψ^{-1} have been found by assuming the validity of an equation $\mathrm{Nu_h} = c\mathrm{Re}_h^{a}\ \mathrm{Pr}^{b}$ with a hydraulic diameter in $\mathrm{Nu_h}$ and $\mathrm{Re_h}$, which is proportional to the particle diameter, d, and to the ratio $\psi/(1-\psi)$ [26].

The experimentally verified range of validity is given as:

$0.02 < \mathrm{Re} < 9{,}400$	$1.65 < \mathrm{Pr} < 7{,}700$
$3.85 < \mathrm{Ar} < 6.7 \cdot 10^7$	$\psi_{mf} < \psi < 1$

The relationship between bed expansion (or the liquid volume fraction ψ) and the flowrate (or the Reynolds number, Re) for the liquid-fluidized bed is given by Eq. (4) with Eqs. (2a) and (3a) for $\mathrm{Re_{mf}}$ and $\mathrm{Re_t}$ respectively. With these, Eq. (31) can also be written as

$$\mathrm{Nu} = c\mathrm{Re}_{t}^{a}\ \mathrm{Pr}^{b}(1-\psi)^{1-a}\psi^{na-1} \tag{32}$$

with n, as already given in Eq. (4),

$$n = \frac{\ln(\mathrm{Re_{mf}}/\mathrm{Re_t})}{\ln \psi_{mf}}, \tag{33}$$

as a function of (ψ_{mf}, Ar, Pr, ψ) in place of (Re, Pr, ψ).

The maximum heat transfer coefficient can be found from Eq. (32) as

$$\mathrm{Nu} = c\mathrm{Re}_{t}^{a}\ \mathrm{Pr}^{b}(1-\psi_{opt})^{1-a}\psi_{opt}^{na-1} \tag{34}$$

at a liquid volume fraction ψ_{opt}, which can be obtained from

$$\psi_{opt} = \frac{n-1/a}{n-1}. \tag{35}$$

4.2 Limits of Application

At $\psi = \psi_{mf}$ the lower limit of the range of existence of fluidization is reached. Below that, for $\psi < \psi_{mf}$ there is the range of fixed beds, where heat transfer is to be calculated from Chap. M7. For $\psi \to 1$ Eqs. (31) and (32) give $\mathrm{Nu} \to 0$. It is recommended to check for $\psi > 0.95$ whether the heat transfer coefficients for fluidized beds from these equations are already lower than the corresponding value for single-phase liquid flow according to Chap. G1. If so, the heat transfer coefficient ought to be calculated from Chap. G1 for single-phase liquid flow.

Example 3

In a vertical shell-and-tube heat exchanger the fouling of the surface by crystallizing salt should be avoided by fluidized solid particles (see Chap. C4). In the tubes, glass beads of a diameter of d = 3 mm should therefore be fluidized by the upward flowing aqueous solution at an average temperature of 20°C.

What are the values of heat transfer coefficients that can be expected at the inner walls of the tubes within the range of existence of the liquid-fluidized bed of these glass beads?

Tube length	l = 2,100 mm
Inner diameter of the tubes	d_{it} = 21 mm
Glass beads	
Diameter	d = 3 mm
Void fraction	ψ_{mf} = 0.4
Density	ρ_P = 2,500 kg/m^3
Aqueous solution	
Density	ρ = 1,183 kg/m^3
Specific heat capacity	c_P = 3,081 J/(kg K)
Conductivity	λ = 0.545 W/(K m)
Viscosity	$\eta = 2.41 \cdot 10^{-3}$ Pa·s
Archimedes number	$\mathrm{Ar} = g\,d^{3}(\rho_P - \rho)\rho/\eta^2$

Ar = $9.81 \cdot 3^3 \cdot 10^{-9}$ (2,500 − 1,183) 1,183/$(2.41 \cdot 10^{-3})^2$ = 71,051.

Equation (2a): Reynolds number at minimum fluidization

$\mathrm{Re_{mf}} = 42.9\ (1 - 0.4)\ (1 + 0.4^3 \cdot 71{,}051/(0.6^2 \cdot 3{,}214))^{0.5} - 1 = 31.4$.

$u_{mf} = \eta\ \mathrm{Re_{mf}}/(\rho\ d)$, u_{mf} = 0.0213 m/s.

Equation (3a): terminal Reynolds number

$\mathrm{Re_t} = 18\ ((1 + (71{,}051)^{0.5}/9)^{0.5} - 1)^2$; $\mathrm{Re_t}$ = 369.9; u_t = 0.251 m/s.

Equation (33): exponent of the bed expansion equation

n = ln (31.4/369.9)/ln (0.4) = 2.691.

Equation (35): optimum void fraction

$\psi_{opt} = (2.691 - 1/0.75)/(2.291 - 1) = 0.803$.

Corresponding Reynolds number: $\mathrm{Re} = \mathrm{Re_t}\ \psi^n$

$\mathrm{Re_{opt}} = 369.90.803^{2.691} = 205$.

Equation (34): maximum Nusselt number

$\mathrm{Pr} = \eta c_P/\lambda = 13.62$;

$\mathrm{Nu_{max}} = 0.0734\mathrm{Re}_t^{0.75}\ \mathrm{Pr}^{0.63}(1-\psi)^{0.25}\psi^{0.75n-1} = 17.1$; α_{max} = 3,106 W/(m^2 K)

at minimum fluidization, with $\mathrm{Re_{mf}}$ = 31.4 and ψ_{mf} = 0.4, Nu, and α, are found

$Nu = 0.0734 \cdot 31.4^{0.75} \cdot 13.62^{0.63} \cdot 0.6^{0.25} \cdot 0.4^{-1}$; $Nu_{mf} = 11.1$; $\alpha_{mf} = 2{,}017\ W/(m^2\ K)$

at terminal velocity, with $Re_t = 369.9$ and $u_t = 0.251$ m/s, that is, at $\psi \to 1$, Eqs. (31) and (32) give $Nu \to 0$. Here the *Reynolds* number of the tube flow

$Re = (d_{it}/d)\ Re_t = (21/3)\ 369.9 = 2589.3$,

and one finds from Chap. G1 for tube-flow $Nu = 15.60$

$\alpha = (\lambda/d_{it})\ Nu = 0.545 \cdot 15.6/(21 \cdot 10^{-3})\ W/(m^2\ K) = 405\ W/(m^2\ K)$.

M6 Heat Transfer from a Wall to Stagnant and Mechanically Agitated Beds

Evangelos Tsotsas
Otto-von-Guericke-Universität Magdeburg, Magdeburg, Germany

1 Introduction

Granular and powdery products are often treated in contact equipment of various geometrical configurations (tray, paddle, drum, etc.). Heat transfer from the wall of the apparatus to the bed, or vice versa, is essential for this kind of processing and will, therefore, be discussed in the present chapter. Immersed surfaces such as the shaft of stirring devices may be used additionally to the apparatus wall for heating or cooling. Modelling of heat transfer will be presented in Sects. 2–5 on the basis of a model that considers the bed of particles as one continuous phase. This is usually called the penetration model. The heat exchanged between the wall and the bed may be used to just change bed temperature. Alternatively, a part of the supplied heat may be consumed for phase change or chemical reaction in the interior of the bed. These two cases will be distinguished, describing the former as heat transfer to beds without latent sinks (Sect. 2) and the latter as heat transfer to beds with latent heat sinks (Sect. 3). In case of merely heating or cooling, further distinction will be made between stagnant (static) and mechanically agitated beds (Sects. 2.1 and 2.2, respectively). Mechanical agitation can be provided by the rotation of the equipment (e.g., rotary drum) or by embedded, rotating stirrers. Modelling with heat sinks will be discussed for drying, distinguishing between drying in pure vapor atmosphere (vacuum contact drying, Sect. 3.1) and drying in the presence of inert gas (atmospheric contact drying, Sect. 3.2). Only mechanically agitated beds will be treated explicitly in Sect. 3. Parameters, which are necessary in order to conduct calculations with the penetration model, will be presented in Sect. 4. Extensions and some recent applications will be briefly outlined in Sect. 5, with reference to the relevant literature. Subsequently, a short introduction to emerging new modelling approaches that consider every particle of the bed individually (discrete models) will be given in Sect. 6. At the end, four examples that document and further illustrate calculations according to Sects. 2–4 will be provided.

2 Heat Transfer to Beds Without Latent Sinks

Figure 1 gives a qualitative impression of the temperature profile between a heating wall and an adjoining bed, which is free of latent sinks. There is a steep temperature drop in the immediate vicinity of the wall, $\vartheta_W - \vartheta_0$, followed by a further decrease toward the interior of the bed, $\vartheta_0 - \vartheta_{bed}$ (ϑ_{bed}: average caloric bed temperature). The temperature jump $\vartheta_W - \vartheta_0$ and the temperature difference $\vartheta_0 - \vartheta_{bed}$ are assigned to a contact heat resistance, $1/\alpha_{WS}$, and to a penetration resistance, $1/\alpha_{bed}$, respectively. Therefore, it is

$$\alpha_{WS} = \dot{q}/(\vartheta_W - \vartheta_0), \quad (1)$$

$$\alpha_{bed} = \dot{q}/(\vartheta_0 - \vartheta_{bed}). \quad (2)$$

The overall heat transfer coefficient

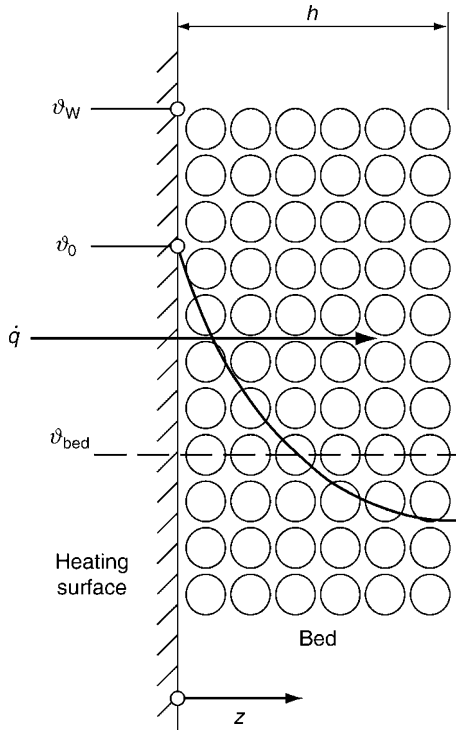
$$\alpha = \dot{q}/(\vartheta_W - \vartheta_{bed}) \quad (3)$$

is obtained to

$$\frac{1}{\alpha} = \frac{1}{\alpha_{WS}} + \frac{1}{\alpha_{bed}}. \quad (4)$$

Equations for the calculation of α_{WS} are given in Sect. 4.1. To derive α_{bed}, the bed is considered as a quasi-continuum with effective properties. These are the density $\rho_{bed,dry}$, the specific heat capacity $c_{bed,dry}$, and the thermal conductivity $\lambda_{bed,dry}$, where the subscript "dry" indicates the absence of latent sinks (in many cases moisture). In this way, Fourier's theory of

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_55,



M6. Fig. 1. Scheme of heat transfer from a wall to an adjoining bed of particles.

conduction can be applied. Applying Fourier's theory, stagnant and mechanically agitated beds will be distinguished in the following.

2.1 Stagnant Beds

Using the standard boundary condition of constant temperature ϑ_0, the time-averaged heat penetration coefficient of the stagnant bed is obtained to

$$\alpha_{\mathrm{bed,dry}} = \frac{2}{\sqrt{\pi}} \frac{\sqrt{(\rho\lambda c)_{\mathrm{bed,dry}}}}{\sqrt{t}}. \tag{5}$$

Here, t is the residence time of the bed on the heating surface. The thermal conductivity of the bed $\lambda_{\mathrm{bed,dry}}$ can be calculated according to Subchap. D6.3.

Equations (5) and (4) yield an overall heat transfer coefficient of

$$\frac{\alpha}{\alpha_{\mathrm{WS}}} = \frac{1}{1+\sqrt{\pi\tau}/2}, \tag{6}$$

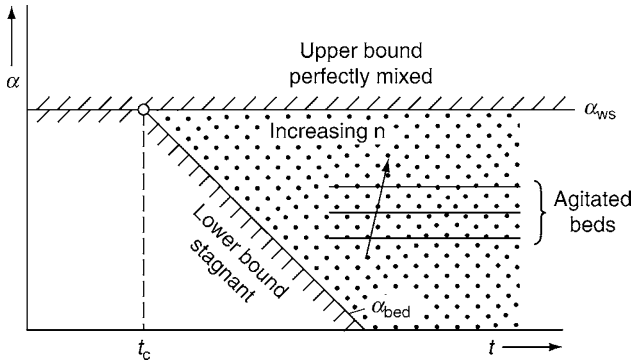
with

$$\tau = \frac{\alpha_{\mathrm{WS}}^2}{(\rho\lambda c)_{\mathrm{bed,dry}}} t. \tag{7}$$

A critical residence time

$$t_c = \frac{4}{\pi} \frac{(\rho\lambda c)_{\mathrm{bed,dry}}}{\alpha_{\mathrm{WS}}^2} \tag{8}$$

for the heating process can be derived from the condition $\alpha_{\mathrm{WS}} = \alpha_{\mathrm{bed}}$. Thus, it is



M6. Fig. 2. Wall-to-bed heat transfer coefficient α as a function of time t. Under the critical time t_c, it is approximately $\alpha = \alpha_{\mathrm{WS}}$. Above the critical time t_c, the heat transfer coefficient α decreases with the square root of time for stagnant beds. In case of mechanically agitated beds, α reaches some constant final value, which depends on the quality of mixing, but cannot overcome α_{WS}.

$$t << t_c \rightarrow \alpha \approx \alpha_{\mathrm{WS}}, \tag{9a}$$

$$t >> t_c \rightarrow \alpha \approx \alpha_{\mathrm{bed}}. \tag{9b}$$

Consequently, the contact resistance $1/\alpha_{\mathrm{WS}}$ is rate controlling at short times, whereas the penetration resistance $1/\alpha_{\mathrm{bed}}$ dominates at long times, as illustrated in Fig. 2.

The critical time t_c depends, among others, on particle diameter d and pressure p. At normal pressure, it usually counts seconds; in vacuum, it may reach several minutes. This behavior has been verified experimentally by Wunschmann [1], as Fig. 3 – where momentaneous overall heat transfer coefficients are plotted against time – shows. At high pressures, it is $t >> t_c$, and the measurements agree with Eq. (5). On contrary, at low pressures, it is $t << t_c$, so that the overall heat transfer coefficient equals the contact heat transfer coefficient α_{WS}. Details about the experiments and their evaluation can be found in [1], along with further data from the literature.

Equations (5–9) can also be applied to beds gliding as a rigid body along a heating surface. In this case, the residence time results from the velocity u of bed movement (assumed constant) and from the length L of the heating surface to

$$t = L/u. \tag{10}$$

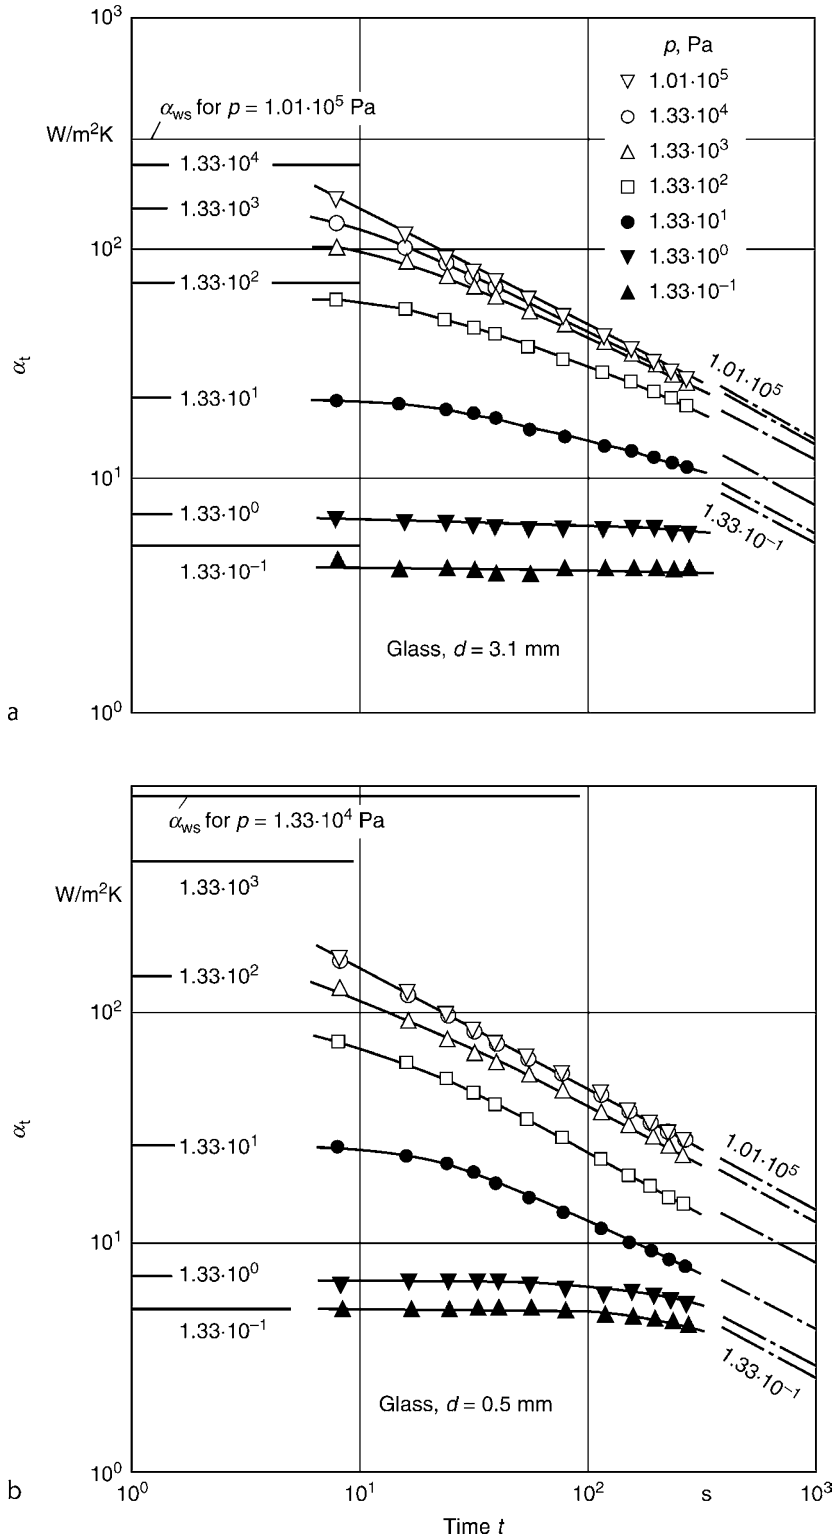
2.2 Mechanically Agitated Beds

Heat transfer to mechanically agitated beds can be described in a similar way as for stagnant beds by the so-called penetration model that replaces continuous mixing by a sequence of stagnant periods. Every fictitious static period is of duration t_{R}, which inserted in Eq. (5) results to a coefficient for heat penetration of

$$\alpha_{\mathrm{bed}} = \frac{2}{\sqrt{\pi}} \frac{\sqrt{(\rho\lambda c)_{\mathrm{bed,dry}}}}{\sqrt{t_{\mathrm{R}}}}. \tag{11}$$

Stagnant periods are assumed to end with instantaneous and perfect mixing. Their duration t_{R} can be correlated in the form

$$t_{\mathrm{R}} = t_{\mathrm{mix}} N_{\mathrm{mix}}, \tag{12}$$



M6. Fig. 3. Evolution of the momentaneous heat transfer coefficient α_t between wall and stagnant bed: measurements by Wunschmann [1] for glass spheres ($\rho_{bed,\,dry} = 1{,}800$ kg m^{-3}, $c_{bed,\,dry} = 633$ J kg^{-1} K^{-1}, $\lambda_p = 0.93$ W m^{-1} K^{-1}) in air at various pressures p and particle diameters d.

with the time constant of the stirring device

$$t_{mix} = 1/n, \tag{13}$$

where n is the rotational frequency of the shaft of the stirrer and N_{mix} is a mixing number. The mixing number depends on the mechanical properties of the system (apparatus, stirrer, particles) and on n. It denotes how often the shaft of the stirrer must turn around, before perfect mixing of the bed can be achieved once. The determination of N_{mix} is discussed in Sect. 4.3.

The overall heat transfer coefficient α is still obtained by the series combination of resistances according to Eq. (4). By

improving mechanical mixing (small t_R), it is possible to increase the penetration coefficient α_{bed} and, therefore, also the overall coefficient α. However, the latter can never overcome the upper bound set by the contact coefficient α_{WS}. This is shown in Fig. 4 by means of measured data from [1]. After some transient, constant values of the overall heat transfer coefficient are reached. Depending on stirrer frequency, these values lie between α_{WS} and the heat transfer coefficient to the stagnant bed according to Eq. (5) (compare with Fig. 2).

From Eqs. (4), (11), and (12), it follows

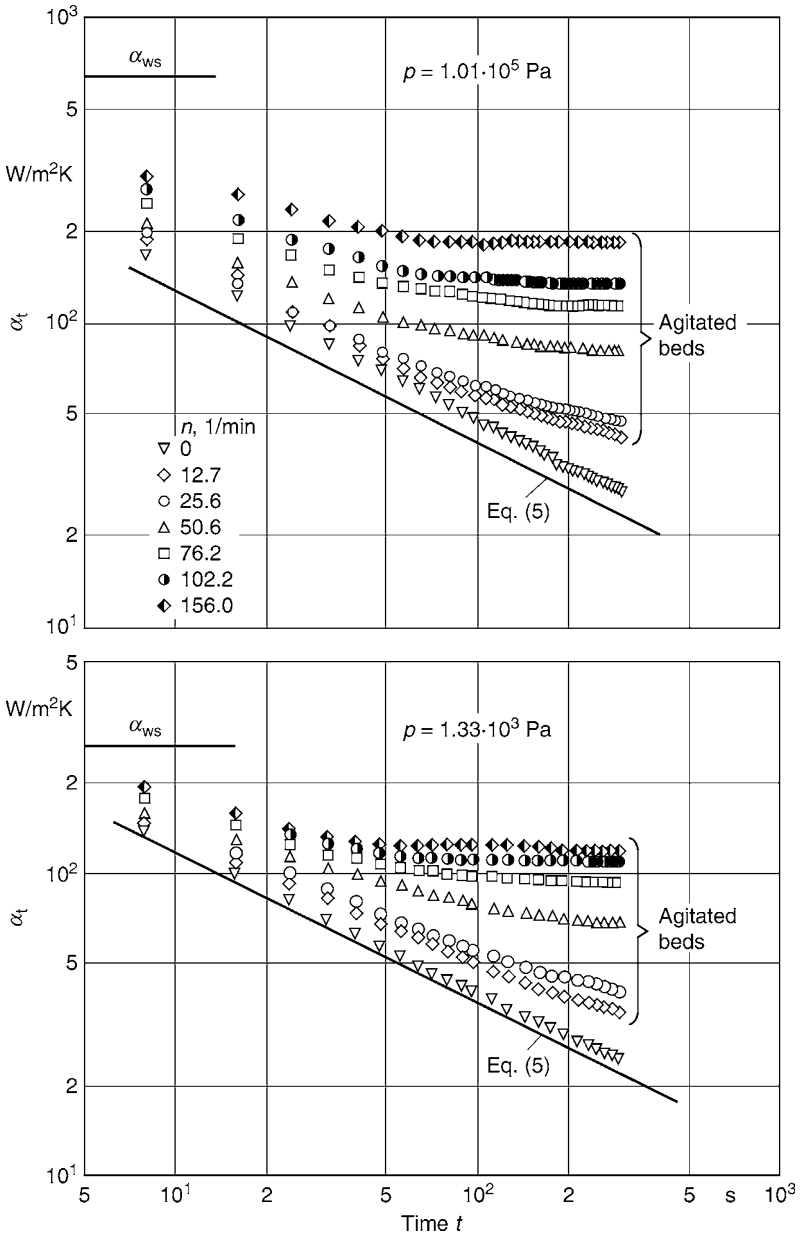
$$\frac{\alpha}{\alpha_{WS}} = \frac{1}{1 + \sqrt{\pi N_{therm} N_{mix}/2}}, \tag{14}$$

with

$$N_{therm} = \frac{\alpha_{WS}^2}{(\rho\lambda c)_{bed,dry}} t_{mix}. \tag{15}$$

All nonmechanical properties of the system are summarized in the parameter N_{therm}.

A common presentation of Eqs. (6), (7), (14), and (15) is given in Fig. 5 [2] – in comparison with, again, data from [1] for glass spheres with d = 1.0 mm. The values of N_{mix} for agitated beds have been fitted to the measurements. This resulted to N_{mix} = 23 for a blade and to N_{mix} = 3 for a broom stirrer. Better performance of the broom stirrer is due to the fact that the bristles efficiently sweep the heating surface clean of already



M6. Fig. 4. Momentaneous heat transfer coefficients α_t to mechanically agitated beds over time: measurements by Wunschmann [1] for glass spheres (d = 1 mm) at different pressures p and various stirrer frequencies n. The limiting case of the stagnant bed (n = 0) is included.

(6). *Agitated beds*: Reduced steady-state values of the heat transfer coefficient α/α_{WS} versus N_{therm}. Solid lines according to Eq. (14).

heated particles. The dependence of N_{mix} on n has been neglected in this presentation.

3 Heat Transfer to Mechanically Agitated Beds with Latent Sinks

As mentioned in the Introduction, drying (the removal of bed moisture by evaporation) will be used in order to explain the calculation of heat transfer from the wall when heat consumption by phase change or chemical reaction takes places in the bed. Distinction is made between two different modes of operation, namely processing in pure vapor atmosphere (vacuum contact drying) and processing in inert gas atmosphere (atmospheric contact drying), because the presence or not of inert gas has a significant influence on the mechanisms of heat transfer. The discussion will be restricted to mechanically agitated beds.

It is assumed that all the liquid phase is present in the interior of porous particles, not in the voids of the bed.

3.1 Pure Vapor Atmosphere

The penetration model has been extended to vacuum contact drying by Schlünder and Mollekopf [3], who assumed that a steep drying front propagates into the bed during every fictitious stagnant period. Not only temperature, but also moisture profiles are levelled out at the end of every such period (Fig. 6). Profiles within a stagnant period are illustrated in more detail in Fig. 7. Here, X is the moisture content of the bed (in kg moisture per kg dry solids), which is evenly distributed above the drying front; ϑ_{bed} is the respective bed temperature, z_T is the position of the drying front at the considered point of time.

Heat transfer kinetics can, again, be expressed in the form

$$\alpha_{WS} = \dot{q}_0/(\vartheta_W - \vartheta_0), \tag{16}$$

$$\alpha_{bed} = \dot{q}_0/(\vartheta_0 - \vartheta_{bed}). \tag{17}$$

The contact heat transfer coefficient α_{WS} does not change in principle and can be calculated according to Sect. 4.1 for pure vapor atmosphere. On contrary, the consumption of heat by evaporation in the interior of the bed (the latent heat sink) has a significant influence on the penetration coefficient, which is in this case obtained to

$$\alpha_{bed} = \frac{2}{\sqrt{\pi}} \frac{\sqrt{(\rho\lambda c)_{bed,dry}}}{\sqrt{t_R}} \frac{1}{\operatorname{erf}\zeta} = \frac{\alpha_{bed,dry}}{\operatorname{erf}\zeta}. \tag{18}$$

For the sake of distinction, the penetration coefficient of the dry bed according to Eq. (11) is denoted by $\alpha_{bed,dry}$ in Eq. (18). Similarly, α_{dry} is the overall heat transfer coefficient to the dry bed. The serial combination of resistances (Eq. (4)) remains valid and leads for the overall heat transfer coefficient of the wet bed to the relationship

$$\alpha = \frac{\alpha_{WS}}{1 + (\alpha_{WS}/\alpha_{dry} - 1)\operatorname{erf}\zeta}. \tag{19}$$

As the equations show, material properties of the dry bed are sufficient for the calculation of vacuum contact drying. The influence of the latent sink appears only in the dimensionless position of the drying front

$$\zeta = \frac{z_T}{2\sqrt{\kappa_{bed,dry}\, t}}, \tag{20}$$

with

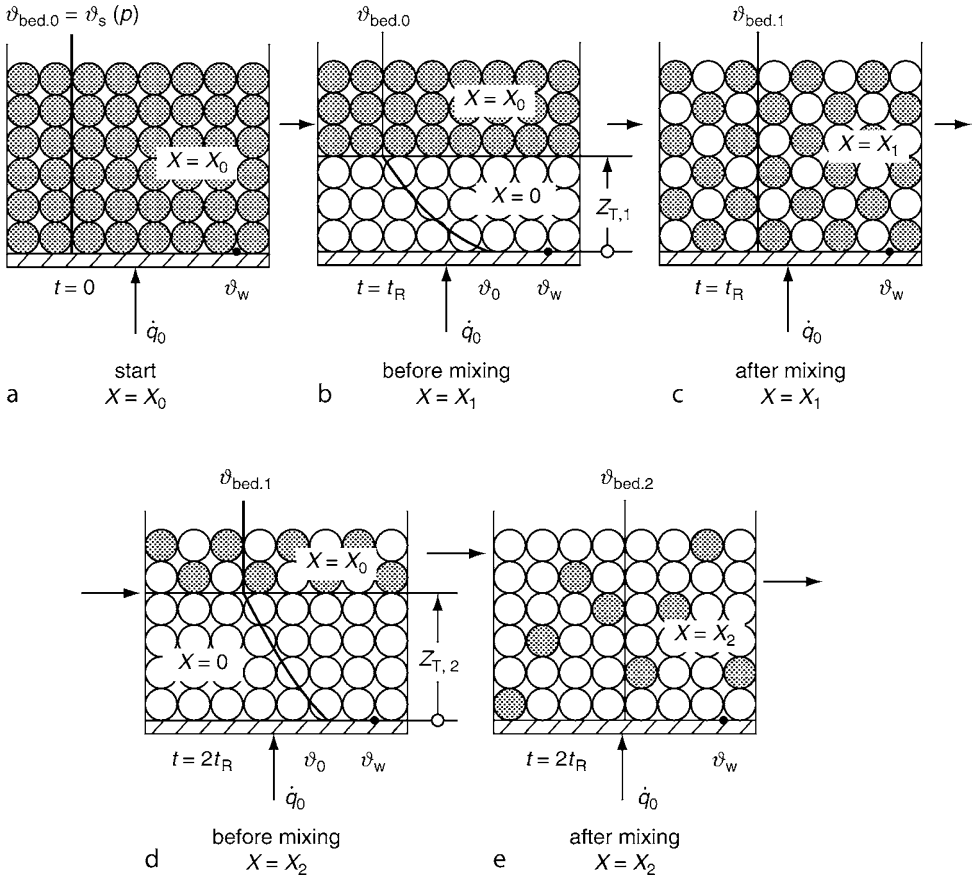
$$\kappa_{bed,dry} = \frac{\lambda_{bed,dry}}{(\rho c)_{bed,dry}}. \tag{21}$$

According to [3] (Neumann's solution) ζ is determined by the relationship

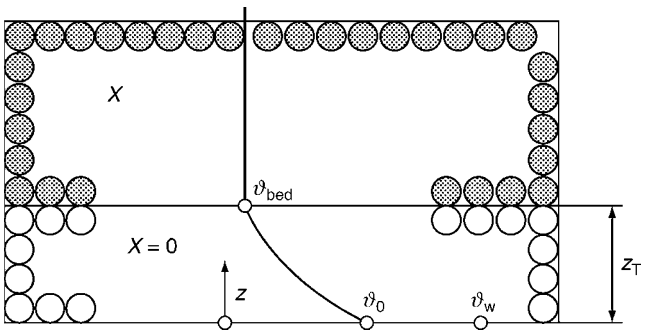
$$\sqrt{\pi}\zeta \exp(\zeta^2)\left[\left(\frac{\alpha_{WS}}{\alpha_{dry}} - 1\right)\operatorname{erf}\zeta + 1\right] = \frac{1}{Ph}\left(\frac{\alpha_{WS}}{\alpha_{dry}} - 1\right), \tag{22}$$

with

$$Ph = \frac{X\Delta h_v}{c_{bed,dry}(\vartheta_W - \vartheta_{bed})}. \tag{23}$$



M6. Fig. 6. Scheme of the penetration model for vacuum contact drying.



M6. Fig. 7. Temperature and moisture profiles during a fictitious stagnant period.

With decreasing moisture content X, the phase change number Ph decreases, the penetration depth of the drying front increases, and the penetration heat transfer coefficient α_{bed} (Eq. (18)) decreases. At the limit of $X \to 0$, one obtains $\zeta \to \infty$, $\mathrm{erf}\,\zeta \to 1$ and $\alpha_{bed} \to \alpha_{bed,dry}$. The increase of z_T with progressing drying is indicated in an exaggerated way in Fig. 6.

According to [4], accurate values of the error function can be obtained from

$$\mathrm{erf}\,\zeta = 1 - (a_1 t + a_2 t^2 + a_3 t^3)\exp(-\zeta^2), \tag{24a}$$

with

$$t = 1/(1 + p\zeta) \tag{24b}$$

and $a_1 = 0.3480242$, $a_2 = -0.0958798$, $a_3 = 0.7478556$, and $p = 0.47047$.

Heat fluxes at the wall, $\dot{q}_0$, and at the phase change front, $\dot{q}_{lat}$, are calculated by

$$\dot{q}_0 = \alpha(\vartheta_W - \vartheta_{bed}), \tag{25}$$

$$\dot{q}_{lat} = \alpha(\vartheta_W - \vartheta_{bed})\exp(-\zeta^2). \tag{26}$$

The comparison with measured data shows a good agreement when using the heat flux at the phase change front $\dot{q}_{lat}$ in order to calculate the drying rate $\dot{m}$:

$$\dot{m} = \dot{q}_{lat}/\Delta h_v. \tag{27}$$

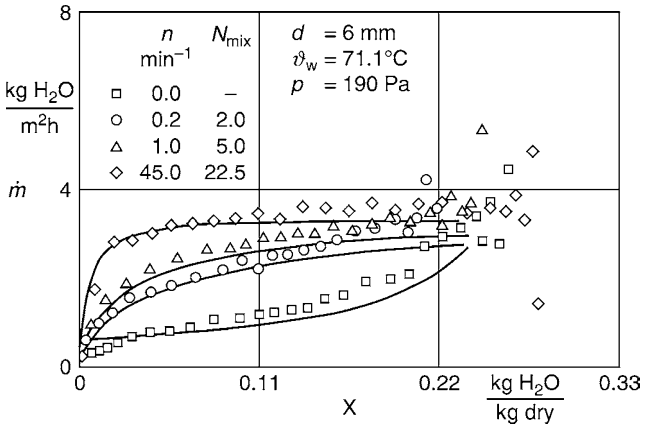
The remaining heat input is used to increase the temperature of the bed [3]. Consequently, the changes of moisture content and average caloric bed temperature within a stagnant period are obtained to

$$\Delta X = \frac{\dot{m} t_R A}{M_{dry}} \tag{28}$$

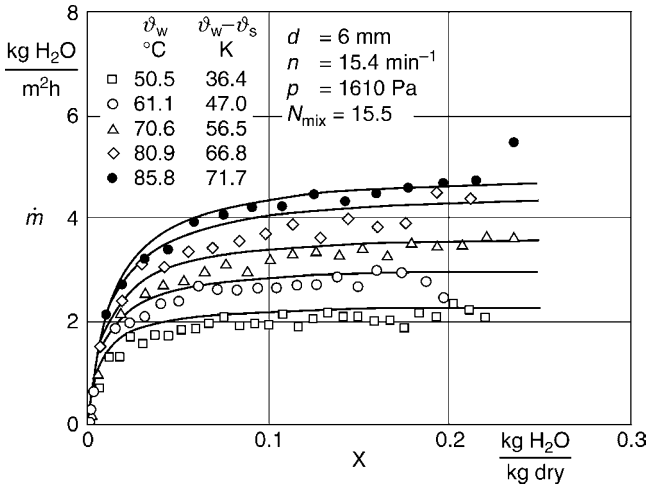
and

$$\Delta\vartheta_{bed} = \Delta X \frac{\Delta h_v}{c_{bed,dry} + c_1 X}[\exp(\zeta^2) - 1]. \tag{29}$$

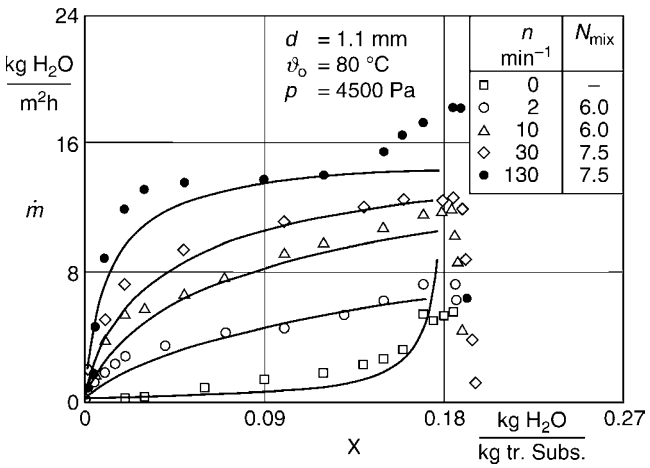
Here, A is the covered area of the heating wall and M_{dry} is the dry mass of the product. The term $c_1 X$ accounts for still existing liquid moisture. Moisture content and bed temperature at the beginning of the $(i + 1)$th stagnant period result from the respective values of the foregoing period to



M6. Fig. 8. Influence of stirrer frequency n on vacuum contact drying of coarse-grained, water-loaded material (magnesium silicate, d = 6.0 mm) in a tray dryer (D = 240 mm) according to [5] ($\rho_{bed,dry}$ = 980 kg m^{-3}, $c_{bed,dry}$ = 800 J kg^{-1} K^{-1}, $\lambda_{bed,dry}$ = 0.151 W m^{-1} K^{-1}, δ = 20 µm, α_{WS} = 32 W m^{-2} K^{-1}, ϑ_W = 71°C, p = 190 Pa).



M6. Fig. 9. Influence of heating plate temperature ϑ_W on vacuum contact drying of coarse-grained, water-loaded material (magnesium silicate, d = 6.0 mm) in a tray dryer (D = 240 mm) according to [5] ($\rho_{bed,dry}$ = 980 kg m^{-3}, $c_{bed,dry}$ = 800 J kg^{-1} K^{-1}, $\lambda_{bed,dry} \approx$ 0.175 W m^{-1} K^{-1}, δ = 20 µm, α_{WS} = 46 W m^{-2} K^{-1}, p = 1,610 Pa (ϑ_S = 14.1°C), n = 15.4 min^{-1}, N_{mix} = 15.5).



M6. Fig. 10. Influence of stirrer frequency n on vacuum contact drying of fine-grained, water-loaded material (aliminum silicate, d = 1.1 mm) in a paddle dryer (D = 134 mm) according to [5] ($\rho_{bed,dry}$ = 1,020 kg m^{-3}, $c_{bed,dry}$ = 800 J kg^{-1} K^{-1}, $\lambda_{bed,dry}$ = 0.153 W m^{-1} K^{-1}, δ = 2.5 µm, α_{WS} = 226 W m^{-2} K^{-1}, ϑ_o = 80°C, p = 4,500 Pa).

$$X_{i+1} = X_i - \Delta X_i, \tag{30}$$

$$\vartheta_{bed,i+1} = \vartheta_{bed,i} + \Delta\vartheta_{bed,i}. \tag{31}$$

For $i = 0$, it is $X = X_0$ (initial moisture content) and $\vartheta_{bed} = \vartheta_S$ (saturation temperature at the imposed pressure). Consequently, the drying curve, $\dot{m}(X)$, and the temperature curve, $\vartheta_{bed}(X)$, can be calculated step-by-step.

Equation (4) yields simple limiting cases for vacuum contact drying:

1. $\alpha_{WS} << \alpha_{bed} \rightarrow \alpha \approx \alpha_{WS}$ and $\dot{m}(X_0) \sim (\vartheta_W - \vartheta_S)^n$ with $n \approx 1$.
2. $\alpha_{WS} >> \alpha_{bed} \rightarrow \alpha \approx \alpha_{bed}$ and $\dot{m}(X_0) \sim (\vartheta_W - \vartheta_S)^n$ with $n < 1$.

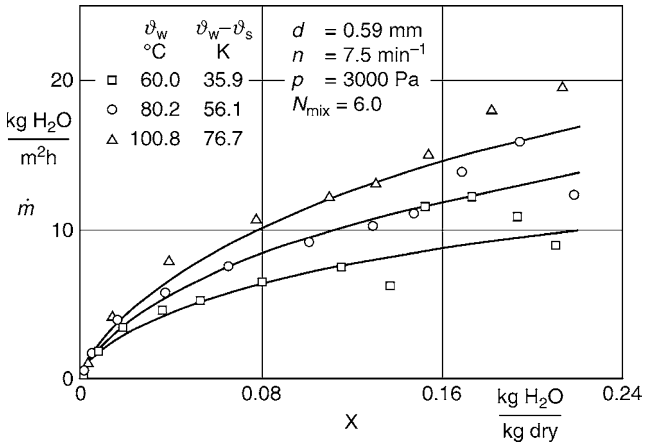
The condition $\alpha_{WS} << \alpha_{bed}$ is fulfilled with big particles. Then, the contact resistance is rate controlling. Heat transfer and drying rate can hardly be increased by better mixing (Fig. 8). Drying rate at the beginning of the process $\dot{m}(X_0)$ is almost directly proportional to the driving temperature difference $\vartheta_W - \vartheta_S$ (Fig. 9).

The condition $\alpha_{WS} >> \alpha_{bed}$ is approximated with fine-grained materials. Then, the penetration resistance of the bed is rate controlling. This resistance can be reduced significantly by intensifying the mechanical agitation, as Fig. 10 shows. Since the coefficient α_{bed} decreases with increasing difference between heating surface temperature and bed temperature – due to deeper penetration of the drying front – the dependence of initial drying rate $\dot{m}(X_0)$ from $\vartheta_W - \vartheta_S$ is weaker than linear (Fig. 11).

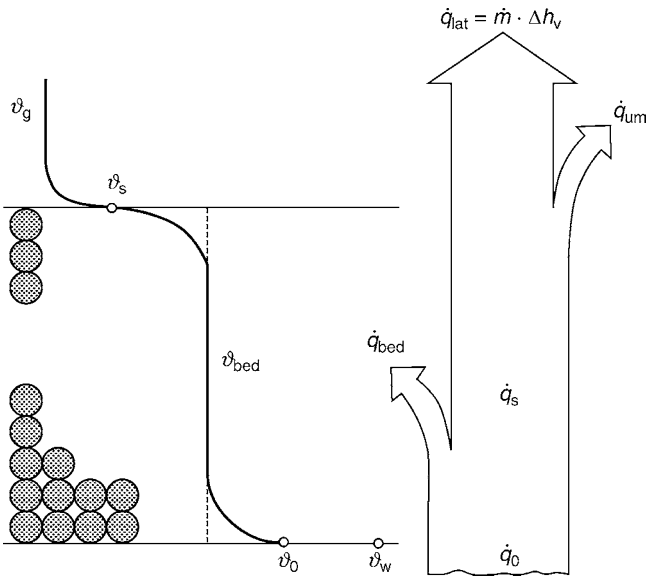
3.2 Inert Gas Atmosphere

Atmospheric conditions (the presence of inert gas) do not change the calculation of either the contact coefficient α_{WS} or the parameters of the penetration model (t_R or N_{mix}). However, they do modify essentially the processes taking place in the interior of the bed, because emerging vapor must – instead of leaving the bed – recondense at the next cold position along the temperature profile. Consequently, net evaporation occurs only at the free surface of the bed. These effects are taken into account in the scheme of Fig. 12, which was proposed by Tsotsas and Schlünder [6] for heat transfer. According to it, both the bed temperature ϑ_{bed} and the moisture content X are known and evenly distributed at the beginning of the considered fictitious stagnant period. During this period, heat comes from the wall into the bed with a time-averaged flux of $\dot{q}_0$. By analogy to the previous paragraphs, it is

$$\dot{q}_0 = \alpha_{WS}(\vartheta_W - \vartheta_0), \tag{32}$$



M6. Fig. 11. Influence of heating plate temperature ϑ_W on vacuum contact drying of fine-grained, water-loaded material (aluminum silicate, d = 0.59 mm) in a tray dryer (D = 240 mm) according to [5] ($\rho_{bed,dry}$ = 1,030 kg m^{-3}, $c_{bed,dry}$ = 800 J kg^{-1} K^{-1}, $\lambda_{bed,dry} \approx$ 0.140 W m^{-1} K^{-1}, δ = 2.5 µm, $\alpha_{WS} \approx$ 318 W m^{-2} K^{-1}, p = 3,000 Pa (ϑ_S = 24.1°C), n = 7.5 min^{-1}, N_{mix} = 6.0).



M6. Fig. 12. Temperature profiles and heat fluxes during one fictitious stagnant period for contact drying in inert gas atmosphere. At the beginning of the stagnant period, temperature (dashed line) and moisture content are evenly distributed. Moisture is assumed to remain equally distributed throughout the stagnant period.

$$\dot{q}_0 = \alpha_{bed}(\vartheta_0 - \vartheta_{bed}), \alpha_{bed} \text{ at } (\vartheta_0 + \vartheta_{bed})/2. \quad (33)$$

Assuming t_R as short enough for the formation of a drying front to be avoided, leads to the conclusion that the heat penetration coefficient can be calculated under atmospheric conditions by Eq. (11), replacing however the properties of the dry bed with those of the wet bed (subscript: wet):

$$\alpha_{bed} = \frac{2}{\sqrt{\pi}} \frac{\sqrt{(\rho\lambda c)_{bed,wet}}}{\sqrt{t_R}}. \quad (34)$$

Whereas the capacity

$$(\rho c)_{bed,wet} = (c_{bed,dry} + X c_l)\rho_{bed,dry} \quad (35)$$

is nearly temperature-independent, the thermal conductivity $\lambda_{bed,wet}$ is a strong function of temperature (calculation in Sect. 4.2). Therefore, the unknown temperature ϑ_0 cannot be simply eliminated (as in Sects. 2 and 3.1), but must be determined by iterative solution of Eqs. (32) and (33). The value of $\dot{q}_0$ also results from this iteration.

Simultaneously with the heat transfer from the wall to the bulk of the bed, heat is also transferred from the bulk of the bed to the free bed surface. There, this heat is used to evaporate moisture or it gets lost to the environment (Fig. 12). In the time average, one can write

$$\dot{q}_s = \alpha_{bed}(\vartheta_{bed} - \vartheta_s), \alpha_{bed} \text{ at } (\vartheta_{bed} + \vartheta_s)/2, \quad (36)$$

$$\dot{q}_s = \dot{q}_{lat} + \dot{q}_{um}, \quad (37)$$

$$\dot{q}_{lat} = \dot{n}\Delta\tilde{h}_v, \quad (38)$$

$$\dot{n} = n_g\beta_g \ln\frac{p - p_g}{p - p_S(\vartheta_s)} \quad (39)$$

and

$$\dot{q}_{um} = (\alpha_g + \alpha_{rad})\ (\vartheta_s - \vartheta_g). \quad (40)$$

The heat transfer coefficient α_{bed} can, again, be calculated with the help of Eq. (34).

Equation (39) is the usual expression for one-side diffusion kinetics in case of convective drying, with the partial pressure of the evaporating component in the bulk of the gas phase p_g and the saturation pressure at the free surface of the bed $p_S(\vartheta_s)$. By means of the analogy between heat and mass transfer, the gas-side mass transfer coefficient β_g can be eliminated. For the combination of water and air with a Lewis number close to unity, one obtains in mass units

$$\dot{q}_{lat} = \dot{m}\Delta h_v, \quad (41)$$

$$\dot{m} = \frac{\alpha_g}{c_{p,g}} \frac{\tilde{M}_{H_2O}}{\tilde{M}_{air}} \ln\frac{p - p_g}{p - p_S(\vartheta_s)} \quad (42)$$

instead of Eqs. (38) and (39).

Should the surrounding gas be hotter than the free surface of the bed ($\vartheta_g > \vartheta_s$), then the heat flux $\dot{q}_{um}$ would change direction. This case is usually denoted by combined contact and convective drying. Heat transfer coefficients to or from the gas by convection (α_g) or radiation (α_{rad}) can be estimated with the help of respective chapters of Heat Atlas.

Due to the temperature dependence of α_{bed} and the coupling between heat and mass transfer at the free surface of the bed, the bed surface temperature ϑ_s must be calculated iteratively from Eqs. (36–40), or Eqs. (36), (37), (40–42). At the end of the iteration values for the heat fluxes and the drying rate $\dot{m}$ are also obtained.

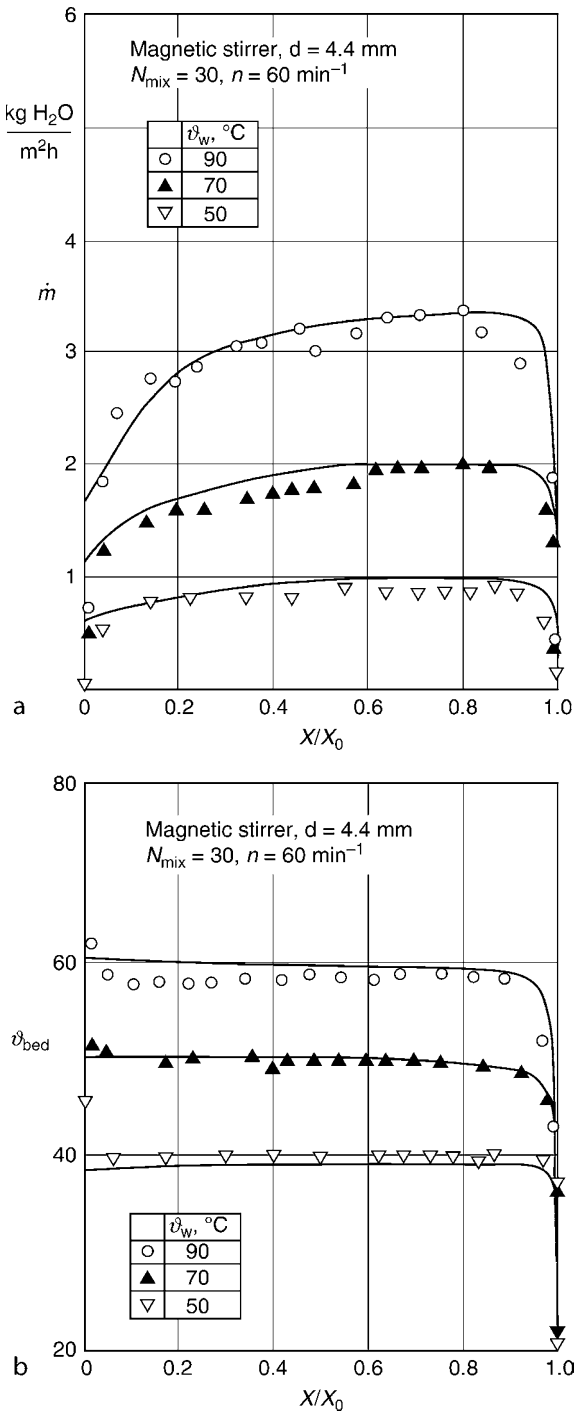
The change of average bed temperature during the considered stagnant period is

$$\Delta\vartheta_{bed} = \frac{\dot{q}_{bed}\, t_R}{(\rho c)_{bed,wet} h}, \quad (43)$$

with the bed height h and

$$\dot{q}_{bed} = \dot{q}_0 - \dot{q}_s. \quad (44)$$

The change of moisture content is obtained from Eq. (28). Similarly to vacuum contact drying, the calculation is conducted from one to the next fictitious stagnant period with the help of Eqs. (30) and (31). The initial values $X = X_0$ and $\vartheta_{bed} = \vartheta_{bed,0}$ are not subjected to any restrain.

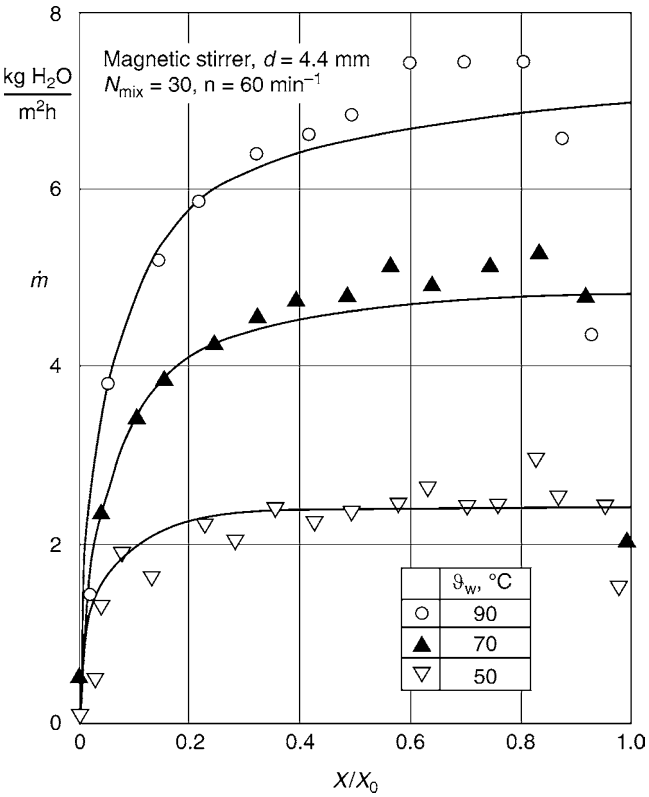


M6. Fig. 13. (a) Drying curves and (b) bed temperature curves during atmospheric contact drying of water-loaded aluminum silicate (d = 4.4 mm) in a mini-plant tray equipment (D = 100 mm) according to [6] ($p = 10^5$ Pa, $n \cong 60$ min^{-1}, $N_{mix} = 30$, $X_0 = 0.24$, $\vartheta_{bed,0} \cong 20$°C, free convection to ambient air at the upper surface of the bed).

The foregoing discussion and Sect. 4.2 indicate that the wet bed works in a similar way like a heat pipe, transporting heat from the wall to the free surface of the bed, where it is consumed by evaporation. The transportation of moisture back to the hot side, which is achieved by capillarity in classical heat pipes, takes place by mechanical agitation of the particle system.

Typical drying and temperature curves for water-loaded aluminum silicate in an open, mini-plant tray dryer are shown in Fig. 13. The bed temperature ϑ_{bed} attains a nearly constant value over a broad range of moisture content. The described calculation (solid lines, see also Sect. 4.2) is in good agreement with the experimental results, can, however, not predict the decrease of drying rate to zero and the increase of bed temperature at the end of the process. This can be repaired by multiplying the right-hand side of Eq. (42) with an empirical correction factor, which should change value from unity to zero as a function of X/X_0 at small moisture contents. Reduction of the surface area available for evaporation by successive drying out of particles is the physical background of this behavior.

By closing the mini-plant dryer and imposing water-jet vacuum on it, the drying curves of Fig. 14 are obtained. All other conditions are identical to those of Fig. 13. One can see that change from the atmospheric to the vacuum mode of operation increases the drying rates by a factor of approximately two. This result may be due to additional mass transfer resistances in the presence of inert gas, but should not be generalized. It should be noticed that the value of the mixing number N_{mix} does not change with the operational mode. Similar results have been obtained with larger dryers and with smaller particles.



M6. Fig. 14. Drying curves measured under water-jet vacuum for the same material, equipment and operating conditions as in Fig. 13.

4 Calculation of Relevant Quantities

4.1 Contact Heat Transfer Coefficient

According to Schlünder [2], it is

$$\alpha_{WS} = \varphi\alpha_{WP} + \alpha_{rad}, \tag{45a}$$

$$\alpha_{WP} = \frac{4\lambda_g}{d}\left[\left(1+\frac{2\,(l+\delta)}{d}\right)\ln\left(1+\frac{d}{2\,(l+\delta)}\right)-1\right], \tag{45b}$$

$$\alpha_{rad} = 4\,C_{W,bed}\,T^3, \tag{45c}$$

$$C_{W,bed} = \sigma/(1/\varepsilon_W + 1/\varepsilon_{bed} - 1). \tag{45d}$$

The symbols mean:

α_{WP}	wall–particle heat transfer coefficient,
φ	surface coverage factor ($\varphi \approx 0.8$ for mono-dispersed beds of spheres),
α_{rad}	heat transfer coefficient by radiation,
σ	radiation coefficient of the black body ($\sigma = 5.67 \cdot 10^{-8}$ W m^{-2} K^{-4}),
ε_W, ε_{bed}	emission coefficients of wall and bed, respectively,
λ_g	thermal conductivity of the gas,
d	particle diameter,
δ	surface roughness of particles.

l is the modified mean free path of gas molecules:

$$l = 2\frac{2-\gamma}{\gamma}\sqrt{\frac{2\pi\tilde{R}T}{\tilde{M}}}\frac{\lambda_g}{p(2\,c_{p,g}-\tilde{R}/\tilde{M})}, \tag{46}$$

with

p	pressure,
$c_{p,g}$	specific heat capacity of the gas,
$\tilde{M}$	molar mass of the gas,
$\tilde{R}$	universal gas constant ($\tilde{R}$ = 8.314 J mol^{-1} K^{-1}),
γ	accommodation coefficient.

The accommodation coefficient γ can be calculated according to [7] by means of the correlation:

$$\log\left(\frac{1}{\gamma}-1\right) = 0.6 - \frac{(1000\ \mathrm{K}/T)+1}{C}. \tag{47}$$

Here, T is the absolute temperature. The quantity C depends on the molar mass of the gas (He: $C = 50$, H_2O: $C = 3.6$, air: $C = 2.8$).

The surface roughness of the particles can be estimated with the help of, e.g., REM-pictures. Schlünder [2] uses $\delta = 0$ for glass, polymeric, and metallic particles, whereas Mollekopf [5] applies a value of $\delta = 2.5$ µm for particles made of aluminum silicate.

4.2 Thermal Conductivity of Wet Packed Beds in Inert Gas Atmosphere

Based on Krischer [8], see also ◉ Subchap. D6.3, Tsotsas and Schlünder [6] have proposed to calculate the thermal conductivity λ_p of partially wet porous particles in the presence of inert gas by series and parallel combination of the resistances of all possible paths of heat transfer according to the equations:

$$\lambda_l = (1-\psi_p)\lambda_s + \psi_l\lambda_l + b\,(\psi_p-\psi_l)\,(\lambda_g+\lambda_{diff}) + (1-b)\,(\psi_p-\psi_l)\,\lambda_g, \tag{48a}$$

$$\lambda_{ll} = \left[\frac{1-\psi_p}{\lambda_s}+\frac{\psi_l}{\lambda_l}+\frac{b\,(\psi_p-\psi_l)}{\lambda_g+\lambda_{diff}}+\frac{(1-b)\,(\psi_p-\psi_l)}{\lambda_g}\right]^{-1}, \tag{48b}$$

$$\lambda_p = \left(\frac{1-a_p}{\lambda_l}+\frac{a_p}{\lambda_{ll}}\right)^{-1}, \tag{48c}$$

$$b = 1-\left(1-\frac{X}{X_S}\right)^9, \tag{49}$$

$$\psi_l = (\rho_p/\rho_l)X. \tag{50}$$

The symbols mean:

λ_s	thermal conductivity of the solid phase,
λ_l	thermal conductivity of the liquid,
λ_g	thermal conductivity of the gas,
λ_{diff}	thermal conductivity by evaporation, diffusion, recondensation (heat pipe effect),
ψ_p	particle porosity,
ψ_l	volumetric fraction of liquid in particles,
X_S	saturation moisture content (can be different from X_0),
ρ_p	particle density,
ρ_l	liquid density.

The parameter b in Eq. (49) defines empirically the ratio of pore volume contained between wet pore walls to the total pore volume. The proportion of series combination in the overall resistance scheme is denoted by a_p. A value of a_p = 0.075 can be recommended for capillary porous particles with ψ_p = 0.30–0.40.

No liquid or solid are present in the voids of the bed, but the mechanism of evaporation, diffusion, and recondensation can still work transporting heat from wet to dry patches of the surfaces of adjoining particles. Therefore, the thermal conductivity in the voids of the bed can be approximated by

$$\lambda_H = \left(\frac{1-a_H}{\lambda_l}+\frac{a_H}{\lambda_{ll}}\right)^{-1}, \tag{51a}$$

with

$$\lambda_l = b\,(\lambda_g+\lambda_{diff})+(1-b)\,\lambda_g, \tag{51b}$$

$$\lambda_{ll} = \left(\frac{b}{\lambda_g+\lambda_{diff}}+\frac{1-b}{\lambda_g}\right)^{-1}. \tag{51c}$$

For packed beds, a value of a_H = 0.20 can be used (◉ Subchap. D6.3).

The thermal conductivity of the wet bed in inert gas atmosphere $\lambda_{bed,wet}$ is calculated by combining λ_p and λ_H according to the model of Zehner, Bauer, and Schlünder, as described in ◉ Subchap. D6.3. Doing so, λ_H should be put in place of fluid thermal conductivity λ_f.

For the thermal conductivity λ_{diff}, it holds

$$\lambda_{diff} = \frac{\delta}{\tilde{R}^2 T^3} \frac{p_S}{[1-(p_s/p)]} \Delta\tilde{h}_v^2, \tag{52}$$

where p is the total pressure and $\Delta\tilde{h}_v$ is the molar evaporation enthalpy. In case of water and air, the Antoine equation

$$p_S(\text{Pa}) = \exp\left[23.462 - \frac{3,978.205}{233.349 + \vartheta(^\circ\text{C})}\right] \tag{53}$$

and the correlation

$$\delta(\text{m}^2\,\text{s}^{-1}) = \frac{2.252}{p\,(\text{Pa})} \left(\frac{T(\text{K})}{273}\right)^{1.81} \tag{54}$$

can be used in order to calculate the saturation pressure p_S and the binary diffusion coefficient in the gas phase δ, respectively. The mechanism of evaporation, diffusion, and recondensation, which is expressed in the thermal conductivity λ_{diff}, depends strongly on temperature, so that very large (at the limit infinite) values of λ_{diff} are obtained when the boiling point of the liquid at the prevailing total pressure is approached (see Eq. (52)). Consequently, λ_p, λ_H, and $\lambda_{bed,wet}$ are also strong functions of temperature [9]. The same quantities depend additionally on moisture content X. For $X > 0$, it is always $\lambda_{bed,wet} > \lambda_{bed,dry}$, whereas the thermal conductivity of the dry bed $\lambda_{bed,dry}$ results at $X = 0$.

One further method for calculating $\lambda_{bed,wet}$ has been reported in [10]. In case of particles much different from the capillary porous structure with $\psi_p = 0.30$–0.40, $\lambda_{bed,wet}$ should be measured. The apparatus described in [10] can be used to this purpose.

4.3 Mixing Number

The mixing number N_{mix} must be gained by fitting to experimental data. Mollekopf [5] recommends for free-flowing products the empirical correlation

$$N_{mix} = C\text{Fr}^x, \tag{55a}$$

with

$$\text{Fr} = \frac{(2\pi n)^2 D}{2g}. \tag{55b}$$

Here, n is the revolution frequency of the shaft of the stirrer or of the drum, D is the diameter of the apparatus, and g is the acceleration of gravity. The quantities C and x depend on the type of apparatus used. Mollekopf [5] evaluated vacuum contact drying experiments in two tray dryers (D = 240 and 400 mm), two paddle dryers (D = 134 and 506 mm), and one rotary drum dryer (D = 340 mm), obtaining the following results:

Tray dryer	$C = 25$, $x = 0.2$,
Paddle dryer	$C = 9$, $x = 0.05$,
Rotary drum dryer	$C = 16$, $x = 0.2$.

Only experiments in the tray dryer with D = 240 mm stem from Mollekopf himself, the other results originating from less well-documented industrial data. Therefore, the use of these correlations should be precautious. Another reason for precaution is that N_{mix} may additionally depend on moisture content or temperature in case of cohesive or agglomerating materials. Consequently, values of N_{mix} should be controlled by comparison of a few full-scale experiments with the model whenever possible. A scheme that may be used in order to derive N_{mix} for new products on the basis of lab-scale experiments, when data with a reference product are available at both the laboratory and the production scale, is described in [11]. Coarse first estimates for processing of free-flowing particulate material in contact equipment may be obtained with a value of $N_{mix} = 10$.

5 Extensions and Applications

In case of equipment heated by steam or oil, an additional resistance, $1/\alpha_o$, exists at the heating medium side. This resistance can be accounted for by serial combination with the contact resistance $1/\alpha_{WS}$:

$$1/\alpha'_{WS} = 1/\alpha_o + 1/\alpha_{WS}. \tag{56}$$

Heat conduction in the wall has been neglected in Eq. (56). The value of α'_{WS} should replace α_{WS} in all calculations. Additionally, the driving temperature difference should be set to $\vartheta_o - \vartheta_{bed}$ (instead of $\vartheta_W - \vartheta_{bed}$), where ϑ_o is the temperature of the heating medium.

In some applications, dry, fine-grained particles glide across bundles of heating tubes at relatively small filling grades of the apparatus. Modifications of the models from Sect. 2 for such applications have been proposed in [12].

An application of the vacuum contact drying model to pasty material has been discussed in [13]. The same model has been extended in order to take hygroscopic interactions between moisture and the solids into account [14, 15]. In this case, the bed depicted schematically in Fig. 8 contains both free and bound moisture with the contents X_f and X_h, respectively. Whereas the invading drying front removes the free moisture completely, temperature increase behind the front will cause some part of bound moisture to evaporate. This can be considered by an effective specific heat capacity of the bed according to the definition

$$c_{bed,h} = c_{bed,dry} + c_l X_h - \Delta h_{v,h} (\partial X_h / \partial \vartheta)_p. \tag{57}$$

Here, $\Delta h_{v,h}$ is the evaporation enthalpy of bound moisture and $(\partial X_h/\partial\vartheta)_p$ is the slope of the sorption isobar. All equations of Sect. 3.1 can still be applied by using $c_{bed,h}$ in place of $c_{bed,dry}$ and X_f in place of X. The decrease of free moisture content and the change of bed temperature during a certain stagnant period are calculated by Eqs. (28) and (29), respectively. The decrease of bound moisture content is then obtained from the change of bed temperature and the isobar slope. Beds without free moisture can be treated by putting $c_{bed,h}$ instead of $c_{bed,dry}$ in the equations of Sect. 2.

Michaud et al. [16, 17] investigate vacuum contact drying of crystalline materials in both stagnant and mechanically agitated beds, where the agitation may be either continuous or intermittent. In this application, which is important for the treatment of

active pharmaceutical ingredients, the particles are compact, so that the liquid phase is located in the voids of the bed and possesses some mobility. The respective extension of the penetration model [16, 17] is especially important for stagnant beds (compare with [18]). The absence of stirring prolongs the drying process significantly, but may be necessary in case of fragile crystals. Notice that the equations of Sect. 3.1 can be immediately applied to stagnant beds when the moisture is immobile, the entire process being just one stagnant period. Calculated curves of this kind are included in Figs. 8 and 10. Quasi-stationary approximations, which are simpler than the exactly solved penetration model, are presented in [16, 17], but also in [15].

Vacuum contact drying of beds composed of two or more size fractions is discussed in [15, 19]. Should the different size fractions be evenly distributed in space, then the equations of Sects. 2 and 3 of this chapter may be applied. Concerning properties, the thermal conductivity of the bed should be calculated with the (lower) porosity of the poly-dispersed packing (Subchap. D6.3). The only information available about the contact resistance under such circumstances is based on simulation results which indicate that the overall value of $1/\alpha_{WS}$ might be close to the value for the finest size fraction [15]. However, stochastically homogeneous multi-component beds are rare in practice, especially when mechanical agitation is applied. In such cases, segregation upon particle size is usually observed. Since the segregation patterns depend on apparatus geometry, modelling must also be specific to certain types of equipment. Such a model has been developed in [19] for vacuum contact drying of binary mixtures in tray dryers, assuming complete segregation with the fine fraction at the bottom and the coarse fraction at the top.

The evaluation of atmospheric contact drying in [6] is based on heat transfer coefficients α_g (Eqs. (40) and (42)) for free convection between the surface of the bed and the ambient gas between 9 and 11.5 W m^{-2} K^{-1}. These values are higher than from a flat plate, due to the rough surface of particle beds. The same effect is discussed in [20], where equations for α_g in aerated rotary drums with and without lifters are given. A further application of the penetration model to atmospheric contact drying can be found in [21].

Rate and selectivity during contact drying of particles loaded with binary liquid mixtures have been discussed extensively in [20, 22–24] for both vacuum and atmospheric conditions. A favorable selectivity is necessary for, e.g., the retention of desired volatiles in foods. It may be reached either by manipulation of operating parameters, such as the composition of inlet gas in the atmospheric case [23], or by combination with membranes [24]. Upgrades of the penetration model describe the contact drying process properly [20, 22].

Finally, it should be noticed that intra-particle mass transport kinetics do not appear in the presented contact drying models, the drying process being considered as either exclusively (vacuum mode) or mainly (atmospheric mode) controlled by heat transfer to the bed. This contrasts the usual treatment of convective drying, which is an upscale of single-particle drying curves to industrial equipment. In spite of ample evidence for validity of the contact drying modelling approach, exceptions are possible in case of either very large particles or of products with very high internal diffusion resistances. Another case of significance of mass transport is freeze drying, where the permeability for vapor flow through the still wet part of the packing may be important and even lead to inverse propagation of the drying front. The drying front always moves from top to bottom (against the direction of heat supply) during contact drying of frozen solutions of pharmaceuticals in vials [25], because the emerging vapor would, otherwise, not be able to escape.

6 Remarks on Discrete Models

The entire previous discussion has been based on the penetration model, which is – in spite of correction by the contact heat transfer coefficient (compare with Sect. 5 of Subchap. D6.3) – a continuous approach. A clear disadvantage of the penetration model is that the motion of particles in agitated beds is not described on first principles, but lumped in the mixing number. Therefore, first efforts toward discrete modelling by the thermal discrete element method (thermal DEM) have been undertaken recently [11, 26, 27]. The results show that the mechanical part of the problem (mixing of identical, but virtually segregated particles in a rotary drum) can be described realistically [26]. As to the thermal part (heat transfer from the wall of the drum to the bed without sinks), the behavior of thermal DEM results is similar to the behavior of the data of Fig. 3 in case of a stagnant bed, and similar to the behavior of the data of Fig. 4 in case of mechanical agitation. However, the penetration of heat to mechanically agitated beds was found to be quantitatively much better than expected [11, 27]. This finding may have various reasons [11] and shows – along with still very high computational times – that thermal DEM is not yet mature for practical use. However, a fast further development can be expected, due to the potential of the method to couple the mechanical with the thermal part of the problem and to provide distributions of significant product properties.

7 Examples

Example 1

The contact, wall-to-bed heat transfer coefficient α_{WS} shall be calculated as a function of pressure for the following cases:
(a) Air, $d = 0.1$ mm, $\delta = 0$; (b) air, $d = 1$ mm, $\delta = 0$; (c) air, $d = 1$ mm, $\delta = 2.5$ µm; (d) helium, $d = 1$ mm, $\delta = 0$.
Given values: $\varphi = 0.8$, $\varepsilon_W = \varepsilon_{bed} = 0.9$, $\vartheta = 60°C$.
Constants: $\sigma = 5.67 \cdot 10^{-8}$ W m^{-2} K^{-4}, $\tilde{R} = 8.314$ J mol^{-1} K^{-1}.
Gas properties: Air: $\tilde{M} = 28.96$ kg kmol^{-1}, $c_{P,g} = 1{,}009$ J kg^{-1} K^{-1}, $\lambda_g = 0.02894$ W m^{-1} K^{-1};
Equation (47) → $\gamma = 0.871$, Eq. (46) → $l = 0.03359/p$ (p in Pa, l in m).
Helium: $\tilde{M} = 4.00$ kg kmol^{-1}, $c_{P,g} = 5{,}200$ J kg^{-1} K^{-1}, $\lambda_g = 0.161$ W m^{-1} K^{-1};
Equation (47) → $\gamma = 0.232$, Eq. (46) → $l = 0.61503/p$ (p in Pa, l in m).

From Eqs. (45a–d), it follows:

α_{WS} in W m^{-2} K^{-1}				
p in Pa	A	B	C	D
10^5	3751.3	591.3	396.4	1791.8
10^4	1813.8	381.3	332.0	771.2
10^3	492.3	187.5	182.2	175.2
10^2	72.6	55.4	55.1	27.2
10^1	13.7	13.4	13.4	8.9

Example 2

Wheat shall be preheated in the first stage of a dryer for cereals. To this purpose, the wheat is gliding along a bank of heating elements (140 heating elements in four rows, Fig. 15). Calculate the outlet temperature of the wheat bed $\vartheta_{bed,out}$.

Inlet temperature of wheat: $\vartheta_{bed,in} = 15°C$.

Material properties of the bed of wheat particles: $\rho_{bed} = 800$ kg m^{-3}, $\lambda_{bed} = 0.2$ W m^{-1} K^{-1}, $c_{bed} = 1{,}800$ J kg^{-1} K^{-1}.

Throughput: $\dot{M} = 30{,}000$ kg wheat per hour.

Total residence time: $t_{total} = 500$ s.

Surface temperature of the heating elements: $\vartheta_W = 100°C$.

Heat transfer surface area per heating element: $A = 0.5$ m^2.

Assumptions

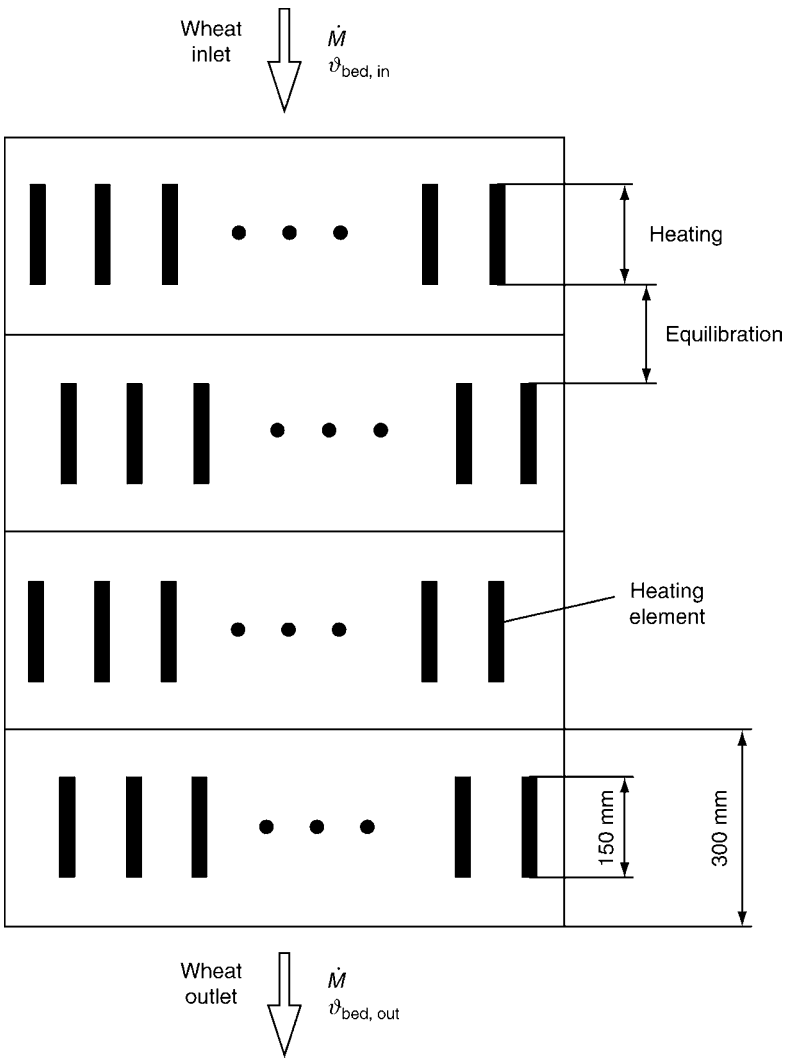
- Mass flow (plug flow of the solids) with a constant gliding velocity.
- No drying during preheating.
- The pre-heater may be subdivided to contact zones and thermal equilibration zones (Fig. 15). Temperature profiles are completely levelled out in the equilibration zones.
- The wheat particles can be approximated by spheres with $d = 2$ mm and $\delta = 0$ for calculating α_{WS}.

The contact heat transfer coefficient α_{WS} is calculated at approximately $(\vartheta_W + \vartheta_{bed,in})/2 \approx 60°C$. From Example 1 with $p = 10^5$ Pa $\rightarrow l = 3.36 \cdot 10^{-7}$ m.

Equations (45c, d) with $\varepsilon_W = \varepsilon_{bed} = 0.9$, $T = 333$ K $\rightarrow \alpha_{rad} = 6.9$ W m^{-2} K^{-1}.

Equation (45b) $\rightarrow \alpha_{WP} = 405.3$ W m^{-2} K^{-1}.

Equation (45a) with $\varphi = 0.8 \rightarrow \alpha_{WS} = 331.1$ W m^{-2} K^{-1}.



M6. Fig. 15. Schematic representation of the preheating stage of the cereal dryer of Example 2; the apparatus is completely filled with product.

Residence time per heating element: $t = t_{total}/8 \rightarrow t = 62.5$ s.
Equation (5) $\rightarrow \alpha_{bed} = 76.6$ W m^{-2} K^{-1}.
Equation (4) $\rightarrow \alpha = 62.2$ W m^{-2} K^{-1}.
Heat balance for the wheat bed per row of heating elements (subscript $i = 1$–4):

$$\Delta T_{bed,i} = \frac{\alpha(\vartheta_W - \vartheta_{bed,i})A_i}{\dot{M} c_{bed}}.$$

With $A_i = 35$ $A \rightarrow A_i = 17.5$ m^2, it follows: $\Delta\vartheta_{bed,1} = 6.2$ K, $\Delta\vartheta_{bed,2} = 5.7$ K, $\Delta\vartheta_{bed,3} = 5.3$ K, $\Delta\vartheta_{bed,4} = 4.9$ K, and $\vartheta_{bed,out} = 37.1$°C.

Example 3

Free-flowing particulate material shall be contact-dried in pure vapor atmosphere (vacuum).
Apparatus: Batch tray dryer with $D = 240$ mm, $\varepsilon_W = 0.9$.
Particles: Ceramic spheres, $d = 1$ mm, $\delta = 2.5$ µm, $\varepsilon_{bed} = 0.9$, $\rho_{bed,dry} = 1{,}000$ kg m^{-3}, $c_{bed,dry} = 800$ J kg^{-1} K^{-1}, $\lambda_{bed,dry} = 0.140$ W m^{-1} K^{-1} (calculated according to Subchap. D6.3 with $\lambda_p = 1$ W m^{-1} K^{-1} and $\vartheta = 50$°C).
Moisture: Water, $X_0 = 0.20$, $\gamma = 0.80$.
Operating parameters: $p = 2{,}000$ Pa ($\vartheta_S = 17.5$°C), $\vartheta_W = 90$°C, $n = 15$ min^{-1}, $M_{dry} = 1$ kg.
The product is initially at boiling temperature.
Calculate the drying rate for the first fictitious contact period of the penetration model.
The contact heat transfer coefficient α_{WS} is calculated at approximately $\vartheta = 50$°C.
Gas properties: $\tilde{M} = 18.01$ kg kmol^{-1}, $c_{P,g} = 1{,}907$ J kg^{-1} K^{-1}, $\lambda_g = 0.0212$ W m^{-1} K^{-1}.
Equation (46) $\rightarrow l = 9.18 \cdot 10^{-6}$ m.
Equation (45) $\rightarrow \alpha_{WS} = 200.8$ W m^{-2} K^{-1}.
Equation (55b) $\rightarrow$ Fr $= 0.0302$.
Equation (55a) with $C = 25$ and $x = 0.2 \rightarrow N_{mix} = 12.4$.
Equation (12) $\rightarrow t_R = 49.6$ s.
Equation (11) $\rightarrow \alpha_{bed,dry} = 53.6$ W m^{-2} K^{-1}.
Equation (4) $\rightarrow \alpha_{dry} = 42.3$ W m^{-2} K^{-1}.
Equation (23) with Δh_v (17.5°C) $= 2{,}460{,}000$ J kg^{-1} $\rightarrow$ Ph $= 8.483$.
Eq.(22) $\rightarrow f(\zeta) = 0.4417 - \sqrt{\pi}\zeta \exp(\zeta^2)(1 + 3.7472\, erf\, \zeta)$.
Solution: $\zeta = 0.1497 \rightarrow$ erf $\zeta = 0.1677$.
Equation (19) $\rightarrow \alpha = 123.3$ W m^{-2} K^{-1}.
Equations (26) and (27) $\rightarrow \dot{m} = 12.79$ kg m^{-2} h^{-1}.
Equation (28) with $A = \pi D^2/4 \rightarrow \Delta X = 0.00798$.
Equation (29) with $c_l = 4{,}190$ J kg^{-1} K^{-1} $\rightarrow \Delta\vartheta_{bed} = 0.27$ K.
Equation (30) $\rightarrow X_1 = 0.1920$.
Equation (31) $\rightarrow \vartheta_{bed,1} = 17.77$°C.
X_1 and $\vartheta_{bed,1}$ are input values for the second stagnant period. The entire drying curve can be calculated step-by-step on a PC.

Example 4

Free-flowing particulate material is processed in a batch tray dryer which is open to the ambient atmosphere. After some time (at $X = 0.11$), a nearly constant bed temperature is obtained. Calculate the drying rate for these quasi-steady-state conditions.

Operating parameters: $\vartheta_W = 90$°C, $n = 60$ min^{-1}, $N_{mix} = 30$, $\vartheta_g = 20$°C, $p = 10^5$ Pa, ambient relative humidity: 40%, $\alpha_g = 11.5$ W m^{-2} K^{-1} (free convection), radiation heat transfer coefficient from the free surface of the bed to the environment: $\alpha_{rad} = 5$ W m^{-2} K^{-1}.

Product: Ceramic spheres, capillary porous, loaded with water; $d = 4.4$ mm, bed porosity $\psi = 0.40$, particle porosity $\psi_p = 0.375$, $\rho_{bed,dry} = 1{,}000$ kg m^{-3}, $c_{bed,dry} = 800$ J kg^{-1} K^{-1}, solid phase thermal conductivity $\lambda_s = 10$ W m^{-1} K^{-1}, particle roughness $\delta = 2.5$ µm, emission coefficients of particles, wall and bed $\varepsilon = 0.9$.

The temperature dependence of the thermal conductivity of the partially wet bed arising from λ_{diff} (Eqs. (52), (53), and (54)) shall be taken into account. Otherwise, 60°C may be used. For the sake of simplicity, properties of dry air may be used in the gas phase.

Calculation of α_{WS}
Equation (47) with $C = 2.8$, $T = 333.15$ K $\rightarrow \gamma = 0.871$.
Equation (46) with $\tilde{M} = 28.96$ kg kmol^{-1}, $\tilde{R} = 8{,}314$ J kmol^{-1} K^{-1}, $c_{P,g} = 1{,}009$ J kg^{-1} K^{-1}, $\lambda_g = 0.0286$ W m^{-1} K^{-1} (dry air at 60°C) $\rightarrow l = 3.321 \cdot 10^{-7}$ m.
Equation (45b) $\rightarrow \alpha_{WP} = 147.291$ W m^{-2} K^{-1}.
Equations (45c, d) (60°C, $\varepsilon = 0.9$) $\rightarrow \alpha_{rad} = 6.861$ W m^{-2} K^{-1}.
Equation (45a) with $\varphi = 0.8$ (packed bed of spheres) $\rightarrow \alpha_{WS} = 124.694$ W m^{-2} K^{-1}.
The bed temperature ϑ_{bed}, which has been assumed to be constant, must be calculated iteratively. Additionally, two smaller iteration loops are necessary in order to determine the temperatures ϑ_0 and ϑ_s, because of the temperature dependence of λ_{diff}. The iterations can be carried out easily by means of, e.g., the half-step algorithm. It follows: $\vartheta_0 = 68.01$°C, $\vartheta_{bed} = 60.21$°C, and $\vartheta_s = 51.43$°C.
Here, calculations shall be presented only for the last step of the iteration.
Calculation for the free-surface side of the bed
$(\vartheta_{bed} + \vartheta_s)/2 = 55.82$°C. At this temperature, one obtains from
Equation (54) $\rightarrow \delta = 3.156 \cdot 10^{-5}$ m^2 s^{-1}.
Equation (53) $\rightarrow p_S = 16{,}393$ Pa.
Equation (52) $\rightarrow \lambda_{diff} = 0.4547$ W m^{-1} K^{-1}.
A value of $\Delta\tilde{h}_v = 42{,}521{,}610$ J kmol^{-1} ($\Delta h_v = 2{,}361{,}000$ J kg^{-1}) was used in Eq. (52), corresponding to a temperature of 60°C. From

$$\rho_p = \rho_{bed,dry}/(1 - \psi) \tag{58}$$

it follows: $\rho_p = 1666.7$ kg m^{-3}. Equation (50) must yield at $X = X_S$ (saturation) the particle porosity ψ_p. Thus, it is

$$X_S = \psi_p \rho_l \big/ \rho_p. \tag{59}$$

With $\rho_l = 983.2$ kg m^{-3} (60°C), it follows $X_S = 0.221$ and from Eq. (49), $b = 0.99795$.
Equations (51b) and (51c) for bed voids $\rightarrow \lambda_I = 0.4824$ W m^{-1} K^{-1}, $\lambda_{II} = 0.4680$ W m^{-1} K^{-1}.
Equation (51a) with $a_H = 0.20 \rightarrow \lambda_H = 0.4794$ W m^{-1} K^{-1}.
Equation (50) $\rightarrow \psi_l = 0.18647$.
Equations (48a) and (48b) with $\lambda_l = 0.6544$ W m^{-1} K^{-1} (60°C) for particles $\rightarrow \lambda_I = 6.4630$ W m^{-1} K^{-1}, $\lambda_{II} = 1.3329$ W m^{-1} K^{-1}.
Equation (48c) $\rightarrow \lambda_p = 5.0153$ W m^{-1} K^{-1}.
Equations (7a–f) from Subchap. D6.3 with $k_p = \lambda_p/\lambda_H = 10.461$, $k_{rad} = \alpha_{rad} d/\lambda_H = 0.0630$ (α_{rad} approximately at 60°C,

same value as in α_{WS}), $k_G = 1$ (Knudsen effect can be neglected), $C_f = 1.25$ (spheres), $\psi = 0.40$, flattening coefficient: 0.0077 (ceramic) $\rightarrow \lambda_{bed,wet} = 1.8245\ W\ m^{-1}\ K^{-1}$.
Equation (35) with $c_l = 4{,}184\ J\ kg^{-1}\ K^{-1}$ (60°C) $\rightarrow (\rho c)_{bed,wet} = 1{,}260{,}240\ J\ m^{-3}\ K^{-1}$.
Equation (13) $\rightarrow t_{mix} = 1$ s.
Equation (12) $\rightarrow t_R = 30$ s.
Equation (34) $\rightarrow \alpha_{bed} = 312.386\ W\ m^{-2}\ K^{-1}$.
Equation(53) for $\vartheta_S \rightarrow p_S = 13{,}261$ Pa.
From Eq. (53) at 20°C and from the given relative humidity of the ambient air (40%), it follows: $p_g = 938$ Pa.
Equation (42) with $\alpha_g = 11.5\ W\ m^{-2}\ K^{-1}$, $\tilde{M}_{H_2O} = 18.01\ kg\ kmol^{-1}$, $\tilde{M}_{air} = 28.96\ kg\ kmol^{-1}$, $c_{p,g} = 1{,}009\ J\ kg^{-1}\ K^{-1}$ (60°C) $\rightarrow \dot{m} = 0.0009416\ kg\ m^{-2}\ s^{-1} = 3.39\ kg\ m^{-2}\ h^{-1}$.
This is the requested drying rate.
Equation (40) with $\alpha_{rad} = 5\ W\ m^{-2}\ K^{-1}$ to the environment (given value) $\rightarrow \dot{q}_{um} = (11.5 + 5)\ (51.43 - 20)\ W\ m^{-2} = 518.60\ W\ m^{-2}$.
Equation (36) $\rightarrow \dot{q}_s = 312.386\ (60.21 - 51.43)\ W\ m^{-2} = 2742.75\ W\ m^{-2}$.
Equation (41) $\rightarrow \dot{q}_{lat} = 0.0009416 \cdot 2{,}361{,}000\ W\ m^{-2} = 2223.12\ W\ m^{-2}$.
Control by means of Eq. (37): $\dot{q}_s - \dot{q}_{um} - \dot{q}_{lat} = 1.03\ W\ m^{-2}$.
The fact that this value is close to zero verifies the results of the iteration loop around ϑ_s.
Calculation for the heating-plate side of the bed
$(\vartheta_0 + \vartheta_{bed})/2 = 64.11$°C. In a similar way as before one obtains $\delta = 3.302 \cdot 10^{-5}\ m^2\ s^{-1}$, $p_S = 24{,}054$ Pa, $\lambda_{diff} = 0.7130\ W\ m^{-1}\ K^{-1}$, $\lambda_H = 0.7330\ W\ m^{-1}\ K^{-1}$, $\lambda_p = 5.3148\ W\ m^{-1}\ K^{-1}$, $\lambda_{bed,wet} = 2.3115\ W\ m^{-1}\ K^{-1}$, $\alpha_{bed} = 351.612\ W\ m^{-2}\ K^{-1}$.
Control
Equation (32) $\rightarrow \dot{q}_0 = 124.694\ (90 - 68.01) = 2742.03\ W\ m^{-2}\ K^{-1}$.
Equation (33) $\rightarrow \dot{q}_0 = 351.612\ (68.01 - 60.21) = 2742.58\ W\ m^{-2}\ K^{-1}$.
Proximity between these two values verifies the closure of the lower iteration loop (around ϑ_0).
With $\vartheta_{bed} = \text{const.}$ (quasi-steady-state assumption), it is $\dot{q}_{bed} = 0$, so that it must be $\dot{q}_0 = \dot{q}_s$. This equality is fulfilled with sufficient accuracy (verification of the large iteration loop around ϑ_{bed}).
The results correspond approximately to the upper experiment of Fig. 13 (empty circles). In practice, a computer program would be used to follow the evolution of bed temperature ϑ_{bed} stepwise. The temperature dependence of material properties can easily be accounted for in such software. The properties of the gas phase should be calculated for air saturated with vapor and not for dry air, as approximately done in this example.

M7 Heat and Mass Transfer in Packed Beds with Fluid Flow

Evangelos Tsotsas
Otto-von-Guericke-Universität Magdeburg, Magdeburg, Germany

1 Introduction

A complete description of heat and mass transfer in packed beds with fluid flow means computation of velocity, concentration, and temperature fields in three dimensions (3D) with full local resolution. For this purpose, the positions and surface contours of every particle in the bed must be precisely known. Subsequent computation of the flow field is not an easy task, and the computational demand increases if mass transfer has also to be considered. Most demanding is the consideration of heat transfer in coupled heat and mass transfer problems. Treating the thermal conductivity of packings with a stagnant fluid phase in Subchap. D6.3, we have pointed out that a dilemma exists between the number of particles that can be considered and the resolution that can be attained in regions with high heat fluxes, such as the regions around particle contact points. The same dilemma applies to flow and mass transfer.

Nevertheless, fully resolved 3D computations are nowadays possible with methods of computational fluid dynamics (CFD). The classical CFD approach, which can be implemented with the help of commercially available codes, is to solve discretized forms of the conservation equations (e.g., Navier–Stokes equations for momentum transfer). Careful and critical computations have been presented for particle-to-fluid heat and mass transfer [1] and for heat transfer in the vicinity of the wall of a packed bed reactor [2]. Alternatively, the Lattice-Boltzmann (LB) method can be used. This is a cellular automata technique comparable to a certain extent with direct numerical simulation in fluid mechanics. Recent applications to isothermal packed bed reactors [3, 4], packed membrane reactors [5], and adsorbers [6] indicate advantages in computational speed. However, nonisothermal conditions pose serious challenges of conceptual, calibration, and computational nature, so that thermal LB techniques are still in the state of development [7].

Some hundreds of particles can be treated by the LB method with a resolution of some tens of voxels per particle diameter when only flow and mass transfer are taken into account. From the practical point of view, this is of interest only for narrow packed tubes with a very small ratio between tube diameter D and particle diameter d. Even if CFD develops toward significantly larger particle ensembles, other simpler models will be necessary for organizing and understanding the enormous amount of produced computational data. Such models are obtained by refraining from a precise description of local topology. Voxels are, instead, grouped together by allocating them either to the particle or to the fluid phase, whereby the volumetric fraction of the fluid phase is described by local porosity. In a packed tube, this kind of smoothening is conducted in a natural way by averaging over the circumferential coordinate, which gives rise to two-dimensional (2D) models. However, loss of microscale features means that transport phenomena cannot be treated on first principles. They have to be approximated by introducing transport coefficients in analogy to Fickian or Fourier kinetics. Dispersion coefficients and effective thermal conductivities are transport coefficients of this kind. Their task is to capture, . . . , at least in the fluid phase – both molecular and flow-dependent transport mechanisms. If the distinction between the phases is preserved, we talk about two-phase models. However, this distinction can also be abandoned by regarding state variables as local averages between the phases. Respective models are called quasi-homogeneous.

Quasi-homogeneous models are most common in practical use and well supported by comparison with experimental data. Therefore, after some discussion on porosity and flow in

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_56,

the following subsections, two models of this kind – the $\Lambda_r(r)$-model and the α_w-model – are treated in detail.

2 Bed Porosity

It is known from the extrapolation of experimental results that infinitely extended, random packed beds made of equally sized spheres have porosities (void fractions) between $\psi_\infty = 0.36$ and 0.42. The range from $\psi_\infty = 0.36$ to 0.38 is occupied by the relatively dense packed beds that can be obtained by shaking the respective container. Without this kind of compaction, the packed beds remain rather loose – with porosities of $\psi_\infty =$ 0.40–0.42. For comparison, regular (ordered) packings of equally sized spheres have porosities between $\psi_\infty = 0.259$ (cubic face-centered or densest hexagonal arrangement) and $\psi_\infty = 0.476$ (simple cubical packing). For dense, random beds of cylinders with $d \approx l$ (d: diameter, l: length) it is $\psi_\infty = 0.25$–0.35. Loose beds of this kind have approximately the same porosity as the beds of spherical particles. Porosity decreases moderately at $d/l > 1$, and increases significantly at $d/l < 1$ [8]. Packings of Raschig rings have approximately the same "external porosity" as packings of full cylinders of equal size. By taking additionally the inner porosity of the rings into account, the total porosity of the bed can be calculated. Increased void fractions are observed with fine powders ($d < 100$ µm) because of repelling interparticle forces.

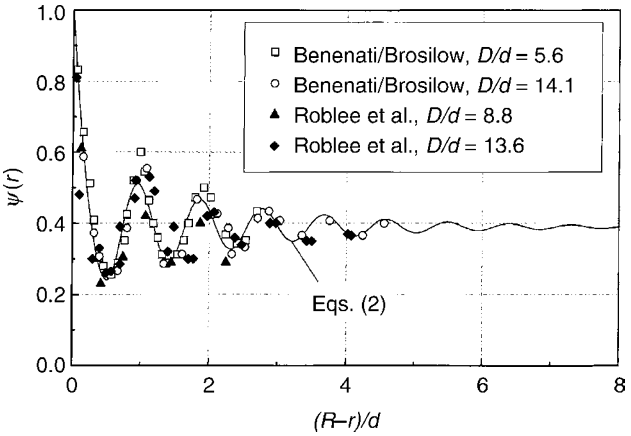
Packed beds made of particles with a broad size distribution are always less porous than monodispersed packed beds. In case of spherical particles, approximate calculations can be performed with the empirical equation [9]

$$\psi_{pd}/\psi_\infty = -0.112\ \zeta^3 + 0.017\ \zeta^2 - 0.259\ \zeta + 1. \qquad (1)$$

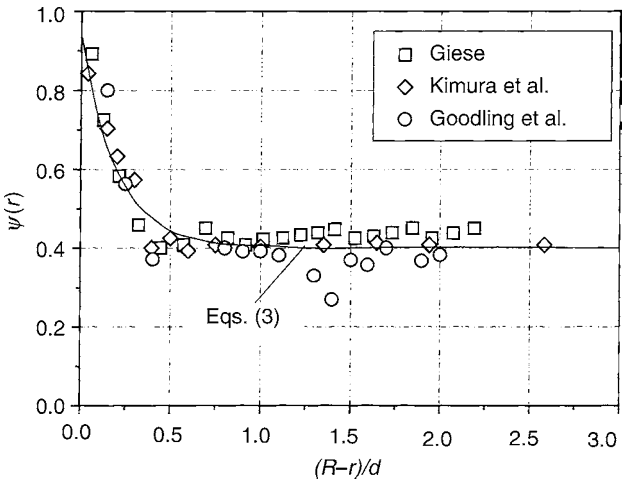
Here, ψ_{pd} is the porosity of the random polydispersed packing of spheres; ψ_∞ is the porosity of the respective monodispersed packing, as previously explained. The parameter ζ can be calculated from the particle size distribution according to Eq. (8) of Subchap. D6.3.

Apart from experiments, various packing algorithms can also be used in order to investigate phase distribution and porosity [10–12]. Both the real and the simulated packed beds show that the presence of a rigid wall disturbs seriously the randomness of the packing. This gives rise to porosity profiles such as those depicted exemplarily in Figs. 1 and 2. Consequently, the porosity of packed beds made of equally sized, smooth spheres decreases steeply with increasing distance from the wall to reach a pronounced minimum after approximately half of a particle diameter. Periodic oscillations are observed at longer distances. These oscillations are damped and vanish after some particle diameters. The precise position of the first minimum, the wavelength, and the decline of amplitude depend for $D/d > 5$ only weakly on the ratio between the tube and particle diameters (Fig. 1).

Oscillations are not very pronounced in case of the relatively rough, not perfectly spherical and not exactly monodispersed particles which are typical in practice. For such particles, the porosity decreases almost monotonously, approaching ψ_∞ after a rather short distance. Particles of irregular shape and polydispersed packings of spheres show the same behavior (Fig. 2).



M7. Fig. 1. Radial porosity profiles in tubes packed with almost perfect spheres; Measurements from [65, 66], calculation after Eq. (2) [13] for $D/d = 16$, $\psi_\infty = 0.39$.



M7. Fig. 2. Radial porosity profiles in tubes packed with imperfect spheres or irregular particles. Measurements from [14] (rough, slightly nonspherical catalyst particles with $d = 6 \pm 1$ mm), from [67] (crashed material), and from [68] (polydispersed spheres); calculations after Eqs. (3) [14].

Similarly, only weak oscillations of bed porosity are observed with Berl saddles or Raschig rings.

The porosity profile in circular tubes filled with smooth spheres of equal size can be calculated by the semiempirical equations proposed by Bey and Eigenberger [13] as follows:

$$r^* < 0 \Rightarrow \psi(r) = \psi_{min} + (1 - \psi_{min})\, r^{*2}, \qquad (2a)$$

$$r^* \geq 0 \Rightarrow \psi(r) = \psi_\infty + (\psi_{min} - \psi_\infty) \exp(-r^*/a_1) \cos(\pi r^*/b_1) \qquad (2b)$$

with

$$r^* = [(R - r)/x_{min}] - 1, \qquad (2c)$$

$$x_{min} = 0.5d\left(\frac{D}{d} - \sqrt{\left(\frac{D}{d} - 1\right)^2 - 1}\right) \qquad (2d)$$

and

$$\psi_{\min} = 0.24, \tag{2e}$$

$$a_1 = 4, \tag{2f}$$

$$b_1 = 0.876 \tag{2g}$$

($R = D/2$: tube radius).

While Eq. (2) considers the mentioned oscillation, simpler relationships are also capable of capturing the main feature of any porosity profile, namely the increase of void fraction in the immediate vicinity of the wall. Giese [14] proposed for this purpose the exponential function

$$\psi(r) = \psi_\infty \left(1 + a_2 \exp\left[-b_2 \frac{R - r}{d}\right]\right) \tag{3a}$$

with

$$a_2 = 1.36, \tag{3b}$$

$$b_2 = 5 \tag{3c}$$

and

$$\psi_\infty = 0.40. \tag{3d}$$

This function agrees well with the data of Fig. 2 and is a good choice for practical calculations with spherical particles in general. The porosity at the wall is $\psi(r = R) = 0.94$ and $\psi(r = R) = 1$ according to Eqs. (3a, b) and (2a, c), respectively. The latter value corresponds to ideal point-contacts.

From the foregoing discussion it is evident that average porosity in a packed tube depends on the ratio D/d. The function $\psi(D/d)$ can be predicted for equally sized spheres and $D/d < 1.86$ from geometrical considerations. In the range $1.86 < D/d < 2$ different packing arrangements are possible, so that only an upper bound and a lower bound of bed porosity can be derived deterministically [15, 16]. As a consequence, significant scattering is obtained in practice upon repacking. Such scattering is typical for diameter ratios up to $D/d \approx 4$ and is enhanced additionally by differences in particle size. Irrespective of this effect, quite reliable values of $\psi(D/d)$ can be calculated at $D/d > 2$ by integration of the porosity profiles according to Eqs. (2a, b) and (3a) from $r = 0$ to $r = R$. Similar results are obtained for monodispersed packings of spheres from the empirical relationship

$$\psi = \psi_\infty + (1 - \psi_\infty)\frac{0.526}{D/d}, \tag{4}$$

which has been derived by Sonntag [17]. Sonntag proposes for cylinders and Raschig rings,

$$\psi = \psi_\infty + (1 - \psi_\infty)\frac{0.480}{D/d}. \tag{5}$$

Here, d is the diameter of a sphere of equal volume to the particle. The average porosity ψ – and not the porosity ψ_∞ of an infinitely extended bed – should be used when calculating the pressure drop in packed beds.

3 Flow

Because of very short inlet and outlet transition regions, flow in a circular packed tube can usually be considered one-dimensional. It can be calculated with the help of the extended Brinkman equation

$$\frac{\partial p}{\partial z} = -f_1 u_0(r) - f_2[u_0(r)]^2 + \frac{\eta_{\text{eff}}}{r}\frac{\partial}{\partial r}\left(r\frac{\partial u_0(r)}{\partial r}\right). \tag{6}$$

The first two terms on the right-hand side of this equation account for pressure drop due to the particles. The third right-hand side term expresses the influence of friction in the vicinity of the wall by means of an effective viscosity η_{eff}.

For imperfect spheres – typical of many practical applications – the equations of Ergun

$$f_1 = 150\frac{[1 - \psi(r)]^2}{[\psi(r)]^3}\frac{\eta_f}{d^2}, \tag{7a}$$

$$f_2 = 1.75\frac{[1 - \psi(r)]}{[\psi(r)]^3}\frac{\rho_f}{d}, \tag{7b}$$

can be applied in combination with local values of porosity $\psi(r)$ from Eq. (3). Viscosity and density of the fluid are denoted by η_f and ρ_f, respectively. The effective viscosity can be calculated according to Giese et al. [18] as

$$\eta_{\text{eff}}/\eta_f = a_3 \exp(b_3 \text{Re}_o), \tag{8}$$

with

$$a_3 = 2.0, \tag{9a}$$

$$b_3 = 2.0 \cdot 10^{-3}. \tag{9b}$$

Herein, the Reynolds number

$$\text{Re}_o = u_0 d/\nu_f \tag{10}$$

is defined with the average value of superficial velocity over the entire cross section of the tube, u_0; (ν_f: kinematic viscosity, $\nu_f = \eta_f/\rho_f$). Giese et al. [18] derived for perfect spheres,

$$a_3 = 2.0, \tag{11a}$$

$$b_3 = 3.5 \cdot 10^{-3}. \tag{11b}$$

In this case, the still applicable Eq. (7) must be combined with porosity profiles from Eq. (2). Equation (6) can be solved numerically with the boundary conditions

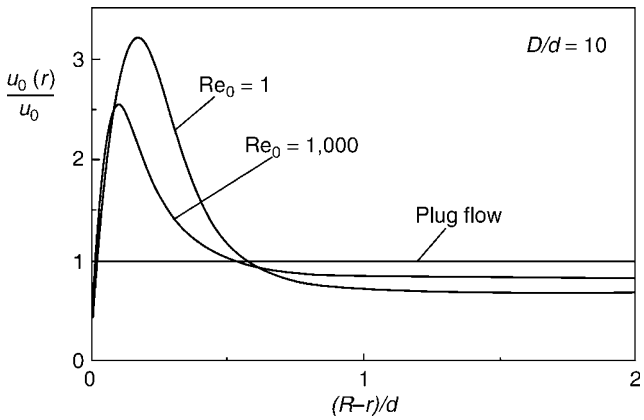
$$r = 0 \;\Rightarrow\; \partial u_0/\partial r = 0, \tag{12a}$$

$$r = R \;\Rightarrow\; u_0 = 0, \tag{12b}$$

at the axis and the wall of the tube.

Pressure drop for particles of other than spherical shape or for annular packed beds is discussed in [11, 19, 20]. Though the use of alternative correlations from Subchap. L1.6 for f_1, f_2 is in principle possible, their usage is still rare. Alternative concepts for the pressure drop calculation can be found in [21, 22]. A computational comparison between the influence of increased porosity in the vicinity of the wall and the influence of wall friction on pressure drop has been presented in [23].

Neglecting both wall friction and the dependence of local porosity on the radial coordinate [i.e., setting $\psi(r) = \psi$ for every r], leads to the limiting case of constant superficial velocity over the entire cross section of the tube [$u_0(r) = u_0$ for every r]. The mistake inherent in this popular approximation of "plug flow" is illustrated in Fig. 3, with velocity profiles calculated by Eqs. (6)–(10), and (12). The profiles show that the through



M7. Fig. 3. Macroscopic flow maldistribution in packed tubes; profiles calculated with Eqs. (6), (7)–(10), (12) for $D/d = 10$.

put at the margin of the bed is larger and in the middle of the tube, smaller than in case of plug flow. The nonslip boundary condition is fulfilled at the wall. This behavior, which is more pronounced at small Reynolds numbers, can be described as macroscopic flow maldistribution [24]. One modern possibility to prove the existence of macroscopic flow maldistribution and to measure radial velocity profiles is laser Doppler anemometry (LDA) [14, 18], the other is nuclear magnetic resonance (NMR) or magnetic resonance imaging (MRI) [25, 26]. Both methods are applicable only in liquid phase. Transparent particles and an adaptation of the refraction index of the liquid to that of the particles are additionally necessary for LDA. LDA measurements from [14, 18] are the origin of the presented equations.

Flow fields, which are two- or three-dimensional at the macroscopic level, may occur in packed beds because of changing cross section of the conduit, obstacles, fluid feed from the side, strong change of fluid properties with temperature, etc. Respective calculations can be conducted with extended (vectorial) versions of Eq. (6) [6].

Apart from macroscopic flow maldistribution, the terms of microscopic and mesoscopic flow maldistributions have also been introduced in [24]. Microscopic flow maldistribution refers to individual voids, and is caused by changing void contour and the nonslip boundary condition at the surface of particles. Mesoscopic flow maldistribution appears due to the formation of relatively dense clusters in the interior of beds packed with small particles. With such particles, ranging in diameter from about 0.5 mm down to some µm, inhomogeneities can occur even over the entire tube cross section. Therefore, good and reproducible packing is an important issue for, e.g., chromatographic columns [27]. Unfortunately, there are hardly any methods for modeling such effects till now.

4 Equations of Quasi-Homogeneous Models

As already mentioned in the Introduction, two quasi-homogeneous models, which are supported by comprehensive comparison with experimental data and frequently used in practice, are treated in more detail. These are the $\Lambda_r(r)$-model and the α_w-model.

According to the $\Lambda_r(r)$-model, heat transport and mass transport in a packed circular tube are described by the relationships

$$\left\{[1-\psi(r)]\,\rho_p c_p + \psi(r)\rho_f c_f\right\}\frac{\partial \vartheta}{\partial t} = \frac{1}{r}\frac{\partial}{\partial r}\left[\Lambda_r(r) r \frac{\partial \vartheta}{\partial r}\right] + \Lambda_{ax}(r)\frac{\partial^2 \vartheta}{\partial z^2} - u_o(r)\rho_f c_f \frac{\partial \vartheta}{\partial z} \tag{13a}$$

and

$$\psi(r)\frac{\partial y}{\partial r} = \frac{1}{r}\frac{\partial}{\partial r}\left[D_r(r) r \frac{\partial y}{\partial r}\right] + D_{ax}(r)\frac{\partial^2 y}{\partial z^2} - u_0(r)\frac{\partial y}{\partial z}, \tag{13b}$$

respectively. Here, ϑ is the temperature, y is the mass fraction or some other measure of composition, t is the time, r is the radial coordinate, and z is the axial coordinate. The subscripts p and f denote the particles and the fluid, respectively. Not only porosity and flow velocity are considered to depend on the radial coordinate [$\psi(r)$, $u_0(r)$, as previously explained] but also the effective thermal conductivities [$\Lambda_r(r)$ and $\Lambda_{ax}(r)$] and the dispersion coefficients [$D_r(r)$ and $D_{ax}(r)$]. Because the dependence of the radial effective thermal conductivity on the radial coordinate, $\Lambda_r(r)$, can be quite important, it gives the model its name. It should be noted that packed beds with fluid flow are anisotropic with respect to heat and mass transport. In the presence of, e.g., adsorption or catalytic reaction, appropriate source or sink terms must be added to the equations. Such terms couple the two equations with each other in case of significant heat release or consumption. Reaction or other kinetics should be determined separately by measurements in gradient-free ("differential") reactors or on single particles.

Apart from the trivial boundary condition at the axis of the tube, initial conditions, boundary conditions at the wall, and boundary conditions at the inlet and outlet of the bed are necessary for the numerical solution of Eqs. (13a, b). These should be selected and defined in a problem-specific way. Concerning the important thermal boundary condition at the wall, one should write in case of, e.g., a constant wall temperature ϑ_w

$$r = R \;\rightarrow\; \vartheta = \vartheta_w. \tag{14}$$

At the end of the bed (outlet) good results can be obtained either by the simple expression

$$z = L \;\rightarrow\; \partial\vartheta/\partial z = 0, \tag{15a}$$

$$\partial y/\partial z = 0 \tag{15b}$$

or, for chemical reactors, by the "softer" boundary condition

$$z = L \;\rightarrow\; \partial^2\vartheta/\partial z^2 = 0, \tag{16a}$$

$$\partial^2 y/\partial z^2 = 0. \tag{16b}$$

Sometimes it will be reasonable to account for heat fluxes by radiation or packed transitional zones at the inlet or outlet.

By assuming uniform distribution of porosity, axial velocity ("plug flow"), and effective transport coefficients over the cross section, Eqs. (13) are transformed to the equations of the α_w-model, which are

$$\left\{(1-\psi)\rho_p c_p + \psi\rho_f c_f\right\}\frac{\partial\vartheta}{\partial t} = \Lambda_r\left[\frac{\partial^2\vartheta}{\partial r^2}+\frac{1}{r}\frac{\partial\vartheta}{\partial r}\right]+\Lambda_{ax}\frac{\partial^2\vartheta}{\partial z^2}-u_0\rho_f c_f\frac{\partial\vartheta}{\partial z} \quad (17a)$$

for the heat transport and

$$\psi\frac{\partial y}{\partial t} = D_r\left[\frac{\partial^2 y}{\partial r^2}+\frac{1}{r}\frac{\partial y}{\partial r}\right]+D_{ax}\frac{\partial^2 y}{\partial z^2}-u_0\frac{\partial y}{\partial z} \quad (17b)$$

for the mass transport. Simultaneously, an artificial thermal boundary condition of the third kind is imposed at the wall:

$$r = R \quad -\Lambda_r(\partial\vartheta/\partial r) = \alpha_w(\vartheta-\vartheta_w). \quad (18)$$

This boundary condition introduces the wall heat transfer coefficient α_w that appears in the name of the model. It is the price to be paid as compensation for the simplification attained in Eqs. (17a, b) in comparison to Eqs. (13a, b). A wall mass transfer coefficient β_w can be defined, if necessary, in analogy to Eq. (18). The remaining boundary conditions, source terms and sink terms, are set in the same way as for the $\Lambda_r(r)$-model.

Both models can be expressed for nonaxisymmetric geometries by appropriate coordinate transformations. The accumulation terms may be eliminated in case of steady-state problems. However, it should be noted that certain solvers approach the steady state from transient numerical computations so that the complete equations have to be implemented. The terms for axial heat transfer and axial dispersion can be eliminated without significant loss of accuracy in many cases, but not always, because e.g., axial conduction plays an important role at small flow velocities. The same is true for reactors operated in the region of multiple reaction states.

The subsequent Sect. 5 of this chapter treats axial dispersion of heat and mass in common for both models. Important differences in the radial transport coefficients between the two models are worked out in Sects. 6 and 7. Some remarks about the validity of quasi-homogeneous approaches appear in Sect. 5 and are discussed further in Sect. 8, together with some hints about more complex models.

5 Axial Dispersion of Heat and Mass

The coefficient D_{ax} for axial dispersion of mass in Eq. (17b) can be calculated for random beds made of equally large spheres according to the equation

$$\frac{D_{ax}}{\delta} = \frac{\delta_{bed}}{\delta}+\frac{Pe_0}{K_{ax}}, \quad (19a)$$

with

$$K_{ax} = 2. \quad (19b)$$

Here,

$$Pe_0 = u_0\, d/\delta \quad (20)$$

is the so-called molecular Péclet number, u_0, and D_{ax} are averages that do not depend upon the radial position. With the help of the "effective" Péclet number

$$PE_{ax} = u_0\, d/D_{ax} \quad (21)$$

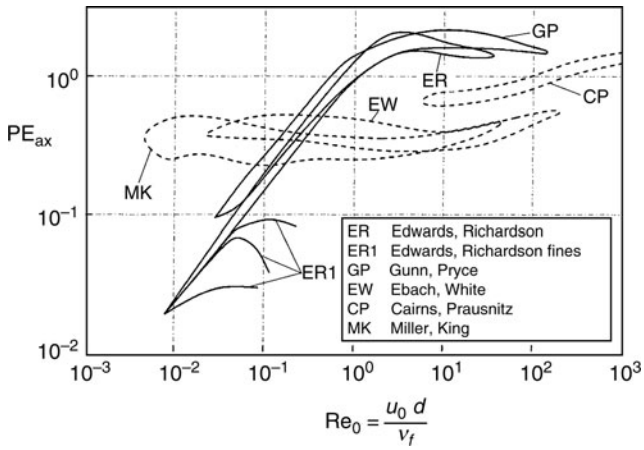
Eq. (19a) can be transformed to

$$\frac{1}{PE_{ax}} = \frac{\delta_{bed}/\delta}{Pe_0}+\frac{1}{K_{ax}}. \quad (22)$$

For $Pe_0 \to 0$, $D_{ax} = \delta_{bed}$ is obtained, which means that axial dispersion is due to diffusion. The ratio δ_{bed}/δ (δ: diffusion coefficient in the solids-free fluid phase) depends on porosity and can be calculated according to Eq. (6) from Subchap. D6.3. On the contrary, $PE_{ax} = K_{ax} = 2$ is obtained for $Pe_0 \to \infty$. At this limit the bed behaves as a cascade of ideally mixed compartments [28], and axial dispersion is caused by mixing of the fluid in the voids of the packing.

Results of respective measurements by several authors are plotted in Fig. 4 in the form of fitting curves and data regions over the Reynolds number. The latter is by definition equal to $Re_0 = Pe_0/Sc$, where $Sc = \nu_f/\delta$ is the Schmidt number. Detailed information can be found in [24]. All measurements were carried out by the transient tracer method. Particles were compact and inert with respect to the tracer. Data acquired with gases ("ER," "GP") agree well with Eqs. (22) and (19b), except for the weak maximum that the data of Fig. 4 show in the region of medium Reynolds numbers.

On the contrary, experiments conducted with liquids ("MK," "EW," "CP") show much smaller effective Péclet numbers, that means much more dispersion. It is evident that, in this case, some additional mechanism that creates axial dispersion must exist apart from diffusion and the cascade effect. According to [24], this could be a combination of microscopic flow maldistribution with lateral mass transport. The resulting axial dispersion is usually called Taylor dispersion [29]. Recent MRI measurements [30] clearly indicate the existence of significant regions with nearly stagnant liquid in packed beds, supporting the mentioned theory. Increased axial dispersion during the flow of aqueous solutions through packed beds can be of considerable



M7. Fig. 4. Axial dispersion of mass according to transient tracer experiments conducted by various authors in randomly packed beds of equally sized spheres. Full lines: Measurements with gases; Broken lines: Measurements with liquids.

importance for the design of bioseparation processes. Correlations that distinguish between liquids and gases on an empirical basis and account for the mentioned weak maximum have been presented in [31, 32].

The behavior of data gained with fine particles (data group "ER 1"with d = 0.1 to 0.2 mm in Fig. 4) can also be assigned to Taylor dispersion, though in this case to Taylor dispersion driven by mesoscopic flow maldistribution (cluster formation) [24]. On the contrary, the macroscopic velocity profiles discussed in Sect. 3 do not appear to be significantly reflected in the results of tracer experiments for axial dispersion.

Since Taylor dispersion is not genuine back-mixing, it can be observed only under transient conditions. At steady state, Eq. (19a) or Eq. (22) can be used. These equations give good results also in case of cylindrical particles, by calculating d as the diameter of a sphere of equal volume. The situation is less clear with Raschig rings, because some authors propose to still use K_{ax} = 2, whereas some others recommend values smaller by up to 50%.

Equations (19)–(22) can be applied locally – that means with the local values of porosity and flow velocity – in order to approximately calculate the function $D_{ax}(r)$ for Eq. (13b). More precise results about radial profiles of the axial dispersion coefficients are not available till now.

Heat transfer in the direction of flow can be treated similarly to mass transfer, calculating Λ_{ax} for Eq. (17a) from

$$\frac{\Lambda_{ax}}{\lambda_f} = \frac{\lambda_{bed}}{\lambda_f} + \frac{Pe_0}{K_{ax}} \tag{23a}$$

or

$$\frac{1}{PE_{ax}} = \frac{\lambda_{bed}/\lambda_f}{Pe_0} + \frac{1}{K_{ax}} \tag{23b}$$

with

$$K_{ax} = 2 \tag{23c}$$

and

$$Pe_0 = u_0 \rho_f c_f d/\lambda_f, \tag{24}$$

$$PE_{ax} = u_0 \rho_f c_f d/\Lambda_{ax}. \tag{25}$$

Similar to the calculation of $D_{ax}(r)$, Eqs. (23)–(25) can be applied locally to obtain $\Lambda_{ax}(r)$ for Eq. (13a). Equations providing the thermal conductivity of the packed bed without flow λ_{bed} have been presented in Subchap. D6.3. Remarks about the local application of such equations are given in Sect. 6.

However, axial dispersion of heat in packed tubes with fluid flow is not due to the effective thermal conductivity Λ_{ax} alone, but to a combination of heat transport in the direction of flow, heat transfer between particle surface and the fluid, and heat conduction in the particles. As several investigations show [33–35], linear combination of these three effects (expressed in the following by the quantity A) provides a good approximation for the axial dispersion of heat according to the equations:

$$A = A_1 + A_2 + A_3, \tag{26}$$

$$A_1 = \frac{(1 + K^*)^2}{Pe_0} \frac{\Lambda_{ax}}{\lambda_f}, \tag{27a}$$

$$A_2 = \frac{K^{*2} Pe_0}{Nu A_v d}, \tag{27b}$$

$$A_3 = \frac{K^{*2} Pe_o}{60\,(1-\psi)\,\lambda_p/\lambda_f}. \tag{27c}$$

In Eqs. (27)

$$K^* = \left[(1-\psi)\,\rho_p c_p\right] \Big/ \left[\psi\,\rho_f c_f\right] \tag{28}$$

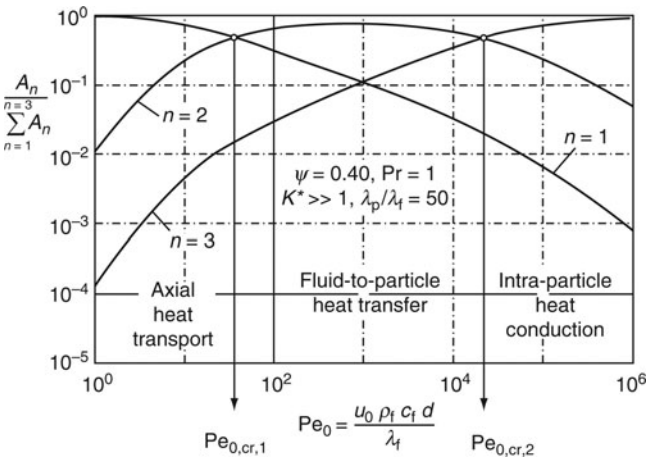
is the thermal capacity ratio and

$$Nu = \alpha d/\lambda_f \tag{29}$$

is the Nusselt number for heat transfer between the particulate (subscript: p) and the fluid (subscript: f) phase. The surface area of the packing per unit volume is denoted by A_v; (for spheres: $A_v d = 6\,(1-\psi)$).

The relative importance of the three terms of Eq. (26) changes with the molecular Péclet number Pe_0, as shown in Fig. 5, with calculations carried out at ψ = 0.40, Pr = 1, and $K^* >> 1$ (solids/gas). The ratio λ_{bed}/λ_f was obtained from Eq. (5) in Subchap. D6.3, and the Nusselt number was calculated according to Chap. G9. The intersection points of the curves define in Fig. 5 two critical Péclet numbers and three regions. For $Pe_0 < Pe_{0,cr,1}$ axial dispersion of heat is mainly due to the effective thermal conductivity Λ_{ax}. The difference between particle and fluid temperature is small, and application of the quasi-homogeneous model is well justified. On the contrary, fluid-to-particle heat transfer takes over the dominant role at $Pe_{0,cr,1} < Pe_0 < Pe_{0,cr,2}$. Temperature differences between the phases, which should be accounted for by a heterogeneous model, become significant. The same is true for $Pe_0 > Pe_{0,cr,2}$, where heat conduction in the interior of the particles prevails.

The discrimination of mechanisms according to Fig. 5 is crucial for the proper design of thermal storage equipment (regenerators) as well as for the correct identification of transport parameters from transient thermal response experiments. Derivation of Nusselt numbers from such experiments leads in the region $Pe_0 < Pe_{0,cr,1}$ to biased results. Such "apparent" Nusselt numbers deviate from the correlation of Gnielinski (Chap. G9) to lower values and tend even to zero



M7. Fig. 5. Relative contributions of axial heat transport (n = 1), fluid-to-particle heat transfer (n = 2), and intraparticle heat conduction (n = 3) to the experimentally observable axial dispersion.

at $Pe_0 \to 0$. On the contrary, reasonable results, which are in good agreement with Eq. (23a), are obtained when deriving the effective thermal conductivity Λ_{ax} from measured data in this region. An alternative, steady-state method for measuring Λ_{ax} ("back-conduction method") has been discussed in [36], among others.

6 Radial Transport Parameters of the $\Lambda_r(r)$-model

Local values of the radial (or, more general, lateral) effective thermal conductivity $\Lambda_r(r)$ (see Eq. (13a)) can be calculated for (nearly) spherical particles and gases according to Winterberg et al. [37] by means of the following equations:

$$\Lambda_r(r) = \lambda_{bed}(r) + K_1 Pe_0 \frac{u_{0,c}}{u_0} f(R-r)\,\lambda_f, \tag{30}$$

$$0 < R - r \le K_2 d \;\Rightarrow\; f(R-r) = \left(\frac{R-r}{K_2 d}\right)^n, \tag{31a}$$

$$K_2 d < R - r \le R \;\Rightarrow\; f(R-r) = 1\,, \tag{31b}$$

$$K_1 = 1/8, \tag{32a}$$

$$K_2 = 0.44 + 4\exp(-Re_0/70), \tag{32b}$$

$$n = 2. \tag{32c}$$

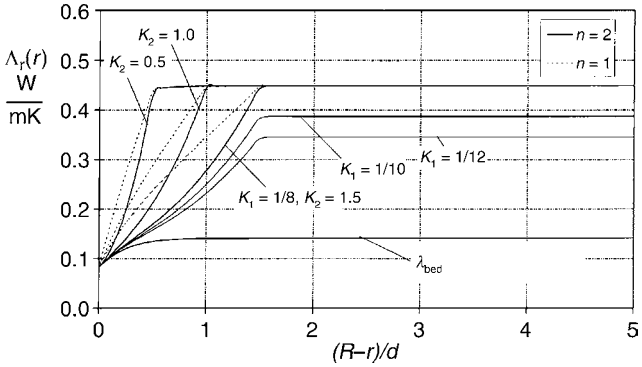
Here, Re_0 and Pe_0 are the Reynolds and the molecular Péclet numbers – defined with the average superficial flow velocity u_0 by Eqs. (10) and (24), respectively. The superficial velocity in the center of the bed, $u_{0,c} = u_0(r = 0)$, is obtained from Eqs. (6) to (10) and Eq. (12), in combination with Eq. (3). The thermal conductivity of the bed without flow is also considered to be a function of radial position $\lambda_{bed}(r)$. In order to derive this function, local values of porosity $\psi(r)$ from Eq. (3) are inserted in Eqs. (5a)–(5e) from Subchap. D6.3, so that the ratio $k_{bed}(r) = \lambda_{bed}(r)/\lambda_f$ is obtained. This ratio, which is denoted by $k_{bed,0}(r)$ for the sake of distinction, is then expanded by additive consideration of thermal radiation according to Zehner and Schlünder [38] to obtain

$$k_{bed}(r) = k_{bed,0}(r) + \left(1 - \sqrt{1-\psi(r)}\right) k_{rad} + \sqrt{1-\psi(r)}\left(\frac{1}{k_{rad}} + \frac{1}{k_p}\right)^{-1}. \tag{33}$$

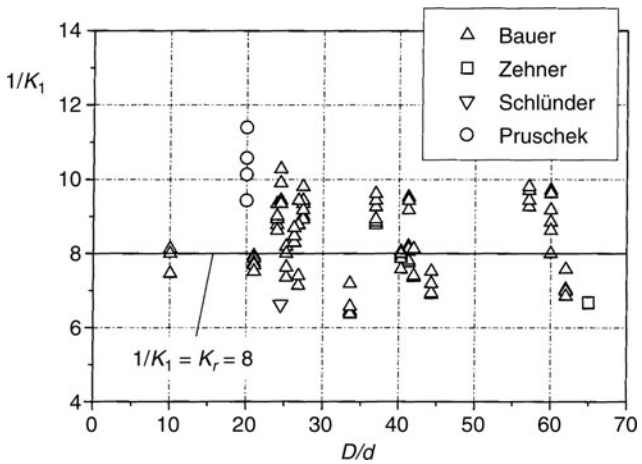
The quantities k_{rad} and k_p are defined in Eqs. (7e) and (3b), respectively, of Subchap. D6.3. The described procedure neglects in comparison to the application of Eqs. (7) from Subchap. D6.3 flattened contacts and the Knudsen effect ($\varphi = 0$ and $k_G = 1$ in Eq. (7a) and (7f) of Subchap. D6.3, respectively). Additionally, there is a difference in the consideration of radiation, which is very small at $\psi = 0.4$, but significant at the very high values of porosity that prevail in the vicinity of the wall. In case of $\varphi > 0$ or $k_G > 1$, Eq. (7) of Subchap. D6.3 should be applied with $k_{rad} = 0$. Then, the result should be inserted as $k_{bed,0}$ in Eq. (33), accounting for radiation with the value of k_{rad} from Eq. (7e), Subchap. D6.3. Data that might support a more accurate calculation of local thermal conductivity without flow in the vicinity of the wall, especially of the contribution of radiation, are not available till now.

Figure 6 illustrates the influence of the parameters K_1, K_2, and n on the profile of thermal conductivity $\Lambda_r(r)$ according to Eqs. (30) and (31). All three parameters have in common that they do not change the basis value of $\lambda_{bed}(r)$, but merely the flow dependent part of the effective thermal conductivity. The increase of this part with increasing flow velocity is defined by the "slope parameter" K_1. Onset and local extent of the inhibition caused by the wall are described by the "damping parameter" K_2 and the exponent n.

Slope parameters derived from thermal injection experiments are compared in Fig. 7 with the recommended value of $K_1 = 1/8$ (Eq. (32a), more details in [37]). In such experiments, a gas stream that has a somewhat higher temperature than the main flow is injected steadily at the axis of the packed tube. Radial profiles of temperature are measured at some position downstream. Because the wall is not reached by the thermal perturbation, such profiles are not influenced by the parameters K_2 and n. Consequently, they can be used for the separate determination of K_1. Figure 7 shows good agreement with the



M7. Fig. 6. Influence of the parameters K_1, K_2, and n on the profile of radial effective thermal conductivity according to Eqs. (30) and (31); (spherical ceramic particles in air, ambient conditions, $Pe_0 u_{0,c}/u_0 = 86$, $D/d = 10$).



M7. Fig. 7. Inverse of the recommended value of the slope parameter K_1 (Eq. (32a)) in comparison with values derived by means of the $\Lambda_r(r)$-model from data measured by various authors (thermal injection experiments, see in [37] for more details).

value $K_1 = 1/8$ or with $1/K_1 = 8$, which is denoted in the literature by K_r. The value of $1/K_1 = K_r = 8$ can be derived on first principles, by flow pattern (stream line deflection and cross-mixing due to the particles [39]) or by random walk [41] considerations. Due to this fundamental agreement, no fine-tuning of K_1 has been conducted in [37]. Independence of the slope parameter from the diameter ratio D/d (Fig. 7) is a merit of the $\Lambda_r(r)$-model. It results from the explicit consideration of porosity and flow profiles, especially of the values prevailing in the center of the tube.

The additive combination between quiescent and flow-dependent thermal conductivities becomes obvious in the limiting case of an unconfined bed. Without wall effects, Eq. (30) reduces to

$$\frac{\Lambda_r}{\lambda_f} = \frac{\lambda_{bed}}{\lambda_f} + \frac{Pe_0}{K_r} \tag{34a}$$

or

$$\frac{1}{Pe_r} = \frac{\lambda_{bed}/\lambda_f}{Pe_0} + \frac{1}{K_r} \tag{34b}$$

with

$$K_r = 1/K_1 = 8, \tag{34c}$$

$$PE_r = u_0 \rho_f c_f d/\Lambda_r \tag{35}$$

and Pe_0 according to Eq. (24). The analogy to Eq. (23) for axial dispersion of heat or Eqs. (19)–(22) for axial dispersion of mass is evident in this form – up to the different values of K_r and K_{ax}. By setting the two right-hand side terms of Eq. (34a) or (34b) equal to each other, a critical molecular Péclet number

$$Pe_{0,cr} = (\lambda_{bed}/\lambda_f) K_r, \tag{36}$$

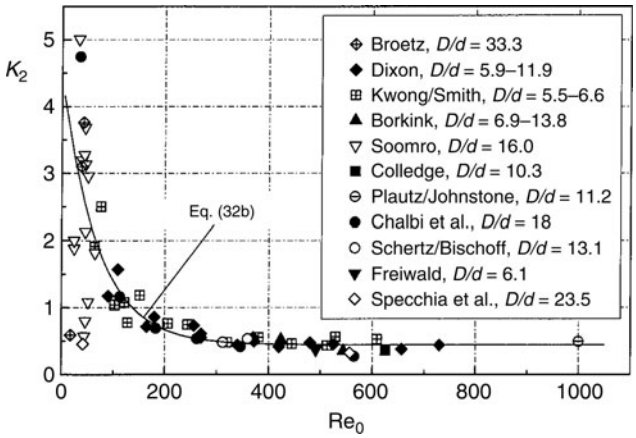
can be derived. The conduction term prevails at $Pe_0 < Pe_{0,cr}$, whereas the flow-dependent (cross-mixing) term is more important at $Pe_0 > Pe_{0,cr}$. For example, with the typical value of $\lambda_{bed}/\lambda_f = 6.25$ and $K_r = 8$, $Pe_{0,cr} = 50$ is obtained for gas-filled packed beds. However, it should be stressed that $Pe_{0,cr}$ is an orientation help, not a stability criterion.

In case of heating or cooling at constant wall temperature (Nusselt–Graetz problem), the result depends on all three model parameters K_1, K_2, and n (Eq. (32)). An exponent of $n = 2$ was found to properly describe respective data in [37]. However, this was rather a choice than an optimization, with other values having also been proposed in the literature (e.g., $n = 1$, that means a linear profile, in [42]). With fixed values for K_1 and n (Eq. (32a, c)), the damping parameter K_2 can be derived from Nusselt–Graetz data by uniparametric fitting. This provides results such as those of Fig. 8, where every point represents the evaluation of one measured temperature profile. As the plot shows, agreement with Eq. (32b) is good, and there is again no explicit dependence on the diameter ratio D/d. Equation (32b) means that the region of inhibited cross-mixing extends at high flow rates over 44% of one particle diameter, which looks like a reasonable value.

For heat transfer in liquid–particle systems a slight modification of Eq. (32b) to

$$K_2 = 0.44 + 4\exp(-Pe_0/50) \tag{37}$$

has been proposed [43].



M7. Fig. 8. Recommended values (Eq. (32b)) of the damping parameter in comparison with values derived by means of the $\Lambda_r(r)$-model from data measured by various authors (heating or cooling at constant wall temperature, more details in [37]).

Furthermore,

$$K_1 = 1/6.25, \tag{38a}$$

$$K_2 = 0.40 + 0.6\exp(-Re_0/230), \tag{38b}$$

can be recommended according to [44] for heat transfer in packed beds made of cylinders with an aspect ratio not too far from unity. As before, the diameter of a sphere of equal volume to the cylindrical particle should be used for d in this case. Equation (3a) should be applied with the parameters

$$a_2 = (0.65/\psi_\infty) - 1, \tag{39a}$$

$$b_2 = 6.0. \tag{39b}$$

Profiles of the radial mass dispersion coefficient appearing in Eq. (13b) are similar to the profiles of $\Lambda_r(r)$. They can be calculated with the help of the relationship

$$D_r(r) = \delta_{bed}(r) + K_1 Pe_0 \frac{u_{0,c}}{u_0} f(R - r)\,\delta, \tag{40}$$

where Pe_0 is the molecular Péclet number according to Eq. (20). Equations (31a) and (31b) remain the same. For imperfect spheres it still holds $n = 2$, whereas the slope parameter is obtained [37] as

$$K_1 = \frac{1}{8}\left[1 + \frac{3}{Pe_{0,c}^{0.5}}\right]^{-1}. \tag{41a}$$

Only the constant part is considered in the damping parameter, so that it is

$$K_2 = 0.44. \tag{41b}$$

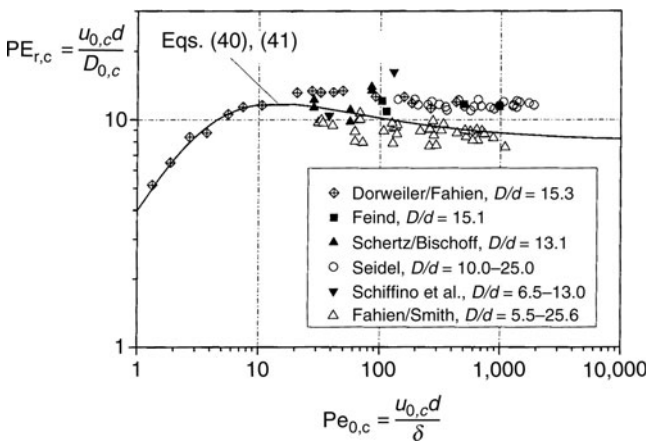
Superficial velocity in the core of the bed $u_{0,c}$ is still calculated by means of Eqs. (6)–(10), combined with Eq. (3). The respective molecular Péclet number is denoted by $Pe_{0,c}$. Local application of Eq. (6) from Subchap. D6.3 provides the ratio between effective diffusion coefficient of the packed bed $\delta_{bed}(r)$ and diffusivity δ.

The equations for radial dispersion of mass have been developed in [37] on the basis of experiments with steady-state

tracer injection at the axis of the bed. Unlike the previously discussed thermal injection, downstream profiles reach the wall, in many experiments of this kind, so that they depend not only on K_1 but also on K_2 and n. Nevertheless, the results can be presented in a similar way as in Fig. 4 – compared with Eq. (22) and (23b) – by considering the middle of the tube ($r = 0$, subscript: c) and defining correspondingly the molecular and the effective Péclet number ($Pe_{0,c} = u_{0,c}\, d/\delta$, $PE_{r,c} = u_{0,c}\, d/D_{r,c}$). In this way, Fig. 9 is obtained. This figure shows, apart from diffusion at small values and cross-mixing at large values of the molecular Péclet number, a weak transitional maximum. In absence of a satisfactory theoretical explanation, this nonlinearity has been approximated empirically in the second right-hand side term of Eq. (40a). Without such secondary considerations, the main mechanisms are the same as already discussed in connection with Eq. (34). Because δ_{bed}/δ is much smaller than the ratio λ_{bed}/λ_f, critical Péclet numbers that can be defined similarly to Eq. (36) have also relatively small values of, e.g., $Pe_{0,cr} = (\delta_{bed}/\delta)\, K_r \approx 2$ ($K_r = 1/8$ and $K_1 = 8$). Taylor dispersion is not an issue at steady state. All the same, increased radial dispersion can be occasionally observed with fine particles ($d <$ 0.5 mm, data not shown here), probably due to cluster formation (the previously discussed mesoscopic maldistribution of flow).

In total, the recommended correlations have been validated by comparison with a large database consisting of more than 600 experiments in the range of $Re_0 = 1.5$–4181, $D/d = 4.1$–101.3, and $d = 0.6$–30 mm [37, 43, 44]. Besides isothermal wall boundary conditions, temperature distributions, adiabatic operation, and constant heat flux have been investigated by appropriate modification of Eq. (14). Different geometries of the cross section of the containment are included in the database, namely circular, annular, or rectangular. Annular or planar geometries can be easily treated by appropriate modification of the spatial coordinates [43].

Restrictions result from the relatively small amount of data with liquids and from steady-state conditions in all experiments



M7. Fig. 9. Radial dispersion of mass, presented on the basis of steady-state injection experiments. Every data point has been obtained from the evaluation of one measured radial profile of tracer concentration (more details in [37]).

of the database. Furthermore, parameters of the $\Lambda_r(r)$-model are missing for particle shapes other than spherical or cylindrical. A possible procedure for such cases would be to use the diameter of the sphere of equal volume (without consideration of internal voids) in place of d, in combination with the correlations for spherical particles for all parameters except λ_{bed} and K_1. The quiescent thermal conductivity λ_{bed} can be calculated according to Eq. (7) from Subchap. D6.3 without the influence of radiation, which should be added subsequently according to Eq. (33). To set the slope parameter K_1 (or $1/K_1 = K_r$) for Raschig rings or for irregular (broken) material, the recommendations by Bauer [8], which are summarized in Table 1, may be used. The constant at the right-hand side of Eq. (38a) should be changed correspondingly. However, it should be stressed that Bauer has evaluated with the α_w-model, so that certain deviations occur for spherical and cylindrical particles between the present recommendations and Table 1 ($1/K_1 = 7$ according to Table 1 instead of $1/K_1 = 8$ according to Eq. (32a) for spheres, $1/K_1 = 4.6$ according to Table 1 instead of $1/K_1 = 6.25$ according to Eq. (38a) for full cylinders). A value of $1/K_1 = 6.7$ has been suggested in [45] for full cylinders. According to [46], $1/K_1$ should be somewhat larger for full cylinders than for Raschig rings, the latter having half the value of $1/K_1$ for spheres. In case of broader than usual particle size distributions, the diameter

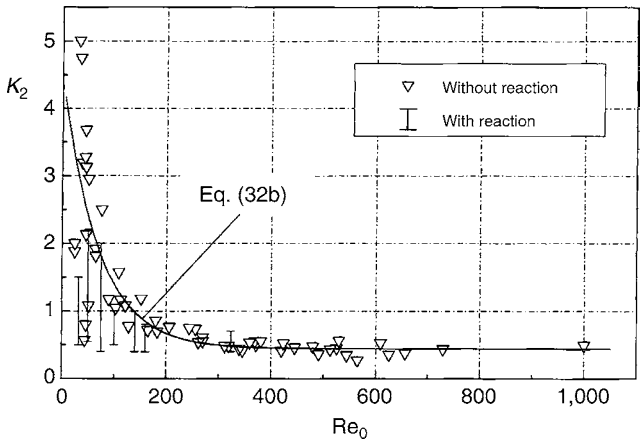
$$d = \left(\sum Q_i/d_i\right)^{-1} \tag{42}$$

can be used (Q_i: volume fraction of ith constituent, compared with Eq. (10) in Subchap. D6.3).

In case of strongly exothermic catalytic reaction, mass transport and heat transport are coupled to each other, but heat transport is more important for overall performance. Respective packed bed reactor experiments with spherical particles from [47–51] have been evaluated in [52] (with separately determined reaction data and the recommended values for all other transport parameters of the $\Lambda_r(r)$-model) for the heat transport damping parameter K_2. Somewhat different results are obtained when fitting K_2 to measured concentration or temperature profiles. Despite this effect, which is indicated by beams, K_2-values from reactor data agree reasonably in Fig. 10 with values from experiments without reaction (compare with Fig. 8). Fine adjustment of Eq. (32b) in the region of small

M7. Table 1. Inverse value of the slope parameter, $1/K_1$, for different particle shapes, as recommended by Bauer [8] for beds with large D/d; (d_i: inner diameter, d_o: outer diameter, l: length)

Particle shape	$1/K_1$ (= K_r)
Sphere	7.0
Full cylinder	4.6
Raschig ring	$K_r = 8/[1.75\ \Delta\psi_1 + 3.46\ (1-\Delta\psi_1)\ (l/d)^{2/3}]$ $\Delta\psi_1 = \left[1 + \frac{1-\psi_1}{\psi_1}\left(\frac{d_i}{d_o}\right)^2\right]^{-1}$ $\psi_1 = 0.39 + 0.02\ [\lvert(l/d_o)-0.85\rvert]^{4/3}$
Irregular (broken)	5.7



M7. Fig. 10. Damping parameters for heat transport gained from purely thermal experiments (compare with Fig. 8) as well from experiments with chemical reaction [52].

Reynolds numbers would not make great sense, because the sensitivity of the model upon K_2, K_1, and n decreases, and λ_{bed} becomes the controlling parameter at low flow velocities.

7 Radial Transport Parameters of the α_w-model

Application of the α_w-model (Eq. (17)) requires values for Λ_r and D_r, which are both considered to be constant over the entire cross section. The radial (or lateral) effective thermal conductivity Λ_r can be calculated according to Eq. (34a). The same equation can be used for the dispersion coefficient D_r – by replacing fluid and bed thermal conductivities (λ_f, λ_{bed}) with diffusion coefficients (δ, δ_{bed}) and calculating the molecular Péclet number from Eq. (20) (instead from Eq. (24)). The heat transfer coefficient at the wall α_w (Eq. (18)) is usually expressed in a Nusselt number

$$Nu_W = \alpha_W d/\lambda_f \tag{43}$$

and correlated with the Reynolds number Re_0 (Eq. (10)) and the Prandtl number Pr in the form

$$Nu_W = N_{W0} + a\ Re_0^{m_1} Pr^{m_2}. \tag{44}$$

The Sherwood number, $Sh_w = \beta_w d/\delta$, would replace Nu_W, and the Schmidt number, $Sc = \nu_f/\delta$, would replace Pr in case of mass transport.

The plethora of proposals that specify the above mentioned relationships in the literature is difficult to evaluate, because parameters are typically fitted by different methods to different but usually small sets of measured data. One of the most comprehensive and reliable evaluations is that by Nilles and Martin [52, 53]. These authors calculate the quantity K_r (Eq. (34c), similar to the inverse of the slope parameter, $1/K_1$) according to [8] as

$$K_r = K_{r,\infty}\left[2 - \left(1 - \frac{2}{D/d}\right)^2\right]. \tag{45}$$

The limiting value $K_{r,\infty}$, which is valid for the unconfined bed ($D/d \to \infty$), should be set according to Table 1, and the Nusselt number at the wall should be calculated from

$$Nu_W = \left(1.3 + \frac{5}{D/d}\right)\frac{\lambda_{bed}}{\lambda_f} + 0.19 Re_0^{0.75} Pr^{1/3} \tag{46}$$

(λ_{bed}/λ_f from Eq. (7), Subchap. D6.3, with the average bed porosity). Nilles and Martin indicate a validity range from Pe_0 = 1 to 10^4 ($Pe_0 = Re_0\ Pr$) and from D/d = 1.2 to 51 for heat transfer; (mass transfer was not investigated systematically). The correlations can be applied to particles of other than spherical shape by using the diameter of the sphere of equal volume.

The explicit dependence on the diameter ratio D/d, especially in Eq. (45), is mainly caused by the fact that macroscopic flow maldistribution has been neglected in Eq. (17). From a physical point of view, a boundary condition of the third kind (Eq. (18)) is justified only in the presence of a thin unmixed fluid layer at the wall. This can be assumed at high Péclet numbers ($Pe > Pe_{0,cr}$, see Eq. (36)), but not in the region $Pe_0 < Pe_{0,cr}$ [55]. The necessary correction is implemented by Nu_{w0} on the right-hand side of Eq. (46). As systematic comparisons show [37, 43, 44], the model of Martin/Nilles is usually in good agreement with the $\Lambda_r(r)$-model for thermal experiments. However, significant deviations may arise in the presence of exothermic reaction in relatively thin tubes, because of a tentative overestimation of temperature and reaction rate near the wall by the α_w-model. In general, chemical reaction magnifies the effect of even small temperature differences [49].

8 Complementary Remarks

Use of two separate heat and mass balances for the fluid and the solid phases instead of Eqs. (13a) and (17a) leads to heterogeneous or two-phase models (see, e.g., [56]). The solids can be considered either a second continuum or discrete inclusions, using reactor coordinates or spherical, intraparticle coordinates, respectively. Interface fluxes, which can be expressed in terms of a Nusselt number (Eq. (29)) or a Sherwood number ($Sh = \beta d/\delta$) for fluid-to-particle transfer, couple the phase balance equations with each other.

One-dimensional heterogeneous models are relatively easy to apply. In fact, the treatment of axial dispersion of heat in Sect. 5 of this chapter stems from such models. On the contrary, the application of two-dimensional heterogeneous models has the difficulty of additional transport parameters (e.g., separate effective thermal conductivities for the two phases), which are – in spite of some progress in this direction [47] – not accurately known. Thorough investigations about conditions of equivalence between heterogeneous and quasi-homogeneous models [57, 58] have not yet provided generally accepted and validated criteria. Qualitatively, it can be stated that heterogeneous models should be used when large differences in temperature or concentration can be expected between the solid and the fluid phases. Such steep gradients may occur in the course of fast dynamic processes (e.g., in regenerators with high throughput, during start-up, in the presence of moving reaction fronts, during reactor runaway). At steady state, steep gradients require

chemical (e.g., catalysis) or physical (e.g., drying) transformations which are both fast and accompanied by high release or consumption of thermal energy. Hein [46] measured under the steady-state conditions discussed in [48] temperature differences of maximum 10 K between the particles and the gas in catalytic packed bed reactors.

A further issue is the interconnection between momentum and heat balance because of temperature-dependent fluid properties (density, viscosity). In exothermic packed bed reactors, this can lead to the so-called thermal channeling (bypassing of the central, hot part of the bed). To model thermal channeling, the momentum equation must be expressed in two dimensions and solved iteratively with the heat balance [47].

Recent applications of quasi-homogeneous models include hydrogen storage [59] and membrane reactors [5, 60]. An application of the $\Lambda_r(r)$-model for the design of industrial packed bed reactors is discussed in detail in [61].

9 Examples

Example 1

The results of one experiment by Dixon [45] are calculated. In the experiment, air enters, at a temperature of $\vartheta_{in} = 21.5°C$ and with a mass flow rate of $\dot{M} = 9.1$ kg/h, a steam-heated tube ($D = 75.4$ mm, $L = 203.2$ mm), which has a wall temperature of $\vartheta_w = 100°C$. The tube is filled with spherical ceramic particles of diameter $d = 6.4$ mm ($\lambda_p = 1.2$ W/mK, $c_p = 774.51$ J/kgK and $\rho_p = 3000$ kg/m^3). Without wall influence, the porosity of the bed would be $\psi_\infty = 0.40$. Calculate the radial temperature profile at the outlet of the bed with the help of the α_w-model.

Material properties from Subchap. D2.2 at, approximately, $\vartheta = (\vartheta_{in} + \vartheta_w)/2 \approx 60°C \rightarrow \rho_f = 1.045$ kg/m^3, $c_f = 1009$ J/kgK, $\lambda_f = 0.0286$ W/mK, $\nu_f = 19.27\ 10^{-6}$ m^2/s, Pr = 0.71.

Cross-sectional area of the tube: $F = \pi\ D^2/4 \rightarrow F = 4.465\ 10^{-3}$ m^2.

Average superficial flow velocity: $u_0 = \dot{M}/(F\ \rho_f) \rightarrow u_0 = 0.542$ m/s.

Eq. (10) $\rightarrow Re_0 = 180.0$.

Eq. (24) $\rightarrow Pe_0 = 127.8$.

Calculation of quiescent thermal conductivity λ_{bed} according to Subchap. D6.3:

$\psi_\infty = 0.40$, $D/d = 11.78$, Eq. (4) $\rightarrow \psi = 0.427$.

$k_p = \lambda_p/\lambda_f = 41.958$.

Subchap. D6.3, Table 1 $\rightarrow C_f = 1.25$ (shape factor), $\varphi = 0.0077$.

Subchap. D6.3, Eq. (7f) $\rightarrow k_G \approx 1$.

Subchap. D6.3, Eq. (7e) $\rightarrow k_{rad} = 1.535$;
(with $\varepsilon = 0.9$ (estimated value) and $T = 333.15$ K).

Subchap. D6.3, Eq. (7c) $\rightarrow N = 0.995$.

Subchap. D6.3, Eq. (7b) $\rightarrow k_c = 9.681$.

Subchap. D6.3, Eq. (7a) $\rightarrow k_{bed} = \lambda_{bed}/\lambda_f = 7.919$
$\rightarrow \lambda_{bed} = 0.226$ W/mK.

Calculation of the (constant) radial effective thermal conductivity Λ_r:

Table 1, spherical particles: $\rightarrow K_{r,\infty} = 7$.

Eq. (45) with $D/d = 11.78 \rightarrow K_r = 9.177$.

Eq. (34a) $\rightarrow \Lambda_r/\lambda_f = 21.845 \rightarrow \Lambda_r = 0.625$ W/mK.
(corresponding to $Pe_r = 5.850$)

Calculation of the Nusselt number at the wall Nu_w:

Eq. (46) $\rightarrow Nu_w = 21.986$.

To calculate the required temperature profile, Eqs. (17a) and (18) are applied for the steady state without axial dispersion. The boundary condition at the entrance of the tube is

$$z = 0 \rightarrow \vartheta = \vartheta_{in} = 21.5°C.$$

According to [56] (see also [62]) it is

$$\frac{\vartheta(r) - \vartheta_w}{\vartheta_{in} - \vartheta_w} = D_1 \sum \frac{4J_0(\beta_n r/R)}{(D_1^2 + 4\beta_n^2)J_0(\beta_n)} \exp(-4\beta_n^2/D_2)$$

with

$$D_1 = Nu_w \frac{D/d}{\Lambda_r/\lambda_f} = 11.856 \text{ and } D_2 = Pe_r \frac{D/d}{L/D} = 25.571.$$

The eigenvalues β_n are obtained from the equation

$$f(\beta_n) = [D_1\ J_0(\beta_n)/2]\ -\ \beta_n\ J_1(\beta_n) = 0,$$

where J_0 and J_1 are Bessel functions of 0th and 1st order, respectively.

By linear interpolation in the tables of [62], the first two eigenvalues (higher terms of the series can, in this case, be neglected without significant loss of accuracy) are calculated to

$\beta_1 = 2.0444$ and $\beta_2 = 4.7964$.

The respective values of the Bessel functions can also be obtained from mathematical tables by interpolation [63]. Alternatively, equations that approximate the Bessel functions with a high accuracy may be used. Results based on equations from [63] are summarized in Table 2.

In this way, the radial temperature profile at the outlet of the tube can be calculated. Results are also included in Table 2. Figure 11 shows the comparison with the data measured by Dixon [45].

Example 2

The results of the same experiment as in Example 1 are now calculated with the help of the $\Lambda_r(r)$-model.

Material properties as in Example 1

Calculation of the velocity profile $u_0(r)$:

Equation (8) with $a_3 = 2.0$, $b_3 = 2.0 \cdot 10^{-3}$ from Eq. (9) $\rightarrow \eta_{eff}/\eta_f = 2.8667 \rightarrow \eta_{eff} = 57.74\ 10^{-6}$ Pa s.

Equations (3a)–(3d) $\rightarrow \psi(r)$ as shown in Table 3.

To obtain the velocity profile $u_0(r)$, Eqs. (6), (7), and (12) must be solved with the computed profile of bed porosity. Since this is not possible analytically, a solver, which works with a Newton iteration and adaptive mesh, is used. The results are summarized in Table 3.

Calculation of quiescent thermal conductivity λ_{bed}:

Calculation at the axis of the tube ($r = 0$) with $\psi(r = 0) = 0.40$ (see also the remarks in Sect. 6 of this chapter):

Subchap. D6.3, Eq. (5c): $\rightarrow N = 0.953$.

Subchap. D6.3, Eq. (5b): $\rightarrow k_c = 8.317$.

Subchap. D6.3, Eq. (5a): $\rightarrow k_{bed,0} = 6.667$.

Subchap. D6.3, Eq. (7e): $\rightarrow k_{rad} = 1.535$ (with an estimated value of $\varepsilon = 0.9$ and $T = 333.15$ K).

Eq. (33): → $k_{bed} = 8.162$ → $\lambda_{bed} = 0.233$ W/mK

Values calculated at other positions are presented in the form of $k_{bed}(r) = \lambda_{bed}(r)/\lambda_f$ in Table 4.

Calculation of the axial effective thermal conductivity $\Lambda_{ax}(r)$*:*

Λ_{ax} is calculated according to Eqs. (23) and (24) by using local values of the quiescent thermal conductivity (that means: $\lambda_{bed}(r)$) and, approximately, the average superficial flow velocity u_0. Results (normalized by means of λ_f) are tabulated in Table 4.

Calculation of the radial effective thermal conductivity $\Lambda_r(r)$:

Calculation in the middle of the bed ($r = 0$):

Eq. (32a) → $K_1 = 0.125$.
Eq. (32b) → $K_2 = 0.7457$.
Eq. (32c) → $n = 2$.
Eq. (31b) → $f(R-r) = 1$.
Table 3 → $u_{0,c}/u_0 = 0.833$.
Equation (30) → $\Lambda_r(r = 0)/\lambda_f = 21.47$ → $\Lambda_r(r = 0) = 0.614$ W/mK.

More values of $\Lambda_r(r)/\lambda_f$ are presented in Table 4.

With this input, it is possible to calculate the radial profile of temperature at the outlet of the packed tube by solving Eq. (13a) together with the boundary conditions according to Eqs. (14) and (15a). Additionally, temperature at the entrance of the reactor is set to a constant value:

$$z = 0 \rightarrow \vartheta = \vartheta_{in} = 21.5^{\circ}\text{C}.$$

For reasons of symmetry, the temperature profile must be flat in the middle of the tube:

$$r = 0 \rightarrow \partial\vartheta/\partial r = 0.$$

Computations have been carried out by using a solver for transient, two-dimensional, nonlinear partial differential equations from [64]. This solver implements an implicit method of lines, decomposing the partial differential equation to a system of ordinary differential equations and applying a robust integrator to the latter. The transient converges to the required steady-state solution, which is documented in Table 4 by means of selected results.

Figure 11 compares calculations with the experimental results from [45], also allowing for a comparison with the predictions of the α_w-model from Example 1. The results of both models do not differ significantly in the core of the bed. However, the different boundary conditions become remarkable in the vicinity of the wall. In fact, the $\Lambda_r(r)$-model works with a boundary condition of the first kind according to Eq. (14), that means with the real wall temperature ϑ_w, whereas the α_w-model uses a boundary condition of the third kind at $r = R$, thus calculating a temperature jump. Such differences can be significant in the presence of a chemical reaction. Without reaction, the deviations between the two models are small, with just a slight advantage for the $\Lambda_r(r)$-model, as the evaluation of numerous measured data shows.

M8 Humidifying and Drying of Air

Manfred Zeller[1] · *Ulrich Busweiler*[2]
[1]RWTH Aachen, Aachen, Germany
[2]Sachverständigenbüro, Darmstadt, Germany

1 Moist Air; Properties and Mollier *h,Y*-Diagram

Moist air is a mixture consisting of dry air and water vapor. The formation of freezing fog shall be neglected. In the majority of practical applications, it is valid to assume the gas phase to be an ideal gas mixture. As the mass of dry air does not change during most processes, state variables are specific to the mass of dry air.

Composition of moist air

The humidity ratio is defined as

$$Y = \frac{M_W}{M_L}. \tag{1}$$

Relative humidity is defined as the ratio of the actual partial pressure of water vapor in moist air to the partial saturation pressure at a stated temperature.

$$\varphi = \frac{p_D}{p_{DS}}; 0 \le \varphi \le 1. \tag{2}$$

Both values are interrelated by the following equation

$$Y = \frac{R_L}{R_D} \cdot \frac{p_D}{p - p_D} = 0.622 \frac{\varphi\, p_{DS}}{p - \varphi\, p_{DS}} \tag{3}$$

where R_L = 287 J/kg K, gas constant of air, and R_D = 461 J/kg K, gas constant of water vapor.

The saturation vapor pressure $p_{DS}(\vartheta)$ can be taken from water steam tables. A sufficiently exact approximation for the temperature range $0 \le \vartheta \le 70°C$ can be found in Sect. 3.1 from Chap. N4, Eq. (14), and for the range $0 \le \vartheta \le 60°C$ can be found in Eq. (39) of Chap. M8, respectively.

Density

For moist air with a humidity ratio Y the following equation, specific to the volume of moist air, applies

$$\rho_{wet} = \frac{M_L + M_W}{V} = \frac{p}{R_L T} \cdot \frac{1 + Y}{1 + \frac{R_D}{R_L} Y} \tag{4}$$

while for dry air, specific to the volume of humid air,

$$\rho_{dry} = \frac{M_L}{V} = \frac{\rho_{wet}}{1 + Y} = \frac{p}{R_L T} \cdot \frac{1}{1 + \frac{R_D}{R_L} Y} \tag{5}$$

is valid.

Specific Enthalpy

The term "specific" is used here to describe the reference of a value to the mass of gas (dry air) contained in the gas/vapor mixture (humid air) – in contrast to the common definition, which relates the value to the mixture's total mass. In case of unsaturated moist air, utilizing the usual point of reference at 0°C, the specific enthalpy of moist air with the humidity ratio Y *is*

$$\begin{aligned} &H = c_{pL}\vartheta + Y(\Delta h_{Vo} + c_{pD}.\vartheta), \\ &\text{whereas } c_{pL} = 1\text{kJ/kg K}, c_{pD} = 1.86\text{kJ/kg K} \\ &\text{and } \Delta h_{Vo} = 2,500 \text{ kJ/kg}. \end{aligned} \tag{6}$$

In the so-called fog area, the air is oversaturated, i.e., it contains liquid water droplets as well. The specific enthalpy is then calculated as

$$h = h_S + (Y - Y_S) c_W \vartheta \tag{7}$$

where h_S is the enthalpy, Y_S the humidity ratio at saturation, and c_W = 4.19 kJ/kg K.

h,Y-*diagram according to Mollier.*

In order to graph state changes of humid air, the *h, Y*-diagram as proposed by *Mollier* (Fig. 1) is commonly used. The isotherms are according to Eqs. (8) and (9)

$$\left(\frac{\partial h}{\partial Y}\right)_{\vartheta\,=\,\text{konst}} = \Delta h_{Vo} + c_{pD}\vartheta \tag{8}$$

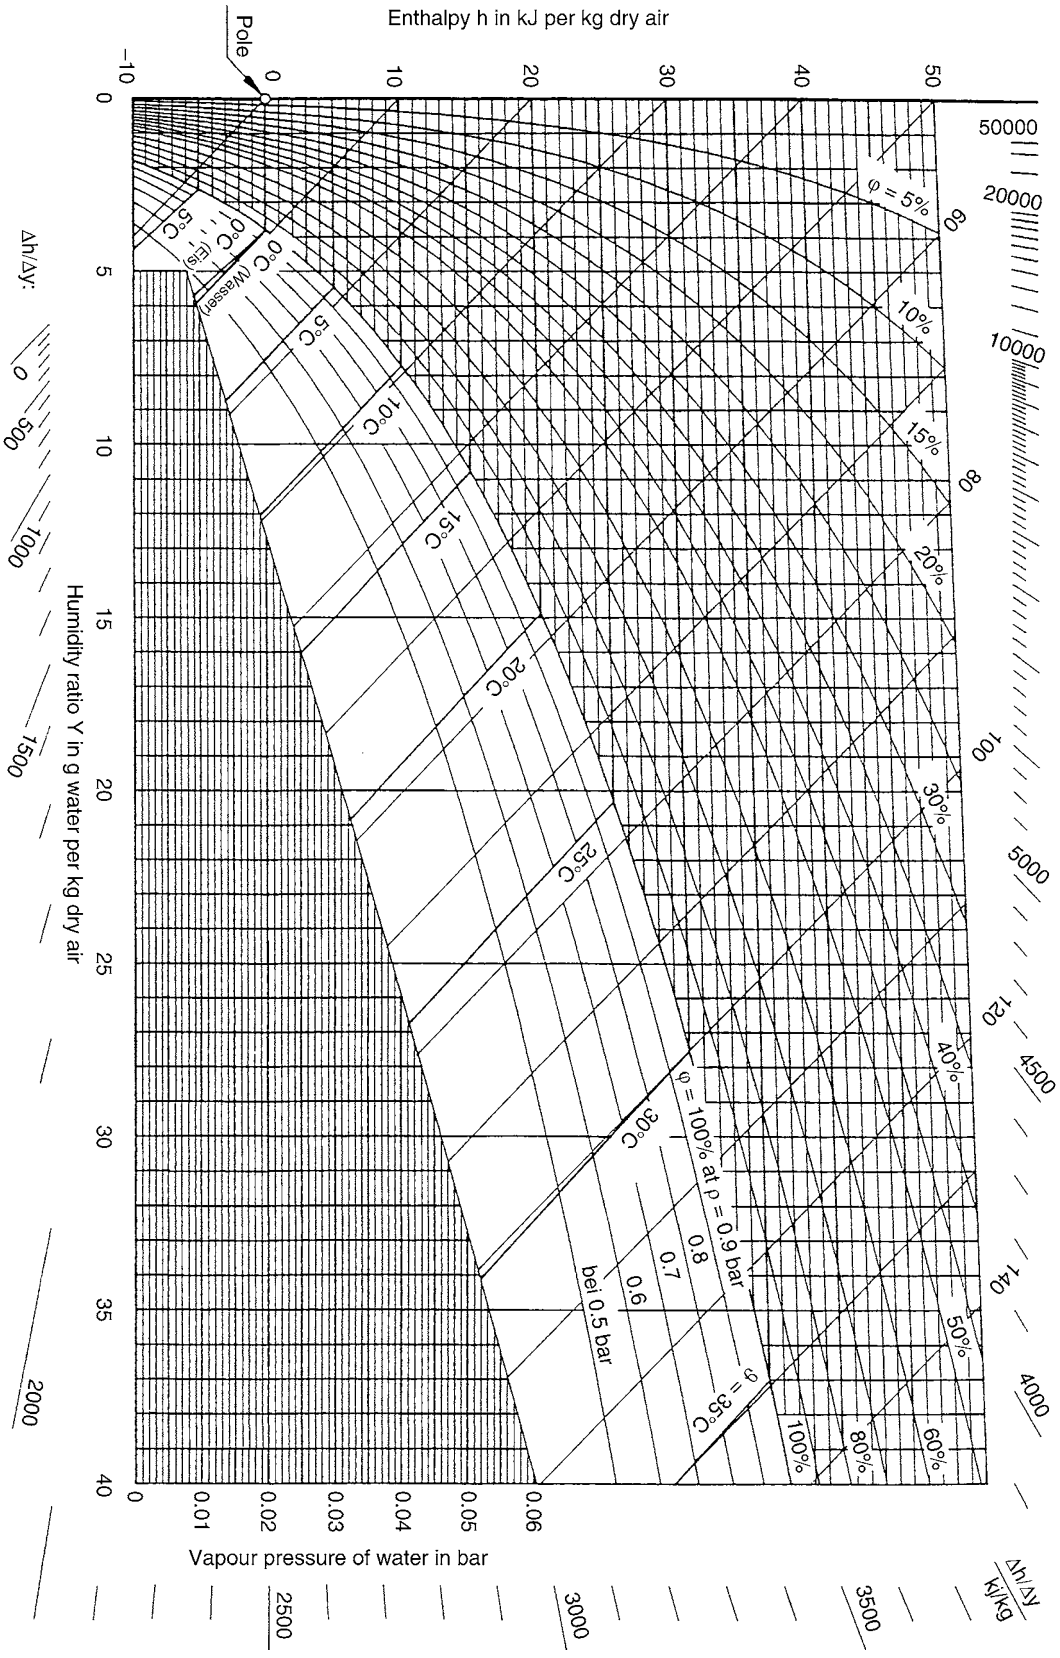
for unsaturated air and

$$\left(\frac{\partial h}{\partial Y}\right)_{\vartheta\,=\,\text{konst}} = c_W \vartheta \tag{9}$$

in fog domain.

To expand the most important part, i.e., the region of unsaturated air, for practical applications, a tilted coordinate system with the isotherm at 0°C running horizontally is applied. This results in the *Y*-axis being rotated downwards by an angle corresponding to $\tan \alpha = \Delta h / \Delta Y = \Delta h_{Vo}$ while taking into account the correct scaling of the axes. The lines of constant Y thus remain vertical, whereas the lines of constant h run parallel to the rotated *Y*-axis. Differences in enthalpy are still represented by vertical distances. The isotherms' gradient in the unsaturated region increases

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_57,



M8. Fig. 1. Mollier *h,Y*-diagram.

slightly by $\Delta h/\Delta Y = c_{pD}\vartheta$. At the saturation line, the isotherms bend. As evident from Eq. (9), the fog isotherm at 0°C coincides with a line of constant enthalpy (h = constant), while at higher temperatures, the fog isotherms run with a minor gradient than the lines of constant enthalpy cutting the saturation line at the inflection points of the isotherms.
Annotation: The so-called fog isotherms are in accordance with the wet bulb temperature lines.

In principle, a *h,Y*-diagram is only valid for a certain total pressure *p*. As long as humid air can be considered an ideal gas ($p < 10$ bar), it is possible to apply a diagram, valid for a certain total pressure *p*, at other total pressures as well as just by using the relation

$$\frac{\varphi_2}{\varphi_1} = \frac{p_2}{p_1}. \tag{10}$$

Only the labels at the lines of constant φ change according to Eq. (10). The isotherms in the unsaturated region remain the same up to the new saturation line, and the corresponding fog isotherms have to be shifted parallel to the new inflexion points. A pressure change from 1 bar to 2 bar would, for example, turn the line of φ = 50% into the new saturation line, and all previous lines with $\varphi < 50\%$ would have their labels multiplied by 2. In the same way, a reduction of the total pressure, for example, from 1 bar to 0.8 bar would imply extending the isotherms of the unsaturated region to the corresponding line of $\varphi = 100\%$ at 0.8 bar and multiplying the labels at the lines for φ = constant with a factor of 0.8.

A useful value for displaying changes of state is the measure of gradient $\Delta h/\Delta Y$ (slope "enthalpy to humidity ratio"). It is therefore included at the outline of the *h,Y*-diagram as sections of a pencil of lines originating from a pole ($Y = 0$, $h = 0$).

2 Humidification

Depending on the type of process that is applied to increase the content of water or water vapor in air, two methods can be distinguished:

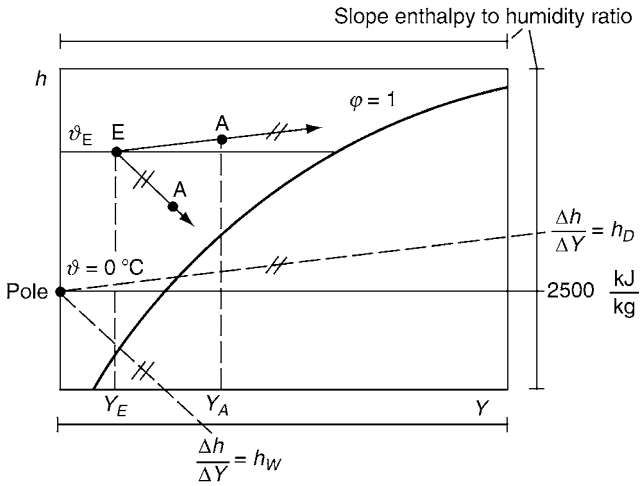
- Humidifying by mixing with steam
- Humidifying by evaporation

When humidifying air with steam, water is added to air as steam that has been produced beforehand. Humidification using evaporation employs various devices to mix air with water, which then evaporates totally or partially while extracting heat from the surrounding air. Therefore, humidification of air by evaporation always leads to a decrease in air temperature in contrast to humidification by steam mixing.

2.1 Humidification by Steam Injection

If a dry air flow $\dot{M}_L$ is mixed with a steam flow $\dot{M}_D$, an energy and mass balance yield the direction of the change of state given by

$$\frac{\Delta h}{\Delta Y} = \frac{h_{LA} - h_{LE}}{Y_A - Y_E} = h_D \tag{11}$$



M8. Fig. 2. Change of state of moist air humidified with steam or liquid water.

which can be easily graphed in the *h,Y*-diagram according to Fig. 2 utilizing the slope scales on the diagram perimeter. For this, the slope corresponding to the calculated gradient is connected with its origin (pole) and the resulting line is shifted parallel to the point of state E at the air entry. The change of state of air then runs along the obtained straight line. The change in humidity ratio and the state of air at the outlet A are derived from the mass balance:

$$\Delta Y = Y_A - Y_E = \frac{\dot{M}_D}{\dot{M}_L} \tag{12}$$

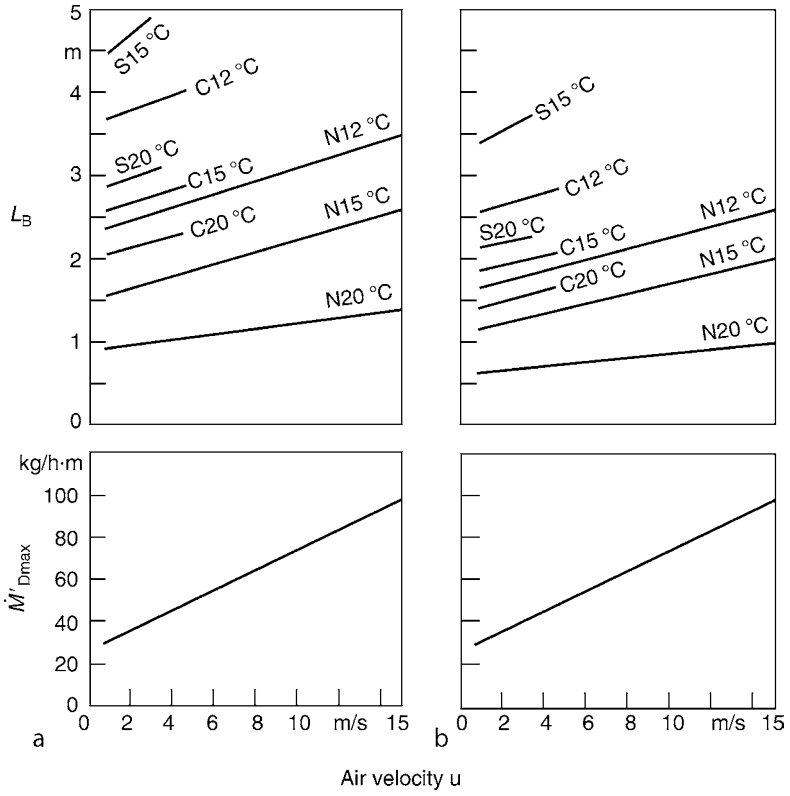
Because of $c_{pD} \cdot \vartheta_D \ll \Delta h_{Vo}$, only a minor change in air temperature occurs (about 1–4 K).

For a proper operation of steam humidifiers, it is crucial to achieve a good mixing of the injected steam through steam lances or distributor pipes in order to avoid condensation at duct walls or successive units. Additional measures, e.g., superheating of the steam by heating the jacket tube or condensing separators have to be installed to prevent condensate dripping from distributor pipes. Only few publications exist about the necessary length of the mixing path. It is determined empirically and can usually be obtained from manufacturer's data. Finer steam spreading and lower steam flow per manifold length yield shorter mixing paths. Additionally, air velocity, humidity levels at the inlet and outlet, exit air temperature, as well as the characteristics of successive installations have a major influence. Irrespective of the really installed system, applicable guide values, which have been determined empirically [1], can be taken from Fig. 3.

These diagrams are based upon the recommended steam pipe arrangement in Fig. 4. They are valid for specific increases in air humidity. Deviations can be accounted for by applying the following adjustment

$$L_B(\Delta Y \pm \Delta(\Delta Y)) = (1 \pm 0.25) \cdot L_B(\Delta Y)_{\text{diagram}}$$

with $|\Delta(\Delta Y)| = 2\,g/kg$.



M8. Fig. 3. Humidification paths L_B in steam humidifiers for different operation modes and boundary conditions according to [1]. Parameters: Air temperature behind the humidifier (°C) and type of obstacles: S filter for suspended matter, C fine filter, N common obstacles (e.g., pipe elbow, blowing fan): (a) Full outside air operation with $Y_E \approx 1$ g/kg and $\Delta Y \approx 7$ g/kg (b) Operation with partially recirculated air with $Y_E \approx 4$ g/kg and $\Delta Y \approx 4$ g/kg.

Another 25% reduction of the humidifier path can also be realized if the steam flow to distribution pipe length ratio is decreased to the half of the maximum value from the diagram.

Behind the mixing path L_B, the humidity distribution will normally not have reached uniformity. Without further measures, this might require a multiple of L_B about the magnitude of 5 L_B.

Example 1

Given:

Geometry of humidifier duct (height $H = 1$ m, width $B = 1.5$ m)
Humidifier path (provided by customer $L_B = 2$ m)
Complete outside air supply
Inlet air conditions: $\vartheta_{LE} = 15°C$, $Y_E = 1$ g/kg
Humidity ratio at exit: $Y_A = 8$ g/kg
Air velocity in front of the humidifier: $u_{LE} = 3$ m/s
Fine filter C behind humidifier
Steam inlet temperature: $\vartheta_D = 102°C$

Find:

Required steam flow $\dot{M}_D$ as well as the number of steam distribution pipes n_R.

Using the dry air density according to Eq. (5)

$$\rho_{trE} = \frac{10^5}{287 \cdot 288} \cdot \frac{1}{1 + 0.001 \cdot 461/288} = 1.2\,\text{kg/m}^3$$

the mass flow of dry air results as

$$\dot{M}_L = \rho_{trE} u_{LE} HB = 1.2 \cdot 3 \cdot 1 \cdot 1.5\ \text{kg/s} = 5.44\ \text{kg/s}.$$

According to Eq. (12) the required steam supply is

$$\dot{M}_D = \dot{M}_L (Y_A - Y_E) = 5.44 \cdot 0.007\,\text{kg/s} = 0.038\,\text{kg/s} = 137\ \text{kg/s}.$$

After rearrangement of Eq. (11) with $h_D = \Delta h_{Vo} + c_{pD}\vartheta_D$ the exit temperature of dry air can be calculated as

$$\vartheta_{LA} = \frac{(Y_A - Y_E)c_{pD}\ \vartheta_D + (c_{pL} + Y_E c_{pD})\vartheta_{LE}}{c_{pL} + c_{pD} Y_A} = \frac{0.007\ \cdot\ 1.86 \cdot 102 + (1 + 0.001 \cdot 1.86) \cdot 15}{1 + 1.86 \cdot 0.008}\ °C = 16.1°C.$$

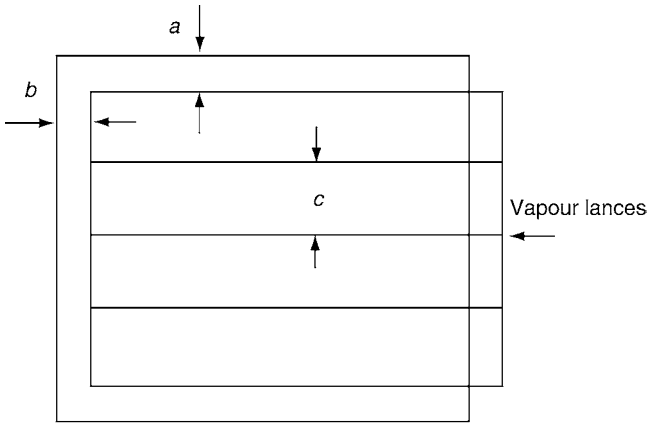
The permissible steam flow per distributor tube length at $u = 3$ m/s is taken from Fig. 3 (complete outside air operation) as

$$\dot{M}'_{D\,max} = 40\,\text{kg/hm}$$

and in the case of a fine filter behind the humidifier and an air temperature of 16.1°C, which has been interpolated linearly between C 15°C und C 20°C, the necessary humidifier path length is read off:

$$L_{B\,max} = 2.6\ m.$$

Applying the condition $\dot{M}'_D \le \dot{M}'_{D\,max}$ and the recommendations according to Fig. 4 for the arrangement of steam distribution pipes, the resulting length of one steam distribution pipe is



u m/s	a mm	b mm	C_{max} mm	$\dot{M}'_{Dmax}$ kg/h je per m tube length
1	300	150	450	30
2	250	150	450	35
3	200	150	400	40
5	150	150	350	50
10	100	150	350	70

M8. Fig. 4. Recommended maximum distance of steam distribution pipes at specified maximum steam flow per meter of tube length according to [1]. *u* = air velocity, *a*, *b* = distances from walls, $\dot{M}_{Dmax}$ = maximum steam flow per meter tube length, and *c* = distance between pipes.

$$L_R = B - b = 1.5\,\text{m} - 0.15\,\text{m} = 1.35\,\text{m}$$

and the number of distribution pipes n_R

$$n_R \geq \frac{\dot{M}_D}{L_R \dot{M}'_{D\,max}} = \frac{137}{1.35 \cdot 40} = 2.54 \text{ Rohre.}$$

Then the number of pipes is chosen as $n_R = 3$ and so the steam mass flow to pipe length ratio can be calculated as

$$\dot{M}'_D = \frac{137}{1.35 \cdot 3}\text{kg/hm} = 33\,\text{kg/hm.}$$

As identified before in Fig. 3, $\dot{M}'_{D\,max} = 40$ kg/h m requires a humidifier path length of 2.6 m. Due to the fact that only a path length $L_B = 2$ m is provided by customer, which is about 25% shorter, the steam flow per pipe length according to [1] (see Sect. 2.2) has to be reduced to $\dot{M}'_{Dmax}/2 = 20$ kg/h m. The number of distribution pipes then increases to

$$n_R = \frac{\dot{M}_D}{L_R \dot{M}'_{D\,max}/2} = \frac{1.37}{1.35 \cdot 20} = 5\,\text{pipes.}$$

2.2 Humidification by Evaporation

Evaporation occurs if water has not yet reached the boiling temperature at the current pressure while the partial pressure of water vapor at the phase interface, i.e., the water surface, is greater than the partial pressure of water vapor in the ambient air. Numerous types of evaporation humidifiers exist. A general difference concerns the supplied water flow rate. It either equals exactly to the amount of steam picked up by the air flow or it is greater than the water vapor retained in air while the none-vaporated fraction is recirculated.

Complete evaporation of supplied water

Main embodiments of these humidifiers comprise spray humidifiers, e.g., rotating centrifugal discs or nozzles, ultrasonic humidifiers and sprinkled mats. Humidification performance can be calculated according to Sect. 2.1. Only h_D and $\dot{M}_D$ have to be replaced by h_W and $\dot{M}_W$. In contrast to steam injection, humidification with water results in a considerable cooling of the air stream as the air has to provide the vaporization heat of water (Fig. 2, case $\Delta h/\Delta Y = h_W$).

Partial evaporation and recirculation of the humidification water

Humidification water is pumped in a cycle with only the evaporated fraction being compensated. Essentially, two constructions can be distinguished: sprinkling humidifiers and spray chamber humidifiers (which in literature are usually denominated "air washers").

Within sprinkling humidifiers the air passes through water-sprinkled installations which consist of packing material or surfaces with various geometries. Basis of calculation is the knowledge of the empirically determined heat and mass transfer characteristics of the installations. If these data are available, e.g., as number of transfer units (NTUs) – characteristic, the installation's dimensions as well as state changes of air can be determined by the method described in Chap. N4. Commonly, however, these data are not available. In most cases, only device specific humidification characteristics equal to those describing the operating behaviour of air washers, as discussed later on, are utilized as the basis for calculations.

Spray chamber humidifiers or rather air washers are employed predominantly. Inside these devices, the humidification water is atomized by nozzles while the air to be humidified is moved in or against the spray direction. If humidification is the primary task, the air washer is operated adiabatically, i.e., no heat is transferred to the recirculated humidifying water except for the normally negligible pumping energy, the enthalpy of the added water, and heat transfer through the walls of the device. The humidification performance of an adiabatic air washer can be characterized with the humidifying efficiency

$$\eta_B = \frac{Y_A - Y_E}{Y_K - Y_E} \approx \frac{\vartheta_{LA} - \vartheta_{LE}}{\vartheta_K - \vartheta_{LE}} \qquad (13)$$

which describes the ratio of the real to the maximal achievable change in air humidity and which approximately, i.e., as long as the isotherms can be assumed to be running nearly parallel ($c_{pD} \cdot \vartheta \ll \Delta h_{Vo}$), corresponds to the ratio of temperature change. The achievable maximum humidity is the saturation humidity ratio at the so-called cooling limit temperature (respectively, adiabatic saturation temperature) ϑ_K corresponding to the entry state of the air. It can be obtained by extending the fog isotherm (line of constant wet bulb temperature) running

through the entry state of the air. As a precondition of this, the *Lewis* factor has to be equal to

$$\frac{\alpha}{\beta_Y c_{p_{1+Y}}} = 1 \tag{14}$$

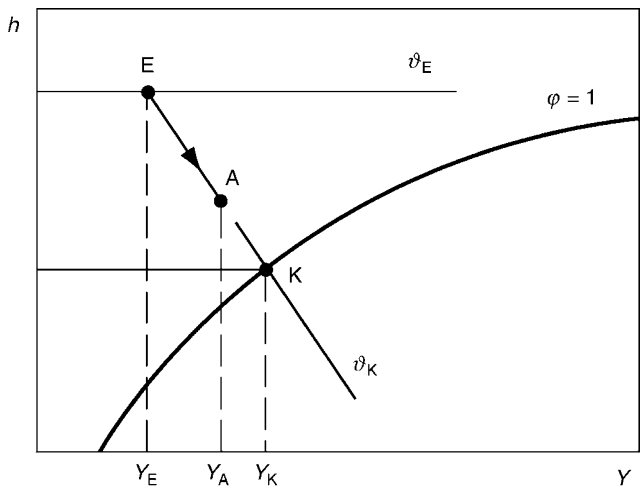
whereas $c_{p_{1+Y}} = c_{pL} + Y c_{pD}$, which is sufficiently exact for mixtures of water vapor and air in the range of usual air humidification processes [2]. The cooling limit state (Y_K, ϑ_K) can be calculated by iterating equation

$$\frac{h_{LE} - h_{LK}}{Y_E - Y_K} = c_W \vartheta_K \tag{15}$$

using the vapor pressure curve $p_{DS} = f(\vartheta_S)$ (e.g., Eq. (39)) or $Y_S = f(\vartheta_S)$ with $\vartheta_S = \vartheta_K$ and h according to Eq. (6), respectively. From Eq. (15) also follows that the state of air inside the humidifier changes along the extended fog isotherm (wet bulb temperature line) ϑ_K, as shown in Fig. 5.

The humidifying efficiency η_B is influenced by many parameters. The most important are the droplet-size distribution of the spray and the resulting overall droplet surface, respectively, the relative velocity between droplets and air as well as the residence time of the droplets. These parameters are determined by the flow rates of water and air, by the type, number, and arrangement of nozzles, by the nozzle inlet pressure, and the dimensions of the spray chamber.

Numerous efforts have been made to precalculate the change of state of air in spray chambers, e.g., [3, 4]. They comprise dividing the droplets into classes and solving numerically the transport equations for the particular droplet classes and the air flow while taking into account the interactions at the phase interface. The shortcoming of these numerical methods is the insufficient knowledge of the droplet-size spectrum. Available are only spectra of single nozzles injecting into free space. Within installations, these spectra change significantly due to the number and arrangement of nozzles, the chamber design, and air flow velocity. This results in unsatisfying agreement between experimental and numerical data. Furthermore, a considerable part of the mass transfer obviously takes place at the water-sprinkled chamber walls. Because of these effects, numerical calculations indeed allow for parametric studies and a deeper understanding of the physical processes, but they do not suffice for quantitative predictions. Hence practical applications still rely on the use of experimentally acquired characteristics hardly suitable for generalization.



M8. Fig. 5. State change of moist air inside an adiabatic spray chamber.

Various approaches exist to describe experimentally determined humidifying efficiencies with equations. The integration of a simple mass balance for an air washer element yields

$$\eta_B = 1 - e^{-K_Y \dot{M}_W / \dot{M}_L}. \tag{16}$$

This equation assumes that the characteristic humidifier number K_Y remains constant along the humidifier and is independent of the ratio of water and air flow rate $\dot{M}_W/\dot{M}_L$. The quantity K_Y contains the droplet surface area relating to the water flow rate. Constancy of K_Y is only valid if the water flow rate is controlled by switching on and off single nozzles and not by alternating the nozzle inlet pressure as it is done usually. Furthermore, Eq. (16) does not take into account the chamber walls therefore not reproducing satisfactorily existing experiments.

Extended approaches, which included, e.g., the humidifier length and the air velocity into the calculation of K_Y [3, 5], did not lead to substantial improvements.

Based on the depicted circumstances, some authors [6, 7] are acting on the assumption of no further physically founded, in terms of dimension theory inconsistent power approach to evaluate experimental data:

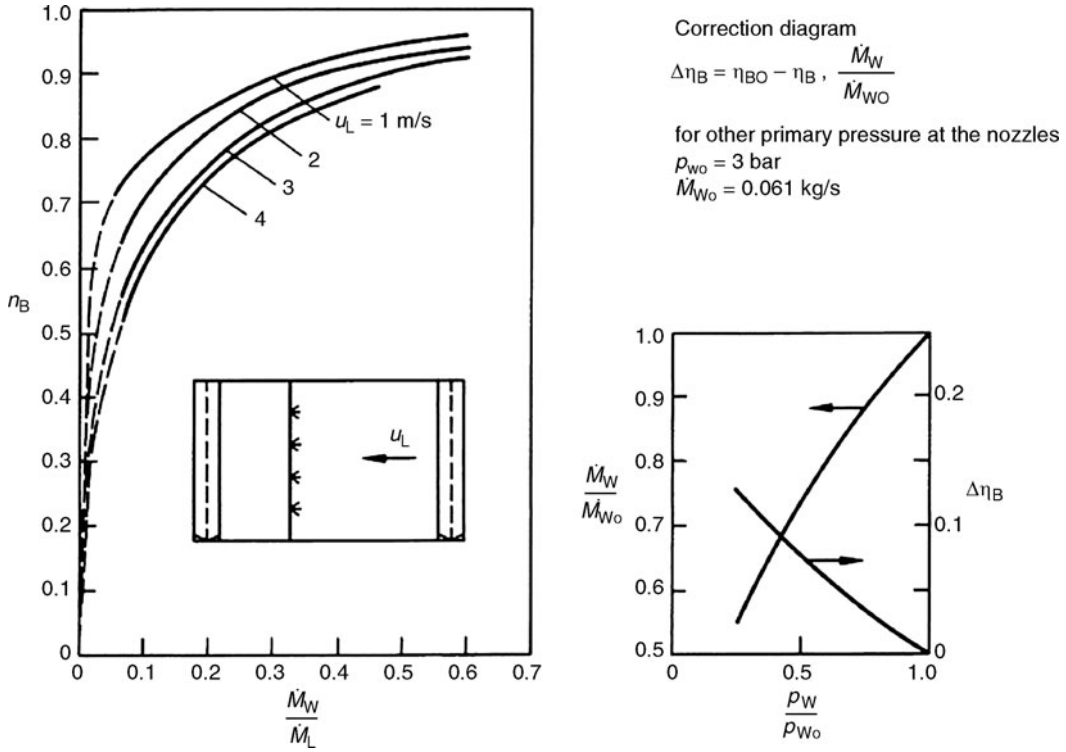
$$\eta_B = C(u_L)^n \left(\dot{M}_W/\dot{M}_L\right)^m. \tag{17}$$

Depending on experimental procedures as well as data analysis methods, the authors obtained different algebraic signs for the exponent n. If the mass flow ratio of water and air is varied at constant air mass flow by means of the nozzle inlet pressure [6, 7], the resulting exponent is positive, because the spectrum of droplet sizes simultaneously shifts toward smaller droplets. However, if the variation of the water mass flow is achieved with the change of number of nozzles at a constant nozzle inlet pressure, the residence time becomes dominant leading to a negative exponent n [8].

The variety of influencing parameters explains why the proposed equation and diagrams for η_B are closely restricted to the underlying experimental boundary conditions and why the humidifier characteristic

$$\eta_B = f\left(\dot{M}_W/\dot{M}_L\right) \tag{18}$$

has to be determined for every humidifier separately. Previous attempts to generalize the empirical findings with respect to the controlling geometrical and process factors have not proved successful. Corresponding to the numerous influencing parameters a large number of characteristic curves based on Eq. (18) is required for designing humidifiers. Parameters of noticeable influence are the type of nozzle, nozzle i.d., nozzle arrangement, number of nozzle banks, nozzle inlet pressure, spray direction related to air flow (upstream or downstream) as well as opposing banks in double-row nozzle banks, fan arrangement (situated ahead or behind the chamber), in case of the fan located ahead also the forming of the downstream diffuser,



M8. Fig. 6. Humidifying efficiency $\eta_B = f(\dot{M}_W/\dot{M}_L, u_L)$ for swirl nozzles with diameter d = 3 mm, nozzle inlet pressure p_{Wo} = 3 bar, fixed chamber geometry and suction fan; correction diagram for differing nozzle inlet pressures [8].

chamber length, air velocity. Figure 6 gives an example of a humidifier characteristic. The correction factor $\Delta\eta_B$ mainly includes the influence of variations in the droplet-size spectrum due to changes of the nozzle inlet pressure.

In general the following applies: Water sprays discharging in opposed direction to the air flow (upstream) yield higher humidifying efficiencies than downstream discharging [8, 9]. In double-row nozzle banks, downstream bank designs are preferable to upstream or opposing designs as well. Furthermore, higher humidifying efficiencies can be achieved with fans situated behind the chamber [8]. If the fan is placed ahead the chamber, the forming of the downstream diffusor and further installations play an important role.

The necessary length of the humidification path depends primarily on the air velocity and the water/air flow ratio. A length of 1–1.5 m is usually sufficient.

Example 2

Given:

Humidifier geometry, nozzle type and arrangement corresponding to Fig. 6.

Furthermore, the following values are known:

$$u_L = 3 \text{ m/s}, \left(\dot{M}_W/\dot{M}_L\right)_o = 0.4 \text{ at } p_{wo} = 3\text{bar},$$

state of air at inlet : $\vartheta_{LE} = 22°\text{C}, Y_E = 7$ g/kg, $p = 1$ bar.

Find:

Humidifying efficiency η_B at p_{Wo} = 3 bar and p_W = 1.5 bar, state of air at outlet ϑ_{LA}, Y_A at p_W = 1.5 bar.

Figure 6 gives at $\dot{M}_W/\dot{M}_L = 0.4$, u_L = 3 m/s and p_{Wo} = 3 bar a humidifying efficiency η_B = 0.88. The water/air flow ratio corresponding to a change in nozzle inlet pressure and as the case may be in air velocity can be calculated from

$$\frac{\dot{M}_W}{\dot{M}_L} = \frac{\dot{M}_W/\dot{M}_{Wo}}{u_L/u_{Lo}} \left(\frac{\dot{M}_W}{\dot{M}_L}\right)_o .$$

In the given case the air velocity remains unchanged, that means that $u_L/u_{Lo} = 1$ applies. The ratio $\dot{M}_W/\dot{M}_L$ amounts to 0.705 according to the correction diagram in Fig. 6 at p_W/p_{Wo} = 0.5. This yields

$$\frac{\dot{M}_W}{\dot{M}_L} = \frac{0.705}{1} \cdot 0.4 = 0.28.$$

At this water/air flow ratio and an inlet pressure p_{Wo} = 3 bar, a humidifying efficiency of η_B = 0.825 would result according to Fig. 6. At the same water/air flow ratio, yet with a lower nozzle inlet pressure p_W, the humidifying efficiency decreases along with the correction diagram in Fig. 6 by $\Delta\eta_B(p_W/p_{Wo} = 0.5)$ to η_B = 0.74.

Calculation of the state of air at the outlet requires knowledge of the adiabatic saturation state (ϑ_K, Y_K) corresponding to (ϑ_{LE}, Y_E). It can be obtained iteratively: The adiabatic saturation temperature is guessed to be $\vartheta_K^* = 14°\text{C}$. Equation (39) then yields

$$p_{DS} = 10^{-3} \cdot 10^{8.3246} - \frac{1799.73}{14 + 238.734} \text{ bar} = 0.016 \text{ bar}$$

and Eq. (3)

$$Y_K = 0.622 \cdot \frac{0.016}{1 - 0.016} = 0.0101\,\text{kg/kg}.$$

Solving Eq. (15) for ϑ_K using Eq. (6) results in

$$\vartheta_K = \frac{(c_{pL} + Y_E c_{pD})\vartheta_{LE} - (Y_K - Y_E)\Delta h_{Vo}}{c_{pL} + Y_K c_{pD} - (Y_K - Y_E)c_W}$$
$$= \frac{(1 + 0.007 \cdot 1.86) \cdot 22 - (0.0101 - 0.007) \cdot 2500}{1 + 0.0101 \cdot 1.86 - (0.0101 - 0.007) \cdot 4.19}$$
$$= 14.5^\circ\text{C} \neq \vartheta_K^*.$$

The new approximation $\vartheta_K^* = 14.2^\circ$C leads to

$$p_{DS} = 0.0162\,\text{bar} \rightarrow Y_K = 0.0102\,kg/kg \rightarrow \vartheta_K = 14.1^\circ\text{C} \approx \vartheta_K^*.$$

Then, the final result is $\vartheta_K = 14.2^\circ$C and $Y_K = 0.0102$ kg/kg.

(Hint: The iteration method which uses the calculated result as new starting value is computationally unstable, therefore relaxation is applied.)

Eqs. (13), (15), and (6) finally yield

$$Y_A = 7 + 0.74 \cdot (10.2 - 7) = 9.37\ \text{g/kg}\ (\text{Eq.}(13))$$
$$h_{LA} = h_{LE} + c_W \vartheta_K (Y_A - Y_E)$$
$$= 39.37 + 4.19 \cdot 14.2 \cdot 0.00237 = 39.93\ \text{kJ/kg}\ (\text{Eq.}(15))$$
$$\vartheta_{LA} = \frac{h_{LA} - Y_A \Delta h_{Vo}}{c_{pL} + Y_A c_{pD}} = 16.2^\circ\text{C}\ (\text{Eq.}(6)).$$

The state at the outlet can be obtained directly from the h,Y-chart by marking off a segment from point LE with the length $0.74.\overline{LE, K}$ on the line of constant wet bulb temperature passing through inlet state point (ϑ_{LE}, Y_E) of the air.

3 Dehumidification

Two in principle different methods exist:

- Dehumidification by absorption or adsorption
- Dehumidification by cooling and condensation

3.1 Dehumidification by Sorption Processes

These processes utilize the ability of sorbents to bind water molecules and therefore to lower the vapour pressure below the saturation water pressure level.

Different types of sorption processes can be distinguished:

- "Liquid sorption" employs liquid sorbents which create a homogenous phase with the absorbed water vapour (absorption).
- "Solid sorption" occurs at the inner surfaces of a solid sorbent where water vapour deposits due to surface forces and creates a separate phase (adsorption).

The binding mechanisms of absorption and adsorption processes can be of chemical or physical nature. Common liquid sorbents for air dehumidification are aqueous solutions of hygroscopic salts like LiCl, LiBr and $CaCl_2$ or mixtures of these. For adsorptive air dehumidification silica gel or synthetic zeolites are used.

Adsorptive processes with silica gel or molecular sieve (zeolite) are applied preferably because of their favourable operational properties. Therefore, only air dehumidification by solid sorption is discussed in the following. Applied techniques are either packed beds of sorbent granulates (fixed bed adsorption) or rotatory adsorbers (desiccant wheels).

During fixed bed adsorption, the humid air has to pass the granulate. As the sorption capacity of the adsorbent is limited, the humidity ratio of the exhausting air flow increases after a certain time (breakdown) and dehumidification has to be stopped. The adsorbent is then regenerated by a hot air reversely flowing through the packed bed.

Desiccant wheels allow for a continuous dehumidification. For that purpose, the wheel is divided in two sectors one with a flow of humid process air and the other with a counterflow of hot regeneration air. Crucual parameters for the dehumidification performance of an adsorption device are

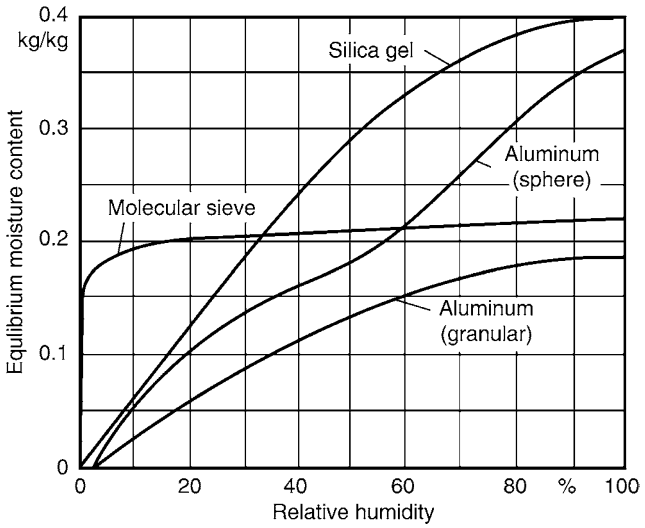
- The sorption equilibrium of sorbent and processed humid air. It defines the theoretically achievable humidity ratio and is a major basis for the dimensioning of the device.
- The sorption kinetics, i.e., the velocity of water vapour deposition inside the adsorbent. This comprises a variety of series-connected heat and mass transfer processes which prohibit deriving a simple calculation method for adsorption devices [10]. Therefore dimensioning is based on empirical data or complex numerical calculations [11, 12].

In Chap. N2, a mathematical model for the coupled heat and moisture transfer is accomplished as well. It enables predicting the process in desiccant wheels, if sorption equilibrium and the heat and mass transfer relations for the flow in the wheel matrix are known.

The sorption equilibrium is usually described by sorption isotherms. They represent the equilibrium moisture content related to the weight of unloaded sorbent in dependency on water vapour concentration or air humidity ratio. Figure 7 shows sorption isotherms of different adsorbents at a consistent temperature of 25°C. For different temperatures and a customary silica gel, the sorption isotherms are displayed in Fig. 8.

In order to calculate adsorptive dehumidification of air, plotting the equilibrium as "isosteres" (W = constant), i.e., lines of constant moisture content, proves to be helpful. Figure 9 contains exemplary isosteres of the same silica gel as in Fig. 8 for $W = 0.02$, 0.05 and 0.2 $\text{kg}_{H_2O}/\text{kg}_{adsorbent}$ in a h,Y-diagram. Using the isosteres, it is possible to determine the reachable moisture contents in case that the entry states of process air and regeneration air are known. For example, if the adsorbent is regenerated with hot air at 80°C and 15 $\text{g}_{H_2O}/\text{kg}_{adsorbent}$ the resulting equilibrium moisture content is 0.02 kg/kg. Therefore, the flow of humid process air can reach in ideal conditions an exit state that is in equilibrium with 0.02 kg/kg, thus being on the 0.02 kg/kg isostere as well.

Adsorption and desorption both occur with changes in the temperature of the air flow. The heat released during adsorption includes the binding energy in addition to the heat of condensation. It depends on the loading and amounts to, e.g., 10% of the heat of condensation in case of water vapour adsorption on silica gel. Heat releases from condensation and binding energy



M8. Fig. 7. Sorption isotherms of different sorbents at 25°C [10, 13].

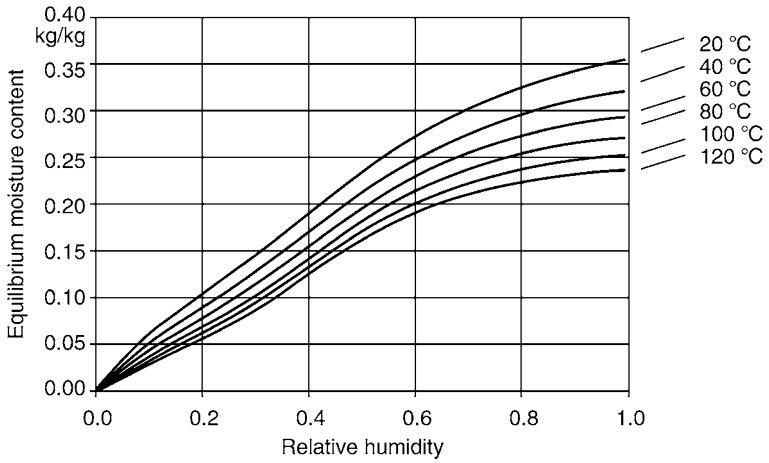
are summarized as sorption heat and cause the temperature of the humid process air to increase. Additionally, the adsorbent is heated up during regeneration and this heat is subsequently transferred to the process air flow. Analogous to the adsorption process, the desorption involves a decrease in regeneration air temperature.

In cases of technical interest (humidity ratio at inlet $Y = 5, \ldots, 15$ g/kg), the specific temperature increase due to adsorption is

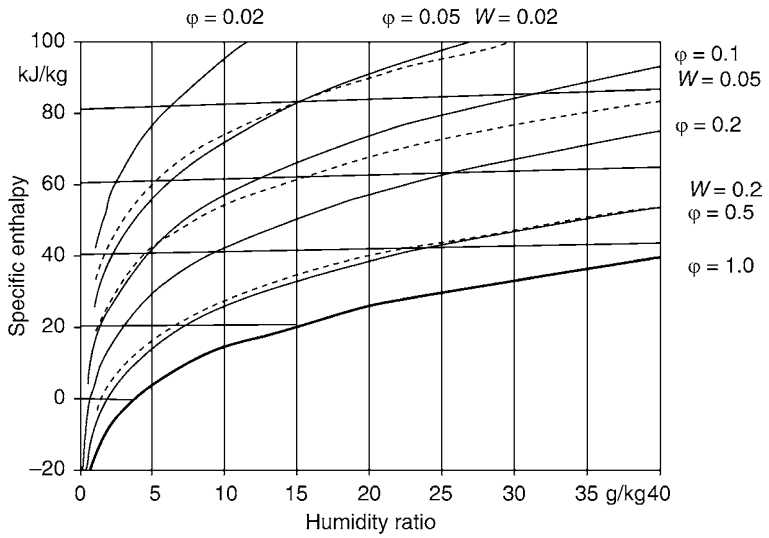
$$\frac{\Delta\vartheta}{\Delta Y} = \text{from } 3 \text{ to } -6\,\frac{K}{g/kg}.$$

Low inlet humidity ratios result in higher specific temperature increases.

Because of sorption kinetics with finite heat and mass transfer coefficients, technical adsorption devices cannot reach the state of equilibrium between air flow and sorbent. In order to estimate the influence of kinetics, *Van den Bulck* et al. [14] defined a



M8. Fig. 8. Sorption isotherms of a commercially available granular silica gel [8].



M8. Fig. 9. *h,Y*-diagram with sorption isosteres for a commercially available granular silica gel.

dehumidifying efficiency for desiccant wheels in analogy to the humidifying efficiency (Eq. 13), which relates the change in humidity ratio of a real adsorption device to the ideal case

$$\eta_E = \frac{\Delta Y_{real}}{\Delta Y_{ideal}}. \qquad (13a)$$

Figure 10 shows the interrelation between ideal dehumidification, determined by sorption equilibrium, and real dehumidification, additionally influenced by sorption kinetics. The dehumidifying efficiency at common operating conditions is about $\eta_E = 0.7–0.9$.

The dehumidification performance of an adsorption device and the achievable outlet humidity ratio depend on more than 20 parameters [15]. Hence, the interrelation between humidity ratio at air inlet and air outlet can only be graphed for one particular adsorption device and certain operation conditions. Figure 11 displays as an example the performance diagram of a customary desiccant wheel. For differing operating conditions, the dehumidification performance has to be determined either experimentally or numerically.

Applying the previously defined characteristic values, "dehumidifying efficiency" and "specific temperature increase," the operating behaviour of a desiccant wheel can be described in a simplified way. They provide an approximate conversion for differing air entry states. As a simplification for this, it is assumed that these values do not change over the considered ranges of temperature and humidity.

If no data about the sorption equilibrium are available, as a further approximation it can be assumed, that the isosteres in the h,Y-diagram are running in parallel to the lines of constant relative humidity.

Example 3a

Given:

The performance diagram according to Fig. 11 (manufacturer information) and the inlet state of process air (ϑ_E = 25°C; Y_E = 10 g/kg). Total pressure P = 1 bar.

Find:

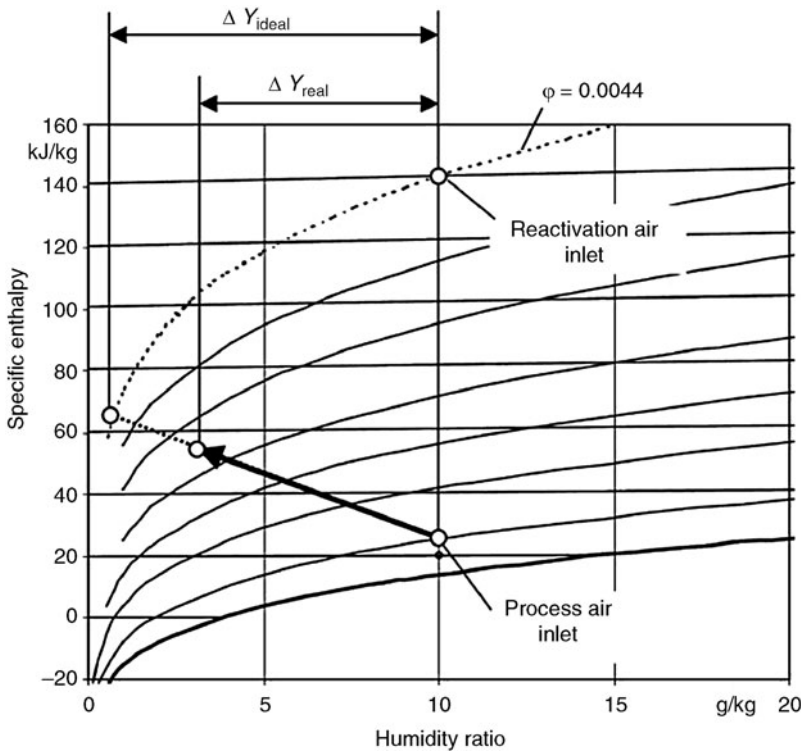
The exit state of dehumidified air (ϑ_A, Y_A).

The outlet temperature ϑ_A and the outlet humidity ratio Y_A can be taken from the diagram in Fig. 11 as: ϑ_A = 53.4°C; Y_A = 3.2 g/kg.

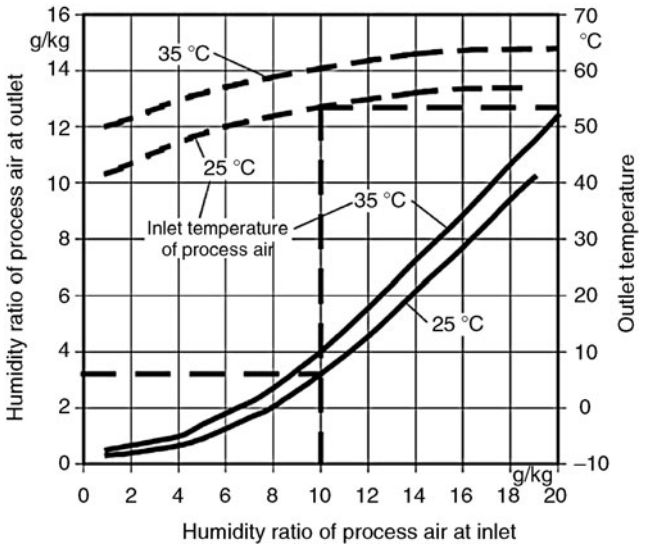
If the humidity ratio at the exit is higher than required, it is possible to lower the value of Y_A e.g., through a larger wheel. This can be only done until the limit of the "ideal" dehumidifier is reached. In order to estimate the potential of improvements, it is necessary to determine the humidity ratio at the exit for the ideal case.

As for this example, no data about the sorption equilibrium are available, except the performance diagram, the simplifying assumption is made, that the isosteres in a h,Y-diagram are running in parallel to the lines of constant relative humidity.

The dehumidification path with air inlet state (ϑ_E = 25°C; Y_E = 10 g/kg) and air outlet state (ϑ_A = 53.4°C; Y_A = 3.2 g/kg) is plotted in the h,Y-diagram. The relative humidity for the inlet



M8. Fig. 10. State change in a desiccant wheel and dehumidifying efficiency.



M8. Fig. 11. Performance diagram of a commercially available desiccant silica gel wheel for the following conditions: inlet temperature of regeneration air: 140°C, inlet humidity ratio of regeneration air = inlet humidity ratio of process air, relation of sectors regeneration air/process air t = 1:3, face velocity in front of the wheel: 3 m/s, depth of the wheel: 200 mm, wheel revolution per hour: 10 h^{-1}.

state of regeneration air (ϑ = 140°C; Y = 10 g/kg) is then determined. (Notice: The performance diagram in Fig. 11 is based on a regeneration air temperature of 140°C and the premise: humidity ratio of regeneration air = humidity ratio of process air.)

It can be taken from a corresponding h,Y- diagram or calculated from Eqs. (2) and (3) as well as a steam pressure table.

$$\varphi = \frac{P_D(Y = 10\,\text{g/kg},\ P = 1.0\ \text{bar})}{P_{DS}(\vartheta = 140°\text{C})} = \frac{P}{P_{DS}} \cdot \frac{Y}{0.622 + Y}$$
$$= \frac{1\,\text{bar}}{3.61\,\text{bar}} \cdot \frac{0.01}{0.622 + 0.01} = 0.0044.$$

If the dehumidification path is extended from state (ϑ_E; Y_E) to state (ϑ_A; Y_A) to the left, it intersects with the φ = 0.44% line at the unknown exit state of an ideal dehumidifier:

$$Y_{A\,ideal} = 0.7\,\text{g/kg};\ \vartheta_{A\,ideal} = 65°\text{C}.$$

Lines for $\varphi < 0.1$ are normally not included in the h, Y-diagrams. But they can be derived from known lines of the same relative humidity. For a given temperature ϑ = 40°C, the conversion is

$$\frac{Y_1}{Y_2} = \frac{\varphi_1}{\varphi_2} \cdot \frac{1 - \frac{\varphi_2 \cdot P_{DS}}{P}}{\frac{\varphi_1 \cdot P_{DS}}{P}}.$$

If $\varphi P_{DS} \ll P$:

$$Y_1 = Y_2 \cdot \frac{\varphi_1}{\varphi_2}$$

applies.

In the considered case, this is φ_1 = 0.1; φ_2 = 0.0044 und $Y_1 = Y(\varphi = 0.1; \vartheta = 40°\text{C})$ = 4.6 g/kg (according to Eq. (3)). Y_2 results as

$$Y_2 = 4.6\,\text{g/kg} \cdot \frac{0.0044}{0.1} = 0.2\,\text{g/kg}.$$

Converting this for several temperatures and connecting the calculated points yields a curve for φ = constant = 0.0044.

The exit state of an ideal dehumidifier can be computationally assessed only with an iterative approach. The values for $Y_{A\,ideal}$ and $\vartheta_{A\,ideal}$ have to fulfil the following conditions:

$$\vartheta_{A\,ideal} = \vartheta_E + \frac{\vartheta_A - \vartheta_E}{Y_A - Y_E} \cdot (Y_{A\,ideal} - Y_E)$$

and

$$\varphi = \frac{P_D(Y_{A\,ideal}, P_{ges} = 1.0\ \text{bar})}{P_{DS}(\vartheta_{A\,ideal})} = 0.0044.$$

Starting at an estimated value $Y^*_{A\,ideal}$<1.0 g/kg yields

$$\vartheta^*_{A\,ideal} = 25° + \frac{(53.4 - 25)\text{K}}{(2.3 - 10.0)\text{g/kg}} \cdot (1.0 - 10.0)\,\text{g/kg} = 63.7°\text{C}$$

and

$$\varphi^* = \frac{P_D(1.0\,\text{g/kg}_1, P_{gcs} = 1.0\,\text{bar})}{P_{DS}(63.7°\text{C})} = \frac{0.16\,\text{kPa}}{23.6\,\text{kPa}} = 0.0068.$$

Because of $\varphi^* > 0.0044$, *a value* $Y^*_{A\,ideal}$<1.0 g/kg has to be chosen for the next iterative step.

Example 3b

Approximated determination of the exit air humidity ratio at another entry state of regeneration air.

Given:

- Entry state of process air same as in Example 3a (ϑ_E = 25°C; Y_E = 10 g/kg)
- Entry state of regeneration air ϑ = 90°C; Y = 12 g/kg instead of ϑ = 140°C; Y = 10 g/kg as in Example 3a
- Performance diagram according to Fig. 11

Find:

Humidity ratio of process air at the exit for the changed entry state of regeneration air. Approximation based on Fig. 11.

A precise determination of the exit air humidity ratio requires a corresponding performance diagram by the manufacturer for the intended state of regeneration air.

As an approximation, the diagram in Fig. 11 can be converted for the changed state of regeneration air.

For the regeneration air state ϑ = 140°C; Y = 10 g/kg, the following values are known:

- Exit state of process air ϑ_A = 53.4°C; Y_A = 3.2 g/kg
- Dehumidifying efficiency $\eta_E = \frac{10.0 - 3.4}{10.0 - 0.7} = 0.71$
- The specific temperature increase
  $\frac{\Delta\vartheta}{\Delta Y} = \frac{53.4 - 25.0}{3.4 - 10.0} \frac{\text{K}}{\text{g/kg}} = -4.3 \frac{\text{K}}{\text{g/kg}}$

(see Example 3a). Using the simplifying assumption that the specific temperature increase and the dehumidifying efficiency

remain constant, the exit state of process air for the new state of regeneration air can be determined.

As in Example 3a, the relative humidity of the new entry state of regeneration air is calculated first:

$$\varphi = \frac{P_D(Y = 12\,\text{g/kg},\ P = 1.0\ \text{bar})}{P_{DS}(\vartheta = 90°\text{C})} = \frac{P}{P_{DS}} \cdot \frac{Y}{0.622 + Y}$$
$$= \frac{1\,\text{bar}}{0.702\ \text{bar}} \cdot \frac{0.012}{0.622 + 0.012} = 0.027.$$

The exit state of process air in an ideal dehumidifier can be obtained as in Example 3a either graphically from the h, Y-diagram or numerically. The values of $Y_{A\ ideal}$ and $\vartheta_{A\ ideal}$ have to fulfil the following conditions:

$$\vartheta_{A\,ideal} = 25°\text{C} - 4.3\frac{\text{K}}{\text{g/kg}} \cdot (Y_{A\,ideal} - Y_E)$$

and

$$\varphi = \frac{P_D(Y_{A\,ideal}, P_{ges} = 1.0\,\text{bar})}{P_{DS}(\vartheta_{A\,ideal})} = 0.027.$$

The outlet state of process air in ideal dehumidification conditions is determined as

$$Y_{A\,ideal} = 2.8\ \text{g/kg};\ \vartheta_{A\,ideal} = 56°\text{C}.$$

The dehumidifying efficiency then yields the outlet air humidity ratio of the real dehumidifier:

$$Y_{A\,real} = Y_E - \eta_E(Y_E - Y_{A\,ideal})$$
$$= 10.0 - 0.71(10.0 - 2.8)\ \text{g/kg} = 4.9\ \text{g/kg}.$$

The real outlet air temperature of the process air results as

$$\vartheta_{A\,real} = \vartheta_E + \frac{\Delta\vartheta}{\Delta Y} \cdot (Y_{A\,real} - Y_E)$$
$$= 25°\text{C} - 4.3\frac{\text{K}}{\text{g/kg}} \cdot (4.9 - 10.0)\,\text{g/kg} = 46.9°\text{C}.$$

3.2 Dehumidification by Cooling

Air drying is usually carried out in surface coolers, which have their surface temperature decreased below the dew point by a coolant (water, brine) or an evaporating refrigerant. Coolers are usually constructed as extended surface heat exchangers with the process air on the outside of the finned pipes. The circular or continuous plate finned pipes have to be arranged in a way that allows the condensate to drain off easily. If the heat exchanger surface is cooled below 0°C, water vapour precipitates as ice or frost. Thus, lower humidity ratios are achievable; however, the cooler has to be defrosted in regular time intervals when the flow resistance has to become high. Such operating conditions will not be considered in this chapter.

Dimensioning air coolers can be accomplished with two methods: either using computer-based numerical simulations of the air flow along the single pipe rows [16, 17] or integral calculations which divide the cooler into a "dry" section, where only sensible heat is transferred and a "wet" section, which includes simultaneous water vapour condensation as well [18]. Comparisons with comprehensive experimental results realized on serial-production coolers show that the differences between the dimensioning methods are in the range of general uncertainties [17]. Therefore, the integral method, which offers easier handling and is based on the American ARI-Standard 410–8, is described in the following:

The substantial assumptions being the basis of this method are:

- The Lewis factor (Eq. (14)) equals to one.
- The heat transfer coefficient for the sensible heat flux on the air side, abbreviated "dry" heat transfer coefficient α_{dry} in the following, is not changing due to retained water. Condensed water causes opposing effects which more or less compensate each other or only cause effects in the range of measurement and numeric inaccuracy [17, 19].

  The precision of the air cooler calculation crucially depends on the dry heat transfer characteristic. The multitude of existing geometric variations regarding finned tube systems makes it necessary to thoroughly examine the conformity with the ascertained system when using literature sources. Differences between systems can result in considerable errors. If possible, an experimentally determined heat transfer correlation tailored to the particular system should be applied and only, if not available, another adequate formula from literature, e.g., Chap. M1, should be used.

- Although the heat transfer coefficient α_{dry} is changing along the fins as well as from one transverse tube row to another, it is assumed constant and equal to the average heat transfer coefficient. The error thus introduced is justifiable [16, 17, 19].
- The logarithmic averaged mean temperature difference is used as a driving force. This has proven feasible for operating conditions being used for air dehumidification even if the flow arrangement differs from pure countercurrent or parallel flow conditions, such as cross-current flow or co-cross flow setups [17].

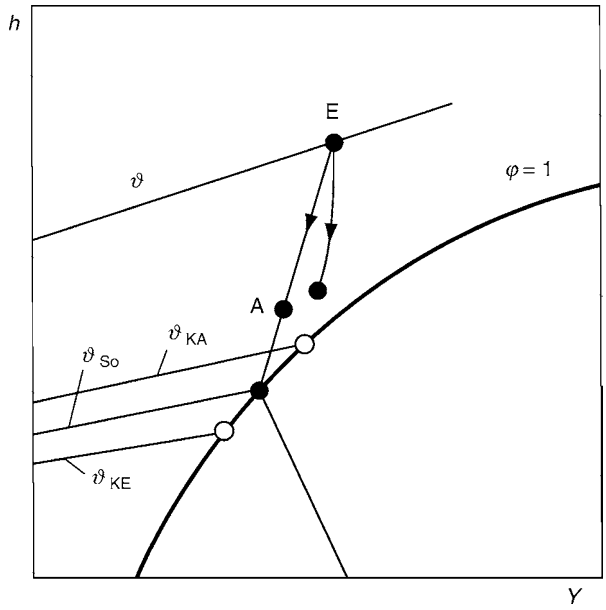
Assuming the validity of $\alpha/(\beta_Y c_{p_{1+Y}}) = 1$ as well as constant temperature at the surface of the cooler, an energy and mass balance yields the state change of the air as

$$\frac{dh}{dY} = \frac{h - h_{So}}{Y - Y_{So}} \tag{19}$$

i.e., it runs linearly in the h,Y-diagram pointing towards the state of saturation at the surface temperature of the cooler ϑ_{So}. In reality, the surface temperature changes due to the limited coolant flow rate. This results in a curved progression of the state of the air according to Fig. 12.

At this point, two tasks arise:

1. Presetting the air mass flow $\dot{M}_L$ together with the state at entry and exit, (Y_E, ϑ_{LE}) and (Y_A, ϑ_{LA}), coolant flow rate $\dot{M}_K$, the inlet temperature of coolant ϑ_{KE}, the cross-section of the coil $B{\cdot}H$ and the type of the heat exchanging system. Then, the surface area of the coil A_{WT}, respectively, the number of pipe rows n_l in the air flow direction is to be determined.



M8. Fig. 12. Air cooling process inside a cooler at constant and at variable surface temperature.

2. Presetting $\dot{M}_L$, Y_E, ϑ_{LE}, $\dot{M}_K$, ϑ_{KE} and the complete dimensions of the cooling coil, consecutively calculating the air exit state (Y_A, ϑ_A) and the exit temperature of the coolant ϑ_{KA}.

As the first mentioned task specifies fixed exit states, the calculation requires less iteration. Therefore it is utilized to illustrate the necessary steps.

Determining the total heat flux and the exit temperature of the coolant

$$\dot{Q} = \dot{Q}_{dry} + \dot{Q}_{wet} = \dot{M}_L \cdot (h_{LE} - h_{LA}) \tag{20}$$

$$\vartheta_{KA} = \frac{\dot{Q}}{\dot{M}_K \cdot c_K} + \vartheta_{KE}. \tag{21}$$

Boundary conditions between dry and wet section

The boundary between the dry and the wet surface region is defined by the constraint that at this point the average surface temperature of the coil ϑ_{SmG} equals the dew point temperature corresponding to the air entry state in case of counterflow or equals the dew point temperature corresponding to the air exit state in case of parallel flow:

$$\begin{aligned} &\vartheta_{SmG} = \vartheta_{LE} \text{ and } h_{SmG} = h\{\vartheta_{LE_\tau}, \varphi = 1\} \text{ at counter flow} \\ &\vartheta_{SmG} = \vartheta_{LA} \text{ and } h_{SmG} = h\{\vartheta_{LA_\tau}, \varphi = 1\} \text{ at parallel flow.} \end{aligned} \tag{22}$$

Local balances yield enthalpy and temperature of the air, h_{LG} und ϑ_{LG}, the temperature of the coolant ϑ_{KG} as well as the pipe surface temperature ϑ_{SoG} at this point:

$$\begin{aligned} h_{LG} &= \frac{\vartheta_{LE_\tau} - \vartheta_{KA} + K \cdot h_{LE} + C \cdot h_{SmG}}{C + K} \text{ counter flow} \\ h_{LG} &= \frac{\vartheta_{LA_\tau} - \vartheta_{KA} + K \cdot h_{LA} + C \cdot h_{SmG}}{C - K} \text{ parallel flow} \end{aligned} \tag{23}$$

$$\vartheta_{LG} = \vartheta_{LE} - \frac{h_{LE} - h_{LG}}{c_{pL} + Y_E \cdot c_{pD}} \text{ counter flow}$$

$$\vartheta_{LG} = \vartheta_{LA} - \frac{h_{LA} - h_{LG}}{c_{pL} + Y_A \cdot c_{pD}} \text{ parallel flow} \tag{24}$$

$$\vartheta_{KG} = \vartheta_{LE_\tau} - C \cdot (h_{LG} - h_{SmG}) \text{ counter flow}$$

$$\vartheta_{KG} = \vartheta_{LA_\tau} - C \cdot (h_{LG} - h_{SmG}) \text{ parallel flow} \tag{25}$$

$$\vartheta_{SoG} = \vartheta_{KG} + \frac{W_K + W_W}{W_K + W_W + W_R}(\vartheta_{LE_\tau} - \vartheta_{KG}) \text{ counter flow}$$

$$\vartheta_{SoG} = \vartheta_{KG} + \frac{W_K + W_W}{W_K + W_W + W_R}(\vartheta_{LA_\tau} - \vartheta_{KG}) \text{ parallel flow} \tag{26}$$

$$with\ K = \frac{\dot{M}_L}{\dot{M}_K \cdot c_K} \text{ and } C = \frac{W_R + W_W + W_K}{c_{p_{1+Y}} W_L}. \tag{27}$$

Applied herein are the following values, which are all related to the total surface area on the air side of the heat exchanger A_{WT}:

	$W_L = 1/\alpha_{dry}$	"Dry" heat transfer resistance on the air side
	$W_R = W_L \frac{1-\psi}{\psi} \frac{c_{p_{1+Y}}}{b}$ (28)	Fin thermal resistance
	$W_W = \frac{A_{WT} \ln \frac{d_a}{d_i}}{2\pi\lambda_W L} \approx \frac{A_{WT}\delta_W}{\pi d_i L \lambda_W}$	Thermal resistance of the prime tube wall
	$W_K = \frac{A_{WT}}{\alpha_K A_K}$	Heat transfer resistance on coolant side
Where		
	$b = \frac{\partial h_S}{\partial \vartheta_S}$	Slope of saturation line $h\{\vartheta_\tau, \varphi = 1\}$ at the mean coil surface temperature $(\vartheta_{Sm} + \vartheta_{So})/2$ Eq. (43)
	$\psi = \frac{A_B + \eta_R A_R}{A_{WT}}$	Total surface effectiveness
	$\eta_R = \frac{\tanh(mH_{R,eq})}{mH_{R,eq}}$ (29)	Fin efficiency
	$m = \sqrt{\frac{2\alpha_{dry}}{\delta_R \lambda_R} \cdot \frac{b}{c_{p_{1+Y}}}}$ (30)	Fin parameter
	$H_{R,\,eq}$	Equivalent fin heigth (see Chap. M1, Eq. (8)).

For the dry section of the cooler

$$W_{R_{dry}} = W_L \cdot \frac{1 - \psi}{\psi}$$

and

$$m = \sqrt{\frac{2\alpha_{dry}}{\lambda_R \delta_R}} \tag{31}$$

apply.

Heat transfer rate and total surface area for heat transfer in the dry surface region

$$\begin{aligned} \dot{Q}_{dry} &= \dot{M}_L \cdot (h_{LE} - h_{LG}) \text{ counter flow} \\ \dot{Q}_{dry} &= \dot{M}_L \cdot (h_{LG} - h_{LA}) \text{ parallel flow} \end{aligned} \tag{32}$$

$$A_{dry} = \frac{\dot{Q}_{tr}(W_L + W_{R_{dry}} + W_W + W_K)}{\Delta\vartheta_{In}} \tag{33}$$

where

$$\Delta\vartheta_{In} = \frac{(\vartheta_{LE} - \vartheta_{KA}) - (\vartheta_{LG} - \vartheta_{KG})}{\ln\frac{\vartheta_{LE}-\vartheta_{KA}}{\vartheta_{LG}-\vartheta_{KG}}} \text{ counter flow}$$

and

$$\Delta\vartheta_{In} = \frac{(\vartheta_{LG} - \vartheta_{KG}) - (\vartheta_{LA} - \vartheta_{KA})}{\ln\frac{\vartheta_{LG}-\vartheta_{KG}}{\vartheta_{LA}-\vartheta_{KA}}} \text{ parallel flow.} \tag{34}$$

Surface area for heat transfer in the wet surface region as well as total surface area of the coil and the required number of cooling tube rows respectively

$$\dot{Q}_{wet} = \dot{Q} - \dot{Q}_{dry} \tag{35}$$

$$A_{wet} = \frac{\dot{Q}_{wet} \cdot W_L c_{p_{1+Y}}}{\Delta h_{In}} \tag{36}$$

where

$$\Delta h_{In} = \frac{(h_{LG} - h_{SmG}) - (h_{LA} - h_{SmA})}{\ln\frac{h_{LG}-h_{SmG}}{h_{LA}-h_{SmA}}} \text{ counter flow}$$

$$\Delta h_{In} = \frac{(h_{LE} - h_{SmE}) - (h_{LG} - h_{SmG})}{\ln\frac{h_{LE}-h_{SmE}}{h_{LG}-h_{SmG}}} \text{ parallel flow} \tag{37}$$

and

$$c_{P1+Y} = c_{pL} + \frac{1}{2}(Y_E + Y_A)c_{pD}.$$

Determination of the saturation enthalpy at mean coil surface temperature

In order to evaluate Eq. (37), the saturation enthalpy corresponding to the average surface temperature either at the exit or entry of the coil is required. It results from a local balance at the appropriate position Z, that is, the air exit in the case of counter flow and the air entry in the case of parallel flow, according to Fig. 13:

$$h_{SmZ} = h_{LZ} + \frac{\vartheta_{KZ} - \vartheta_{SmZ}}{C} \tag{38}$$

with C from Eq. (27) in connection with the saturation enthalpy $h_{SmZ} = h\{\vartheta_{SmZ}, Y_{SZ}\}$.

With the following approximation for the vapour pressure curve which has an accuracy of 0.1% throughout the range $0 \le \vartheta_S \le 60°C$

$$\frac{p_{DS}}{\text{bar}} = 10^{-3} \cdot 10^{8.3246 - \frac{1799.73}{\frac{\vartheta_S}{°C} + 238.734}} \tag{39}$$

and

$$h_S = c_{pL}\vartheta_S + Y_S(\Delta h_{Vo} + c_{pD}\vartheta_S)$$

as well as

$$Y_S = 0.622\frac{p_{DS}}{p - p_{DS}}$$

it is possible to determine h_{SmZ} iteratively when setting $\vartheta_S = \vartheta_{SmZ}$ and $Y_S = Y_{SZ}$. Into the value C of Eq. (38) defined in Eq. (27), the slope b enters according to Eq. (28). Strictly speaking, the determination of the slope b would have been established at point Z. But on the other hand Eq. (36) and Eq. (37) are coming off Eq. (38) assuming a constant gradient averaged between points G and Z, this value is applied as well when calculating h_{SmZ}. In practice, the real impact of the variation in slope b is not important. As a consequence, the following is valid:

$$b = \frac{h_{SmG} - h_{SmZ}}{\vartheta_{SmG} - \vartheta_{SmZ}}. \tag{40}$$

The calculation becomes a little simpler yet sufficiently precise, if the line of saturation is linearized around ϑ_{SmZ}:

$$h_{SmZ} = a + b\,\vartheta_{SmZ}. \tag{41}$$

Thus, using Eq. (38) h_{SmZ} can be obtained from

$$h_{SmZ} = \frac{\vartheta_{KZ} + Ch_{LZ} + \frac{a}{b}}{C + \frac{1}{b}}. \tag{42}$$

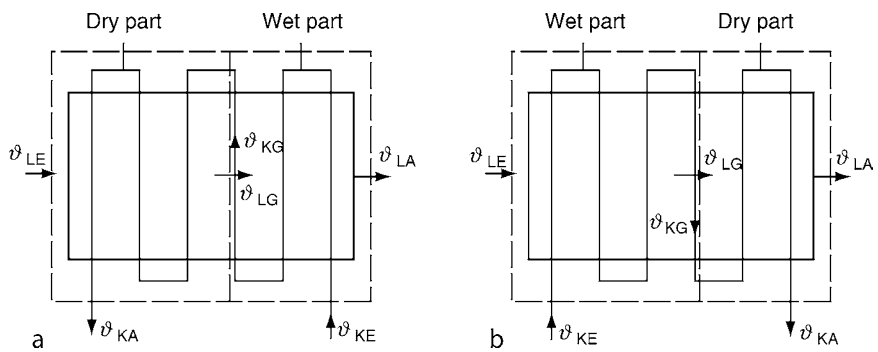
With a given type of cooling coil, i.e., known heat exchanger surface per pipe row A_{WT}/n_l, the required number of pipe rows n_l results from

$$n_l = \frac{A_{WT}}{A_{WT}/n_l}$$

with

$$A_{WT} = A_{dry} + A_{wet}.$$

In general, the resulting number of tube rows will not be an integer making it necessary to round the value up or down. The consecutive calculation then equals the second task where the surface of the cooling coil is known and the air exit state has to be determined. This requires the iteration over the whole procedure in case of counterflow because the exit temperature of



M8. Fig. 13. Temperature distribution: (**a**) cross-counterflow, (**b**) co-cross flow.

the coolant has to be estimated at first. If the altered coil surface shall still achieve the initially given air exit state, an additional adjustment, e.g., by changing the coolant's entry temperature is possible; however, this implies a further iterative step.

Slope b, included in resistance W_R, Eq. (28), and fin parameter m, Eq. (30), of the wet section of the coil, can be likewise expressed by linearizing the saturation line around temperature ϑ_{Sm} or by using the following correlation together with Eqs. (3) and (39):

$$b = c_{pL} + Y_S c_{pD} + 3.7 Y_S (0.622 + Y_S) \times \frac{1799.7}{\left(\frac{\vartheta_S}{°C} + 238.7\right)^2} \left(\Delta h_{vo} + c_{pD} \vartheta_s\right). \quad (43)$$

If solely the humidity ratio at the coil exit Y_A is given and the air exit temperature can adjust freely, the whole coil is conveniently operated below the air dew point. In this case, the calculation is considerably simplified. The states at the surface of the cooler are then known both at air entry and air exit. An integral balance around the cooler and a local balance at either entry or exit yield the initially unknown air exit enthalpy

$$h_{LA} = \frac{\vartheta_{LE} + (K + C) \cdot h_{LE_\tau} - C \cdot h_{SmE}}{K} \text{ counter flow}$$
$$h_{LA} = \frac{-\vartheta_{KE} - (K \cdot h_{LE} + \vartheta_{LA_\tau} + C \cdot h_{SmA}}{C - K} \text{ parallel flow.} \quad (44)$$

Herewith and using Eqs. (38) and (39), the mean driving force is determined according to Eq. (37):

$$\Delta h_{ln} = \frac{(h_{LE} - h_{SmE}) - (h_{LA} - h_{SmA})}{\ln \frac{h_{LE} - h_{SmE}}{h_{LA} - h_{SmA}}}. \quad (45)$$

The necessary cooling surface $A_{WT} = A_{wet}$ then results from Eq. (36).

Determining the air exit temperature

This problem occurs when solving the second task. The calculation procedure provides at first only the air enthalpy at the exit h_{LA}. Using this value in a total balance on the air side yields the average effective saturation enthalpy at the coil surface

$$h_{Sm} = h_{LE} - \frac{h_{LE} - h_{LA}}{1 - e^{-\kappa}}$$
$$\kappa = \frac{A_{WT}}{\dot{M}_L c_{p_{1+Y}} W_L}. \quad (46)$$

The corresponding effective surface temperature of the coil can then be determined iteratively from Eq. (39). Consecutively, the temperature at the air exit is given in an analogous manner as Eq. (46):

$$\vartheta_{LA} = \vartheta_{Sm} + (\vartheta_L - \vartheta_{Sm}) e^{-\kappa}. \quad (47)$$

Figure 14 depicts a flow chart of the calculation procedure for both tasks.

Example 4

Given:

Plate-fin-tube cooling coil in a cross counterflow setup as illustrated in Fig. 15.

Inside diameter of tube d_i = 12.4 mm

Outside diameter of tube d_a = 13.2 mm

Thermal conductivity of the tubes λ_W = 372 W/m K

Longitudinal tube spacing s_l = 27.8 mm

Transverse tube spacing s_q = 31.6 mm

Fin thickness δ_R = 0.15 mm

Fin pitch t_R = 2.4 mm

Thermal conductivity of the fins λ_R = 190 W/m K

Number of transverse tubes n_q = 22

Coil cross section B · H = 0.92 · 0.7 m^2

Heat transfer law on air side: As justified at the beginning of this subchapter, the calculation utilizes an empirical correlation for the considered system of finned tubes [17].

$$\frac{Nu}{Re\,Pr} = \frac{\alpha_L}{c_p u_{max}} = 0.2 Re^{-0.306}$$

where $Re = \frac{u_{max} l_{fcl}}{\nu}$, l_{fcl} as contact length in flow direction (see Chap. M1) and u_{max} being the face velocity at the minimum flow area.

Mass flow rates and thermodynamic states:

$$\dot{M}_L = 2.2 kg/s; \vartheta_{LE} = 32°C; Y_E = 0.015 kg/kg;$$
$$h_{LE} = 70.39 kJ/kg; \vartheta_{LA} = 17°C;$$
$$Y_A = 0.012 kg/kg; h_{LA} = 47.38 kJ/kg.$$

Coolant water: $\dot{M}_K$ = 1.6 kg/s; ϑ_{KE} = 7°C.

Total pressure: p = 1.013 bar.

Calculate:

Heat transfer area A_{WT}, number of transverse tube rows n_l.

Total heat transfer rate, Eq. (20): $\dot{Q}_K = 2.2 \cdot 23 = 50.62$ kW

Temperature of coolant at exit, Eq. (21):

$$\vartheta_{KA} = \frac{50.62}{1.6 \cdot 4.19} + 7 = 14.55°C$$

State at dry-wet boundary, Eq. (22): ϑ_{SmG} = 20.3°C; h_{SmG} = 58.37 kJ/kg.

Air side heat transfer coefficient:

Contact length in flow direction according to Chap. M1:

$$l_{fcl} = \frac{\pi}{2} \sqrt{d_a^2 + \left(s_q \cdot \sqrt{\frac{1}{\pi} \cdot \frac{s_l}{s_q}} - \frac{d_a}{2}\right)^2} = 0.026 m$$

average density, Eq. (4):

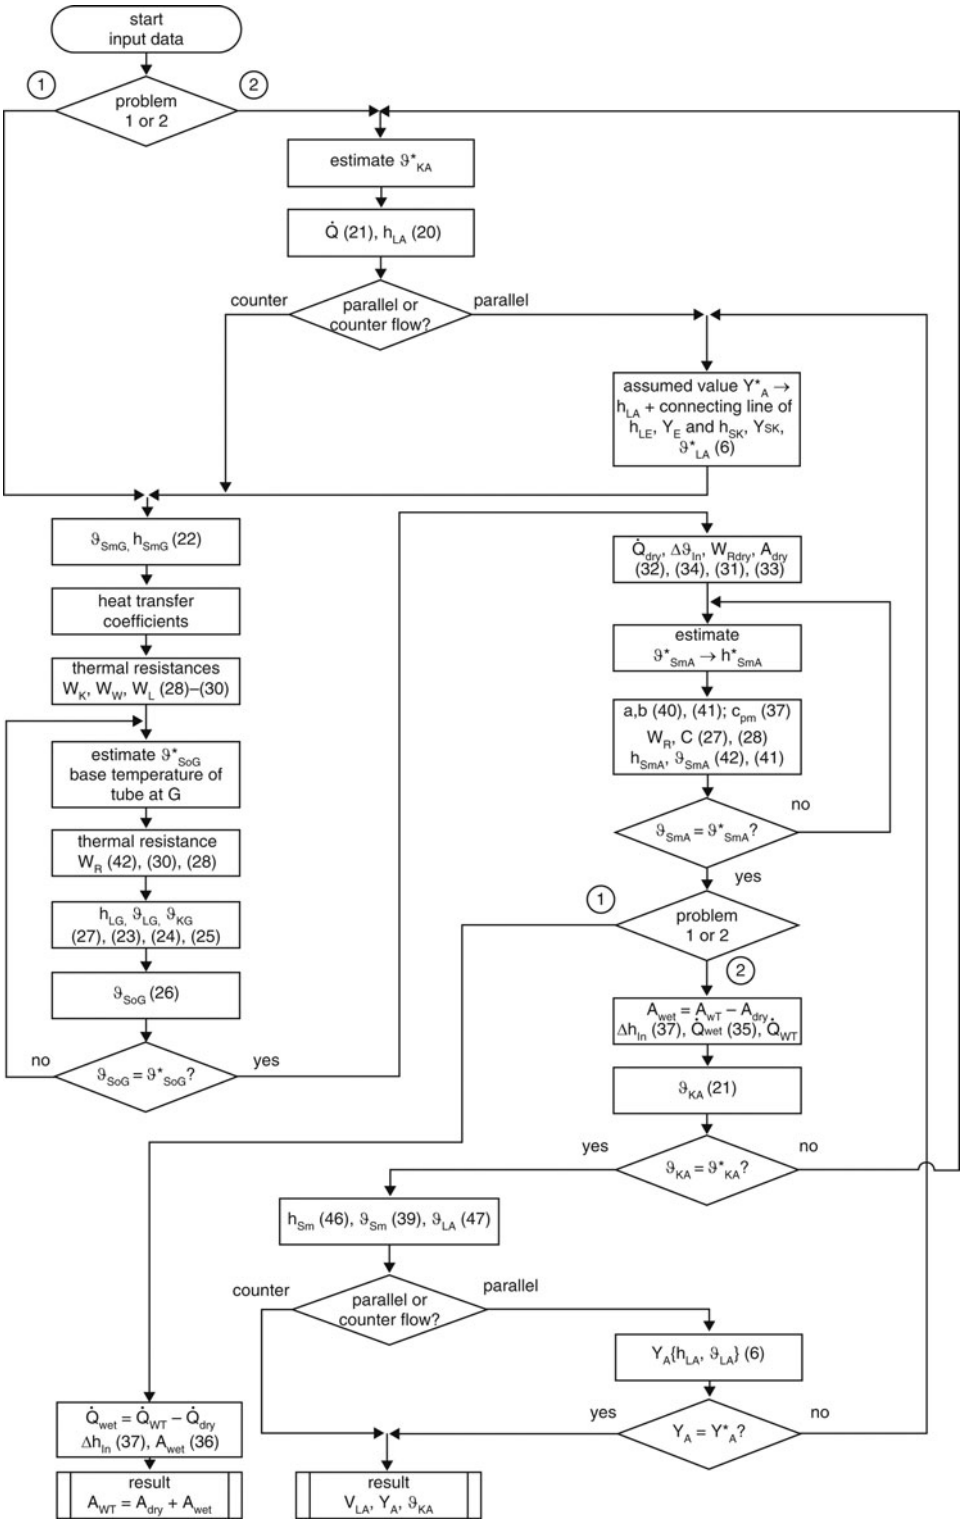
$$\rho_L = \frac{101300}{287 \cdot 297.5} \cdot \frac{1 + 0.0135}{1 + 461/287 \cdot 0.0135} = 1.18 kg/m^3$$

air velocity:

$$u_L = \frac{\dot{M}_L (1 + Y_E)}{B \cdot H \rho_L} = \frac{2.2 \cdot 1.015}{0.92 \cdot 0.7 \cdot 1.18} = 2.95 m/s$$

face velocity at the minimum flow area:

$$u_{L,max} = \frac{u_L}{1 - \frac{d_a}{s_q} - \left(1 - \frac{d_a}{s_q}\right) \frac{\delta_R}{t_R}} = 5.4 m/s$$
$$Re = \frac{u_{L,max} l_{fcl} \rho_L}{\eta_L} = \frac{5.4 \cdot 0.026 \cdot 1.18}{18.45 \cdot 10^{-6}} = 8980$$
$$\alpha_L = \alpha_{dry} = 0.2 \cdot Re^{-0.306} \cdot \rho_L c_{p_{1+Y_m}} \cdot u_{L,max}$$
$$= 0.012 \cdot 1.18 \cdot 1025 \cdot 5.4 = 80 W/m^2 K$$



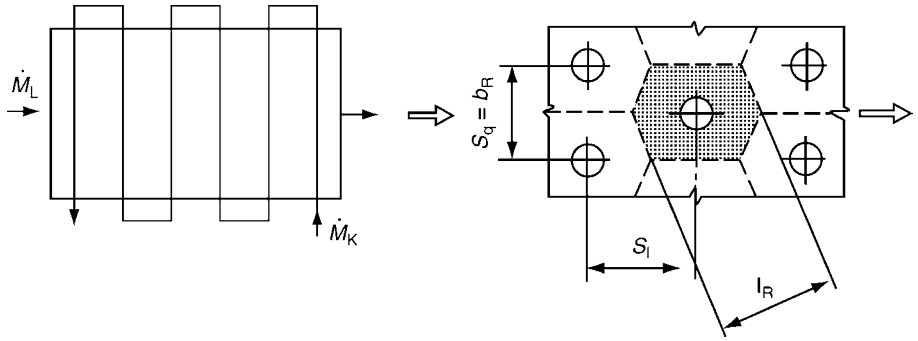
M8. Fig. 14. Flow sheet of the calculating procedure for an air cooler (brackets contain equation numbers).

Water side heat transfer coefficient:

$$\mathrm{Re_K} = \frac{4\dot{M}_K}{\pi d_i n_q \eta_K} = \frac{4 \cdot 1.6}{\pi \cdot 0.0124 \cdot 22 \cdot 0.00128} = 5834.$$

According to ◉ Chap. G1, Eq. (39), applies

$$Nu_K = 0.012(\mathrm{Re}^{0.87} - 280) \cdot \mathrm{Pr}^{0.4}(1 + (d_i/L)^{2/3})$$
$$= 0.012(5834^{0.87} - 280) \cdot 9.3^{0.4}(1 + (0.0124/0.92)^{2/3}) = 49.8$$
$$\alpha_K = \frac{\lambda_K Nu_K}{d_i} = \frac{0.58 \cdot 49.8}{0.00124} = 2335\ \mathrm{W/m^2K}$$



M8. Fig. 15. Schematic flow arrangement and piping layout (staggered tubes).

Heat transfer resistances Eqs. (27–29):

$$\frac{A_R}{n_l} = 2.\frac{B}{t_R}.\left(s_l H - n_q \frac{\pi d_a^2}{4}\right)$$
$$= 2.\frac{0.92}{0.0024}.\left(0.0278\cdot 0.7 - 22\frac{\pi\cdot 0.0132^2}{4}\right)$$
$$= 12.61\,\mathrm{m^2/transverse\ tube\ row}$$

$$\frac{A_{WT}}{n_l} = \frac{A_R + A_B}{n_l} = 13.4\,\mathrm{m^2/transverse\ tube\ row}$$

$$\frac{A_B}{n_l} = n_q.\pi d_a.B.\left(1 - \frac{\delta_R}{t_R}\right) = 0.79\ \mathrm{m^2/transverse\ tube\ row}$$

$$\frac{A_K}{n_l} = n_q.\pi d_i.B = 0.79\ \mathrm{m^2/transverse\ tube\ row}$$

$$W_K = \frac{1}{2335}.\frac{13.4}{0.79} = 0.0073\ \mathrm{m^2K/W}$$

$$W_L = \frac{1}{\alpha_L} = 0.0125\ \mathrm{m^2K/W}$$

$$W_W = \frac{A_{WT}\delta_W}{n_l n_q \pi d_i B \lambda_W} = \frac{13.4\cdot 0.0004}{22\cdot\pi\cdot 0.0124\cdot 0.92\cdot 372}$$
$$= 0\cdot 000018\ \mathrm{m^2K/W}.$$

Equivalent fin height: According to Chap. M1, Eq. (14), the initial result using

$$b_R = s_q \text{ and } l_R = \sqrt{s_l^2 + \left(\frac{s_q}{2}\right)^2}$$

is corresponding to Fig. (15)

$$\varphi' = 1.27\frac{b_R}{d}\sqrt{\frac{l_R}{b_R} - 0.3} = 1.27.\frac{s_q}{d_a}.\sqrt{\sqrt{\left(\frac{s_l}{s_q}\right)^2 + 0.25} - 0.3} = 2.57.$$

The equivalent fin height then equals according to Chap. M1, Eq. (12), together with Chap. M1, Eq. (8),

$$H_{R.eq} = \frac{d_a}{2}.(\varphi' - 1).(1 + 0.35.\ln\varphi') = 0.0137\,\mathrm{m}.$$

Now, the slope of the saturation line

$$b\left\{\frac{\vartheta_{SmG} + \vartheta_{SoG}}{2}\right\}$$

as well as c_p at the dry-wet boundary G is calculated.

As the temperature ϑ_{SoG} is unknown up to this point, it has to be estimated at first. A value $\vartheta_{SoG} < 20.3°C$ is expected. To shorten the process of calculation, the example continues using the iteration result $\vartheta^*_{SoG} = 18.3°C$ as initial value.
Then, from Eqs. (39) and (3) follows $Y_{SoG} = 0.0132$ kg/kg and hence using Eq. (43)

$$b = 1 + 1.86\cdot 0.0141 + 3.7\cdot 0.0141(0.622 + 0.0141)\cdot$$
$$\frac{1799.7}{(19.3 + 238.7)^2}(2500 + 1.86\cdot 19.3) = 3.3\,\mathrm{kJ/kg\ K}.$$

The specific heat capacity of humid air at the dry-wet boundary G is:

$$c_{p_{1+Y}} = c_{pL} + Y_G\cdot c_{pD} = 1 + 0.015\cdot 1.86 = 1.028\,\mathrm{kJ/kg\ K}.$$

Fin efficiency according to Eqs. (30) and (29):

$$m_{wet} = \sqrt{\frac{2\cdot 80\cdot 3.3}{0.00015\cdot 190\cdot 1.028}} = 134.2\mathrm{m^{-1}}$$

$$\eta_{Rwet} = \frac{\tanh(134.2\cdot 0.0137)}{134.2\cdot 0.0137} = 0.52.$$

Fin thermal resistance according to Eq. (28):

$$\psi_{wet} = \frac{0.79 + 0.52\cdot 12.61}{13.4} = 0.545$$

$$W_{Rwet} = 0.0125\cdot\frac{1 - 0.545}{0.545}\cdot\frac{1.028}{3.32} = 0.0032\,\mathrm{m^2K/W}.$$

State variables at the dry-wet boundary G:
Eq. (27) gives

$$K = \frac{2.2}{1.6\cdot 4.19} = 0.328\,\mathrm{kg\ K/kJ}$$

and

$$C = \frac{0.0032 + 0.000018 + 0.0073}{1.028\cdot 0.0125} = 0.82\ \mathrm{kg\ K/kJ}.$$

Eq. (23) yields:

$$h_{LG} = \frac{20.3 - 14.55 + 0.328\cdot 70.39 + 0.82\cdot 58.37}{0.82 + 0.328} = 66.81\,\mathrm{kJ/kg}$$

Temperature results are $\vartheta_{LG} = 28.5°C$ from Eq. (24) and $\vartheta_{KG} = 13.4°C$ from Eq. (25).

Recomputing of the initially estimated tube base temperature at the dry-wet boundary yields, using Eq. (26),

$$\vartheta_{SoG} = \frac{W_W + W_K}{W_W + W_K + W_{Rwet}} (\vartheta_{LE_\tau} - \vartheta_{KG}) + \vartheta_{KG} = 18.2°C.$$

The result agrees well with the estimated value.

Heat transfer rate and heat transfer area of the dry section:
Eq. (32) provides

$$\dot{Q}_{dry} = 2.2(70.39 - 66.81) = 7.88\,kW$$

and according to Eq. (34) is

$$\Delta\vartheta_{ln} = \frac{32 - 14.55 - (28.5 - 13.4)}{\ln\frac{32-14.55}{28.5-13.4}} = 16.25\,K.$$

From Eq. (31) follows:

$$m_{dry} = 74.93 m^{-1};\ m_{dry} H_{Req} = 1.019;\ \eta_{Rdry} = 0.76;$$
$$\psi = 0.77 \text{ and } W_{Rdry} = 0.0037 m^2 K/W.$$

Eq. (33) results in

$$A_{dry} = \frac{7880 \cdot (0.0125 + 0.0037 + 0.000018 + 0.0073)}{16.25} = 11.4\ m^2$$

and consecutively

$$n_{ldry} = \frac{A_{dry}}{A_{WT}/n_l} = 0.85.$$

The cooler thus comprises one pipe row which remains dry.

Saturation enthalpy at the exit:
The calculation of h_{SmA} has to be done iteratively as well. The corresponding saturation temperature ϑ_{SmA} will be between ϑ_{KE} = 7°C and ϑ_{LA} = 17°C, tending towards ϑ_{LA} because of the thermal resistance relationships. Again, an initial estimate, that equals the iterative result within an acceptable tolerance, is used for brevity.

With ϑ^*_{SmA} = 13.8°C, Eq. (39) gives h^*_{SmA} = 38.65 kJ/kg. The constants a and b, which linearize the saturation line between ϑ_{SmG} and ϑ_{SmA} according to Eqs. (40) and (41), then result in $a = -3.22$ and $b = 3.03$.

The value of C from Eq. (27) remains virtually unaltered. In the expression of C, slope b merely enters as a parameter of the thermal resistance W_R. The latter changes to W_{Rwet} = 0.0033 m^2K/W according to Eq. (28), using m_{wet} = 128.6 m^{-1} from Eq. (30), η_{Rwet} = 0.54 from Eq. (29) and Ψ_{wet} = 0.56 from Eq. (28). Hence C = 0.826 kg K/kJ.
Eq. (42) gives

$$h_{SmA=} \frac{7 + 0.826 \cdot 47.38 - 3.22/3.03}{0.826 + 1/3.03} = 39\,kJ/kg$$

and Eq. (41) results in

$$\vartheta_{SmA} = \frac{39 + 3.22}{3.03} = 13.9°C \approx \vartheta^*_{SmA}.$$

Total heat exchanger area and number of transverse pipes rows respectively:

From Eq. (35) results

$$\dot{Q}_{wet} = \dot{Q} - \dot{Q}_{dry} = 42.7\,kW$$

and using Eq. (37)

$$\Delta h_{ln} = \frac{(66.81 - 58.37) - (47.38 - 39)}{\ln\frac{66.81-58.37}{47.38-39}} = 8.41\,kJ/kg.$$

From Eq. (36) then it is obtained

$$A_{wet} = \frac{42700 \cdot 0.0125 \cdot 1.025}{8.41} = 65.1\ m^2.$$

This concludes in

$$n_{lwet} = \frac{A_{wet}}{A_{WT}/n_l} = 4.9.$$

The total heat exchanger area then becomes

$$A_{WT} = 11.4 + 65.1 = 76.5\ m^2$$

and the total number of transverse tube rows

$$n_l = \frac{A_{WT}}{A_{WT}/n_l} = \frac{76.5}{13.4} = 5.7, \text{ i.e., } 6 \textit{ tube rows}$$

4 Symbols

A	m^2	Heat transfer area
C	kg K/J	Operand according to Eq. (27)
$H_{R,eq}$	m	Fin height, equivalent fin height
K	kg K/J	Operand according to Eq. (27)
K_Y	–	Characteristic humidifier number
L	m	Pipe, duct and path length respectively
M	kg	Mass
$\dot{M}$	kg/s	Mass rate of flow
R	J/kg K	Gas constant
W	m^2K/W	Thermal resistance referred to total external area
W	kg/kg	Specific moisture content of adsorbent
b	J/kg K	Slope of saturation line h_S (ϑ, φ = 1)
c	J/kg K	Specific heat
$c_{P_{1+Y}}$	J/kg K	Specific heat of humid air per unit mass of dry air
h	J/kg	Specific enthalpy of air per unit mass of dry air
Δh_V	J/kg	Specific heat of evaporation at 0°C
m	m^{-1}	Fin parameter
p	bar	Total pressure or barometric pressure
p_i	bar	Partial pressure
Y	kg/kg, g/kg	Humidity ratio referred to dry air
α	W/m^2K	Heat transfer coefficient
β_Y	kg/m^2s	Mass transfer coefficient referred to ΔY
δ	m	Thickness
η	–	Humidifying efficiency, dehumidifying efficiency, fin efficiency
ϑ	°C, K	Temperature
ρ	kg/m^3	Density
φ	–	Relative humidity

5 Indices

A	Outlet, exit
B	Humidifying, tube base
D	Vapour
E	Inlet, entry, dehumidifying
G	Dry-wet boundary
K	Cooling limit or adiabatic saturation state or wet bulb state, coolant
L	Air, dry air
R	Fin
S	Saturation
W	Water, tube wall
WT	Heat exchanger
Z	Identification marking of an ascertained position
a	Outside
dry	Dry
i	Inside
m	Averaged over coil surface
o	Refers to $\vartheta = 0°C$ or tube base surface
wet	Wet
τ	Dew point

M9 Convective Heat Transfer at High Velocities

Bernhard Weigand[1] · *Nimai-Kumar Mitra*[2,†]
[1]Universität Stuttgart, Stuttgart, Germany
[2]Bochum, Germany

1 Introduction

High-velocity effects on the heat transfer play an important role in a lot of technical applications, like in re-entry problems for space applications, for heat transfer at high velocities around gas turbine blades or in rocket engines. High-velocity convection involves essentially two different phenomena:

- Conversion of mechanical energy into thermal energy, resulting in strong temperature variations in the fluid
- Variation of fluid properties as a result of temperature variations.

The Mach number is the characteristic dimensionless group which characterizes the compressibility of the fluid ($\mathrm{Ma} = w/w_\mathrm{s}$). For small Mach numbers ($\mathrm{Ma} < 0.3$), the above mentioned phenomena are rather unimportant and the flow can be considered as incompressible. The speed of sound w_s is defined by

$$w_\mathrm{s} = \sqrt{(\partial p/\partial \rho)_\mathrm{s}}, \tag{1}$$

which simplifies for ideal gases to

$$w_\mathrm{s} = \sqrt{\kappa R T} = \sqrt{\kappa(\widetilde{R}/\widetilde{M})T}. \tag{2}$$

Flows with Mach numbers larger than 0.3 are normally considered to be compressible. However, also for very small Mach numbers there might be substantially changes in fluid properties. For such cases, these effects can be treated by using temperature-dependent fluid properties for the incompressible flow [1, 2]. These types of flows will not be considered in this section. In the following, the flows will be subdivided into incompressible flows ($\mathrm{Ma} < 0.3$), subsonic flows ($0.3 \leq \mathrm{Ma} < 0.7$), transonic flows ($0.7 \leq \mathrm{Ma} < 1.3$), supersonic flows ($1.3 \leq \mathrm{Ma} < 6$), and hypersonic flows ($\mathrm{Ma} \geq 6$). An important feature of flows with Mach numbers larger than one is that shock waves can form in the flow. These shock waves result in a strong increase in pressure and temperature in the area behind the shock wave. Figure 1 visualizes a typical shock wave formed around a body and the resulting velocity and temperature profiles [3]. At the stagnation point of the body, the whole kinetic energy will be converted into thermal energy. The stagnation temperature is given by

$$T_0 = T_\infty + w^2/2c_p = T_\infty + \Delta T. \tag{3}$$

For an ideal gas with constant c_p this equation can be rewritten to

$$T_0 = T_\infty\big(1 + \mathrm{Ma}^2(\kappa - 1)/2\big). \tag{4}$$

The highest temperature is normally obtained at the stagnation point of the body. These temperatures can exceed by far the melting temperature of the material. However, when a viscous high-speed boundary-layer flow is decelerated to zero velocity at an insulated wall, it approaches, depending on the Prandtl number, an adiabatic wall temperature T_aw which differs from the stagnation temperature T_0 (due to the disequilibrium between viscous dissipation and heat conduction). The adiabatic

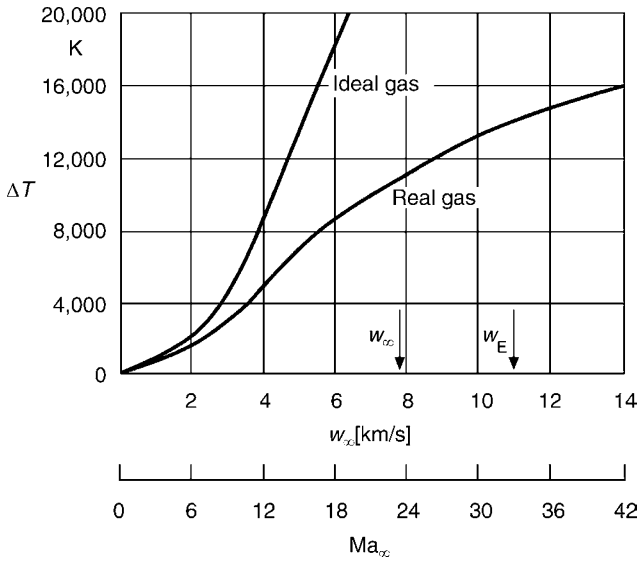
M9. Fig. 1. Supersonic flow ($Ma_\infty > 1$) around a blunt body. For $Ma_\infty >> 1$ the shock wave follows nearly the body geometry [3].



M9. Fig. 2. Temperature increase ΔT (Eq. (3)) as a function of the flight speed ($w_\infty = 7.9$ km/s is the speed of a geostationary satellite, $w_\infty = 11.2$ km/s is the escape velocity [6]).

wall temperature can be calculated from the dimensionless recovery factor r, defined by

$$r = \frac{T_{aw} - T_\infty}{T_0 - T_\infty}. \tag{5}$$

From measurements and analytical calculations it is known that the recovery factor can be calculated approximately by

- Laminar flows ($0.6 < Pr < 15$): $r \approx Pr^{1/2}$ and
- Turbulent flows ($0.25 < Pr < 10$): $r \approx Pr^{1/3}$

The recovery factor is not only a temperature ratio but also gives the percentage of the free-stream kinetic energy, which is converted into thermal energy during deceleration of the flow on an adiabatic wall. For turbulent flows, the recovery factor is also strictly speaking a function of the turbulence structure. Rotta [4] provides an equation, relating the recovery factor for turbulent flows as a function of the friction coefficient and the turbulent Prandtl number.

The heat flux at the wall is given for high-speed flows by

$$\dot{q}_w = -\lambda\left(\frac{\partial T}{\partial n}\right)_w = \alpha(T_{aw} - T_w), \tag{6}$$

where n denotes the normal direction from the wall. It is of major importance that one notices in high-speed flows the correct driving temperature potential for heat transfer is $(T_{aw} - T_w)$. This means whether the heat is transferred to or from the body will depend on whether the surface temperature is above or below the adiabatic wall temperature [5–8].

Beside the Nusselt number, it is convenient to express the heat transfer to or from a body at high velocities in terms of the Stanton number, St, defined by

$$St = \frac{Nu}{Re\ Pr} = \frac{\dot{q}_w}{\rho_\infty w_\infty c_p (T_{aw} - T_w)} = \frac{\alpha}{\rho_\infty w_\infty c_p} \tag{7}$$

The Stanton number is the ratio of the actual to maximum possible heat flow per area. For $St \to 1$, the free-stream energy flux arriving within the frontal area is completely transferred to the body in case of $r = 1$, $T_w = 0$.

For high Mach number flows (hypersonic flows), additional thermodynamic effects can be present like ionization and dissociation, recombination, and excitation of the vibrational energy modes of the molecules [6]. These effects can be observed for example for reentry bodies and hypersonic flows in rocket nozzles. For every body, moving with hypersonic speed, shock structures evolve which cause very high temperatures behind the shock wave. Here, non-equilibrium effects, dissociation, and chemical reaction might be present. The equation of state for dissociating gases differs from the ideal gas law. The excitation of the vibrational energy modes of the molecules and dissociation of the molecules into atoms reduces the stagnation temperature due to the necessary energy consumption for these reactions. This is depicted in Fig. 2 [6, 9], where ΔT from Eq. (1) is shown for different flow speeds for ideal and real gases. The dissociated gas can recombine at the body surface and might result in an enormous heat release at the surface. Here the catalytic character of the surface is of importance [9, 10]. Since heat transfer characteristics depend strongly upon the nature of the non-equilibrium effects, it would by far exceed the scope of the present note to go into details on these effects and their influence on heat transfer. The reader is referred to [9–11] for more details on these effects.

For hypersonic flows, which might be of interest for astronautic applications, the heat transfer can be calculated by assuming rarified gases. These effects are not considered in this section. The reader is referred to Chap. M10 of the present book for more details.

The following discussion of convective heat transfer at high velocities will be based on the Navier–Stokes equations and the energy equation. These equations have to be solved together with an equation of state and are strongly coupled for

compressible flows. As mentioned before, temperature dependent fluid properties need normally to be considered for compressible flows. Here especially the dynamic viscosity varies strongly with temperature. The viscosity for gases can be approximated for a wide variety of gases by the Sutherland law [6]

$$\frac{\eta}{\eta_{\mathrm{ref}}} = \left(\frac{T}{T_{\mathrm{ref}}}\right)^{3/2} \frac{T_{\mathrm{ref}} + T_1}{T + T_1} \tag{8}$$

In this equation, η_{ref} is a reference quantity taken at the reference temperature $T_{\mathrm{ref}} = 288\,\mathrm{K}$. T_1 is a constant and equal to 110 K for air. The Sutherland law has been approximated (especially for analytical solutions) by the simpler expression

$$\frac{\eta}{\eta_{\mathrm{ref}}} = \left(\frac{T}{T_{\mathrm{ref}}}\right)^{\omega}, 0.5 \le \omega \le 1 \tag{9}$$

The other fluid properties (c_p, Pr) can be obtained from Part. D of the Heat Atlas for the gas under consideration. If non-equilibrium effects are absent, c_p and Pr might be considered as constant, depending on the temperature range under consideration. The thermal conductivity λ can then be calculated as follows: $\lambda = \eta c_p / \mathrm{Pr}$.

2 Heat Transfer for External Flows

In contrast to the vast body of correlations existing for heat transfer in incompressible flows, the number of correlations for heat transfer at high velocities is limited. If the fluid properties can be considered to be constant, all so far developed correlations in the Heat Atlas can be used with the only restriction that the heat transfer coefficient need to be based on the correct driving temperature difference given by Eq. (6) [5, 7]. However, normally this assumption can not be made.

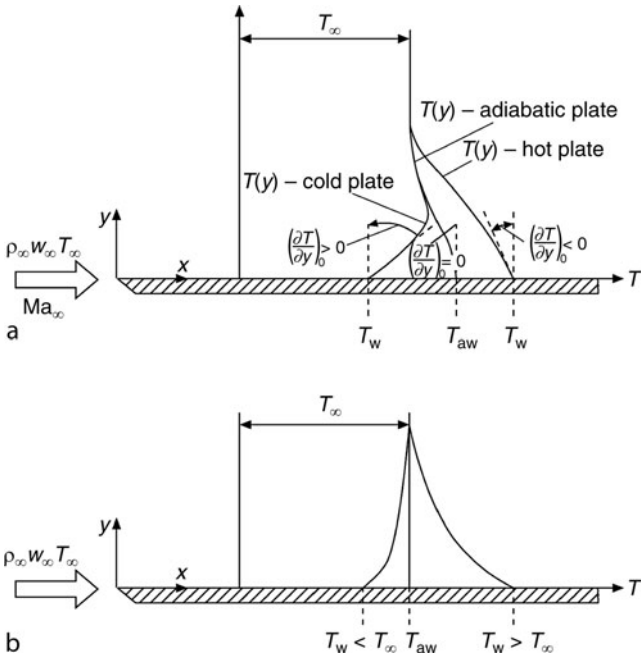
In the following, some solutions are given for simple cases. For more complicated cases, one needs normally to solve the problem numerically. For boundary layer problems, this can be done by using available boundary layer codes [5, 8]. If this simplification is not allowed, 3D CFD methods can be used today [12].

2.1 Laminar Flow Along a Flat Plate

2.1.1 Flow Without Shock-Boundary Layer Interaction

Figure 3 depicts the temperature distribution in a boundary layer at a flat plate [3]. As it can be seen from Fig. 3, the temperature profile depends strongly on the conversion of mechanical energy into thermal energy inside the boundary layer. If the Prandtl number $\mathrm{Pr} = \eta c_p/\lambda$ can be considered to be one (which is an acceptable assumption for a lot of gases), an exact relationship between temperature and velocity profile can be established (see Schlichting [6]). For an adiabatic wall one obtains for the temperature distribution

$$T = T_\infty + \left(w_\infty^2 - w_x^2\right)/\left(2c_p\right) \tag{10}$$



M9. Fig. 3. Flow along a flat plate with typical temperature profile in the boundary layer (**a**) with and (**b**) without dissipative heating [3].

The adiabatic wall temperature is given by Eq. (10) by setting $w_x = 0$ at the wall and one obtains for an ideal gas

$$T_{\mathrm{aw}} = T_\infty + w_\infty^2/\left(2c_p\right) = T_\infty\left(1 + \mathrm{Ma}_\infty^2(\kappa - 1)/2\right) \tag{11}$$

where $T_\infty, w_\infty,$ and Ma_∞ are the temperature, velocity, and Mach number of the free-stream.

For a constant surface temperature of the plate, the exact solution for Pr = 1 is

$$\frac{T}{T_\infty} = 1 + \frac{1}{2}\mathrm{Ma}_\infty^2(\kappa - 1)\left(1 - \left(\frac{w_x}{w_\infty}\right)^2\right) + \frac{T_w - T_{\mathrm{aw}}}{T_\infty}\left(1 - \frac{w_x}{w_\infty}\right) \tag{12}$$

For $\mathrm{Pr} \neq 1$, Eqs. (11–12) can be modified to a first approximation by introducing the recovery factor. Thus,

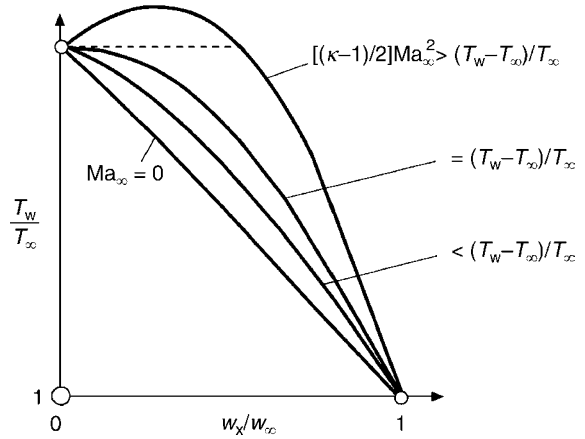
$$T_{\mathrm{aw}} = T_\infty\left(1 + r\mathrm{Ma}_\infty^2(\kappa - 1)/2\right), \tag{13}$$

$$T/T_\infty = 1 + r\left(\mathrm{Ma}_\infty^2\left(1 - (w_x/w_\infty)^2\right)(\kappa - 1)/2\right) + (T_w - T_{\mathrm{aw}})/T_\infty(1 - w_x/w_\infty) \tag{14}$$

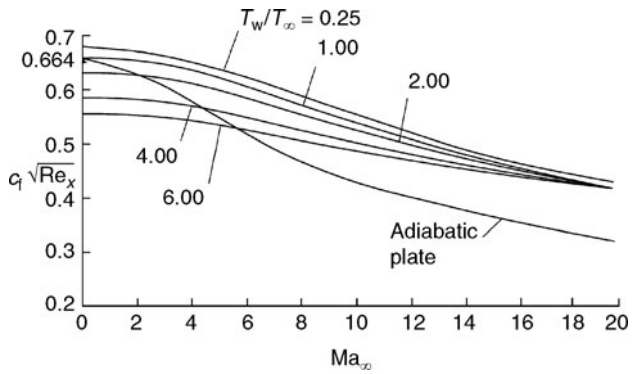
Equations (12) and (14) are independent of the viscosity law and consider the conversion of mechanical energy into thermal energy within the boundary layer [6].

From Eq. (12) one sees that for $(T_w - T_\infty)/T_\infty > \mathrm{Ma}_\infty^2(\kappa - 1)/2$ heat transfer takes place from the fluid to the surface and for $(T_w - T_\infty)/T_\infty = \mathrm{Ma}_\infty^2(\kappa - 1)/2$ no heat transfer takes place, thus the wall is adiabatic. This is shown in Fig. 4 [6]. If the Mach number tends to zero, a linear relationship between the temperature and the velocity is obtained from Eq. (12).

The heat transfer coefficient, defined by Eq. (6), can be obtained from Eq. (12). This results in the following equation for the Nusselt number:



M9. Fig. 4. Temperature distribution T_w/T_∞ as a function of the velocity ratio w_x/w_∞ for a compressible laminar flow along a flat plate with Pr = 1 [6].



M9. Fig. 5. Average value of the friction factor c_f for a flat plate [10].

$$\frac{\mathrm{Nu}_x}{\mathrm{Re}_x} = \frac{c_{fx}}{2} \tag{15}$$

In Eq. (15) the following definitions have been used

$$\begin{aligned} \mathrm{Nu}_x &= \frac{\alpha x}{\lambda}, \mathrm{Re}_x = \frac{w_\infty \rho_\infty x}{\eta_w}, \\ \alpha &= -\lambda_w \left(\frac{\partial T}{\partial y}\right)_w / (T_{aw} - T_w), \\ c_{fx} &= \eta_w \left(\frac{\partial w_x}{\partial y}\right)_w / (\rho_\infty w_\infty^2/2) \end{aligned} \tag{16}$$

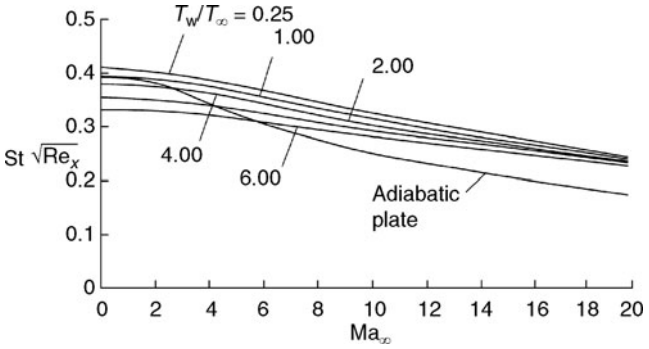
Introducing the Stanton number into Eq. (15), one obtains for Pr = 1

$$\mathrm{St} = \frac{\mathrm{Nu}}{\mathrm{Re}\,\mathrm{Pr}} = \frac{c_{fx}}{2\,\mathrm{Pr}} \tag{17}$$

Equation (17) is strictly valid only for Pr = 1. In the case of arbitrary Prandtl numbers, Eq. (17) might be modified to

$$\mathrm{St} = \frac{c_{fx}}{2\,\mathrm{Pr}^{2/3}} \tag{18}$$

Figures 5 and 6 show the distribution of the mean friction factor and the Stanton number for Pr = 0.75 as a function of the approach Mach number Ma_∞ for different temperature ratios of the wall temperature to free-stream temperature T_w/T_∞.



M9. Fig. 6. Average value of the Stanton number St for a flat plate [10].

The calculations have been obtained by van Driest [10]. It is clearly visible that for a constant temperature ratio T_w/T_∞ the friction factor and the Stanton number decrease with growing Mach numbers.

2.1.2 Flow with Viscous Interaction with the External Flow

The boundary layer development at the plate normally introduces a pressure gradient in the flow. This can cause shock interactions in hypersonic flows. The boundary layer displaces the external flow and this deflection causes a shock wave, or may change the shape of the shock wave in case of a contoured body. The pressure gradient can be characterized by the interaction parameter K defined by [9, 10]

$$K = \mathrm{Ma}_\infty \mathrm{d}\delta_1(x)/\mathrm{d}x \tag{19}$$

where δ_1 denotes the displacement thickness.

Strong interaction: For this case the parameter $K >> 1$ and one obtains a strong shock. Here the following relations can be used [13]

$$\begin{aligned} p_\delta/p_\infty &\approx ((\kappa+1)/2)\kappa K^2 \\ p(x)/p_\infty &= p_0(T_w/T_0)\sqrt{C}\mathrm{Ma}_\infty^3/\sqrt{\mathrm{Re}_{x\infty}} \end{aligned} \tag{20}$$

where p_δ denotes the pressure at the outer edge of the boundary layer and p_∞ is the pressure at approach conditions. In addition, the Chapman-Rubesin parameter C [6] has been introduced. This important dimensionless quantity for compressible flows is defined by

$$C = \frac{\rho\eta}{\rho_\delta \eta_\delta} \tag{21}$$

where ρ_δ and η_δ are the density and the dynamic viscosity at the outer edge of the boundary layer. The friction coefficient and the Stanton number are given by

$$\begin{aligned} c_{fx} &= c_{f0}(T_w/T_\infty)C^{3/4}\left(\mathrm{Ma}_\infty/\sqrt{\mathrm{Re}_{x\infty}}\right)^{3/2} \\ \mathrm{St} &\approx 0.37 c_{fx} \end{aligned} \tag{22}$$

In Eqs. (20, 22), c_{f0} denotes the friction factor for a flat plate without viscous interaction, p_0, T_0 are the stagnation values of pressure and temperature, $p(x)$ is the local pressure along the

plate and $Re_{x\infty}$ is the Reynolds number based on the approach velocity and the fluid properties taken at approach conditions.
Weak interaction: This case relates to $K << 1$ and a weak shock is obtained. For this case the following equations can be used:

$$\begin{aligned} p_\delta/p_\infty &= 1 + \kappa K \\ p(x)/p_\infty &= 1 + KF\sqrt{C}Ma_\infty^3/\sqrt{Re_{x\infty}} \\ F &= 0.968/Ma_\infty^2\, T_w/T_\infty + 0.145(\kappa - 1) \end{aligned} \tag{23}$$

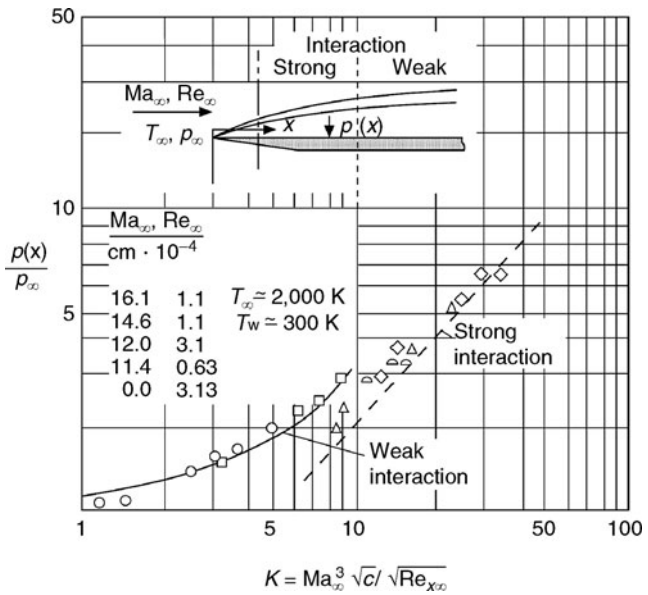
$$(c_{fx} - c_{f0})\sqrt{Re_{x\infty}} = 2CF^2 Ma_\infty^3/\sqrt{Re_{x\infty}} \tag{24}$$

The Stanton number can be calculated approximately from the Reynolds analogy. The position of the strong interaction is located directly after the leading edge of the plate. For a weak interaction, the position is directly after the location for the strong interaction. Figure 7 shows the pressure distribution for strong and weak interactions on a flat plate [13].

2.2 Turbulent Flow Along a Flat Plate

For turbulent flow along a flat plate, the flow and heat transfer can be calculated numerically by using boundary layer codes [5, 8]. The results agree favorable with measurements. Here, a semi-empirical equation for c_f from van Driest [8] will be reported which shows nicely the influencing parameters for the solution. The equation from van Driest is based on a mixing length approach for modelling the turbulent flow and assumes a simplified viscosity law by Eq. (9). The friction coefficient is given by

$$\begin{aligned} &\frac{0.242\left(\sin^{-1}\varepsilon_1 + \sin^{-1}\varepsilon_2\right)}{A\sqrt{c_{fx}(T_w/T_\delta)}} \\ &\quad = 0.41 + \log(Re_x\ c_{fx}) - \omega\log(T_w/T_\delta) \end{aligned} \tag{25}$$



M9. Fig. 7. Pressure distribution for viscous interaction on a flat plate [13].

with the following quantities

$$\begin{aligned} &\varepsilon_1 = \frac{2A^2 - B^2}{Z}, \varepsilon_2 = \frac{B}{Z}, Z = \left(B^2 + 4A^2\right)^{1/2} \\ &B = \frac{T_\delta}{T_w}\left(1 + r\frac{\kappa - 1}{2}Ma_\delta^2\right) - 1, A = \left[r\frac{\kappa - 1}{2}Ma_\delta^2\frac{T_\delta}{T_w}\right]^{1/2} \end{aligned} \tag{26}$$

where the subscript "δ" refers again to the conditions at the edge of the boundary layer. For obtaining the heat transfer, the Reynolds analogy can be used as a first approximation if the Prandtl number Pr = 1 and in addition also the turbulent Prandtl number Pr_t = 1. One obtains

$$St = \frac{c_{fx}}{2} \tag{27}$$

If the molecular Prandtl number is not equal to one, one can use the following equation developed by von Karman, if Pr_t = 1 [6]

$$St = \frac{c_{fx}/2}{1 + 5\sqrt{c_{fx}/2}\left((Pr - 1) + \ln\left(1 + \frac{5}{6}(Pr - 1)\right)\right)} \tag{28}$$

If in addition, also $Pr_t \neq 1$, the following equation developed by Reichardt can be used [6]

$$St = \frac{c_{fx}/2}{Pr_t + \sqrt{c_{fx}/2}((Pr - Pr_t)a + A_1)} \tag{29}$$

The quantity a depends on the ratio of Pr / Pr_t, the turbulence structure and the friction coefficient. Table 1 gives values of a, for different ratios of Pr / Pr_t [6]. The quantity A_1 in Eq. (29) can be approximated by $A_1 \approx 4(1 - Pr_t)$.

2.3 The Use of Reference Properties for Heat Transfer Calculations

The Nusselt number, the Stanton number, and the friction coefficient for compressible flows can be obtained from the related incompressible flow relationships, if the fluid properties are taken at a reference temperature T_{ref} [5, 7, 14]. On the basis of examinations of a number of exact laminar boundary-layer solutions for constant w_∞, T_∞, T_w, Eckert [7] concluded that if the specific heat may be treated as constant, the following reference temperature correlates the available solutions within a few percent for Mach numbers up to 20 and over a wide range of free-stream and surface temperatures:

$$T_{ref} = T_\infty + 0.5(T_w - T_\infty) + 0.22(T_{aw} - T_\infty) \tag{30}$$

For very large temperature differences through the boundary layer, the assumption of constant specific heat, which has been made, is no longer valid. Eckert's reference property method is again applicable if reference enthalpy values are used in Eq. (30) resulting in

$$h_{ref} = h_\infty + 0.5(h_w - h_\infty) + 0.22(h_{aw} - h_\infty) \tag{31}$$

M9. Table 1. Dependence of the quantity a on Pr/Pr_t.

Pr/Pr_t	0.5	0.72	1.44	2.0	5.0	10.0
a	10.22	9.55	8.25	7.66	6.04	5.05

In this case, the heat flux at the wall has of course to be based on the enthalpy difference instead of a temperature difference, resulting in

$$\dot{q}_w = \hat{\alpha}(h_{aw} - h_w)$$
$$\mathrm{St} = \frac{\hat{\alpha}}{\rho w_\infty} \tag{32}$$

where again all fluid properties are evaluated at the reference conditions, given by Eq. (31).

A different concept to evaluate the reference conditions has been followed by Herwig [15]. He derived a reference temperature from an asymptotic theory for a flow along a flat plate with zero pressure gradient. The reader is referred to [15] for more details. In addition, there are several other empirical equations for the reference temperature [12, 16].

2.4 Boundary Layer Flows with External Pressure Gradients

For laminar flows over a flat plate with a superimposed pressure gradient, the density variations can have a large effect on the flow and heat transfer. As a consequence of the external pressure gradient, the temperature distribution on the edge of the boundary layer is no longer constant. Similarity solutions can be found under a number of restrictive conditions [5, 6, 14, 15, 17–19, 37]. One is that the free-stream velocity distribution has to follow the equation

$$w_{x\infty} = C_1 \tilde{x}^m \tag{33}$$

For $m = 0$, one obtains the flow along a flat plate without pressure gradient. If $m > 0$ the flow is accelerated, while for $m < 0$, the flow is decelerated. Cohen and Reshotko [20] reported self- similar solutions for various values of $\beta = 2m/(1 + m)$ and different wall temperatures. They assumed Pr = 1 and a linear viscosity dependence from temperature according to $\eta/\eta_{ref} = bT/T_{ref}$. Figure 8 shows some velocity distributions inside the boundary layer for different acceleration parameters β and the corresponding enthalpy profiles. The profiles are plotted versus a modified y-coordinate, defined by

$$Y = \sqrt{((m+1)/2(U_\delta v_0 \tilde{x})(T_\delta/T_0))} \int_0^y (\rho/\rho_0)\mathrm{d}\bar{y}$$
$$U_\delta = w_{x\delta}\sqrt{(T_0/T_\delta)}, \tilde{x} = \int_0^x b p_\delta/p_0 \sqrt{(T_\delta/T_0)}\mathrm{d}\bar{x} \tag{34}$$

In Fig. 8, the following expressions are used

$$S = \frac{c_p T + w_x^2/2}{c_p T_0} - 1, \; f' = \frac{w_x}{w_{x\delta}} \tag{35}$$

For the friction coefficient and for the Stanton number one obtains from the analytical solution of the compressible boundary layer equations

$$c_f = 2\tau_w/(\rho_w w_{x\delta}^2) = f_w'' \left[2b(1 + S_w)\sqrt{((m+1)/2(v_{\infty 0}/U_\delta \tilde{x}))}\right]$$
$$S_w = T_w/T_0 - 1, \mathrm{Re}_w = w_{x\delta}\tilde{x}/v_w \tag{36}$$
$$\mathrm{St}/c_f = \mathrm{Nu}/(\mathrm{Re}_w \; c_f) = -S_w''/(S_w 2 f_w'')$$

Table 2 summarizes some values for the temperature and velocity gradients at the wall, which have been reported by Cohen and Reshotko [20]. More data can be found in [20].

Eckert [7] gives an empirical equation for the heat flux at the wall for a laminar flow with pressure gradient

$$\dot{q}_{wx} = \left(0.35/\mathrm{Pr}^{2/3}\right)\left(\rho_{ref}\eta_{ref} w_{x\delta} r_0^n c_p (T_w - T_{aw})/\sqrt{x_{ref}}\right)$$
$$x_{ref} = \int_0^x \rho_{ref}\eta_{ref} w_{x\delta} r_0^{2n}\mathrm{d}\bar{x} \tag{37}$$

In Eq. (37) the index "ref" indicates that the fluid properties have to be taken at the reference value T_{ref} and r_0 is the radius of the body ($n = 0$ denotes a planar surface, whereas $n = 1$ denotes a rotational symmetric body). The Stanton number is given by

$$\mathrm{St}_x = \alpha/(w_{x\delta}\rho_{ref} c_p) = 0.35\eta_{ref} r_0^n/\sqrt{x_{ref}} \tag{38}$$

2.4.1 Stagnation Point Flow

From the self-similar solution of the stagnation point flow Fay and Riddle [21] developed a correlation for the heat flux. They considered dissociation and recombination. The equation from Fay and Riddle for the heat flux (without dissociation) at the stagnation points reads

$$\dot{q}_w = B c_p \mathrm{Pr}^{-0.6}\sqrt{\rho_\delta \eta_\delta}\sqrt{\mathrm{d}w_{x\delta}/\mathrm{d}x}(T_{aw} - T_w) \tag{39}$$

where $B = 0.57$ for a two-dimensional stagnation line on a cylinder and $B = 0.763$ for the axis-symmetric stagnation point on a sphere. The velocity gradient of the free-stream is given by the pressure distribution

$$\mathrm{d}w_{x\delta}/\mathrm{d}x = 1/r_0\sqrt{2(p_\delta - p_\infty)/\rho_\delta} \tag{40}$$

Combining Eqs. (39) and (40) one sees that the heat flux is proportional to $1/\sqrt{r_0}$, where r_0 denotes the radius of the body in the stagnation area. From Eq. (39) one can derive the following equation for the Stanton number

$$\mathrm{St} = \dot{q}_w/\left[(T_{aw} - T_w)\rho_\delta w_{x\delta} c_p\right] = B\,\mathrm{Pr}^{-0.6}\sqrt{\tilde{w}'_{x\delta}/\mathrm{Re}_{2r_0}}$$
$$\tilde{w}'_{x\delta} = (2r_0/w_{x\delta})\mathrm{d}w_{x\delta}/\mathrm{d}x \tag{41}$$

The Stanton number, which has been derived by Lees [13] from the laminar boundary layer theory for the stagnation point heat transfer is

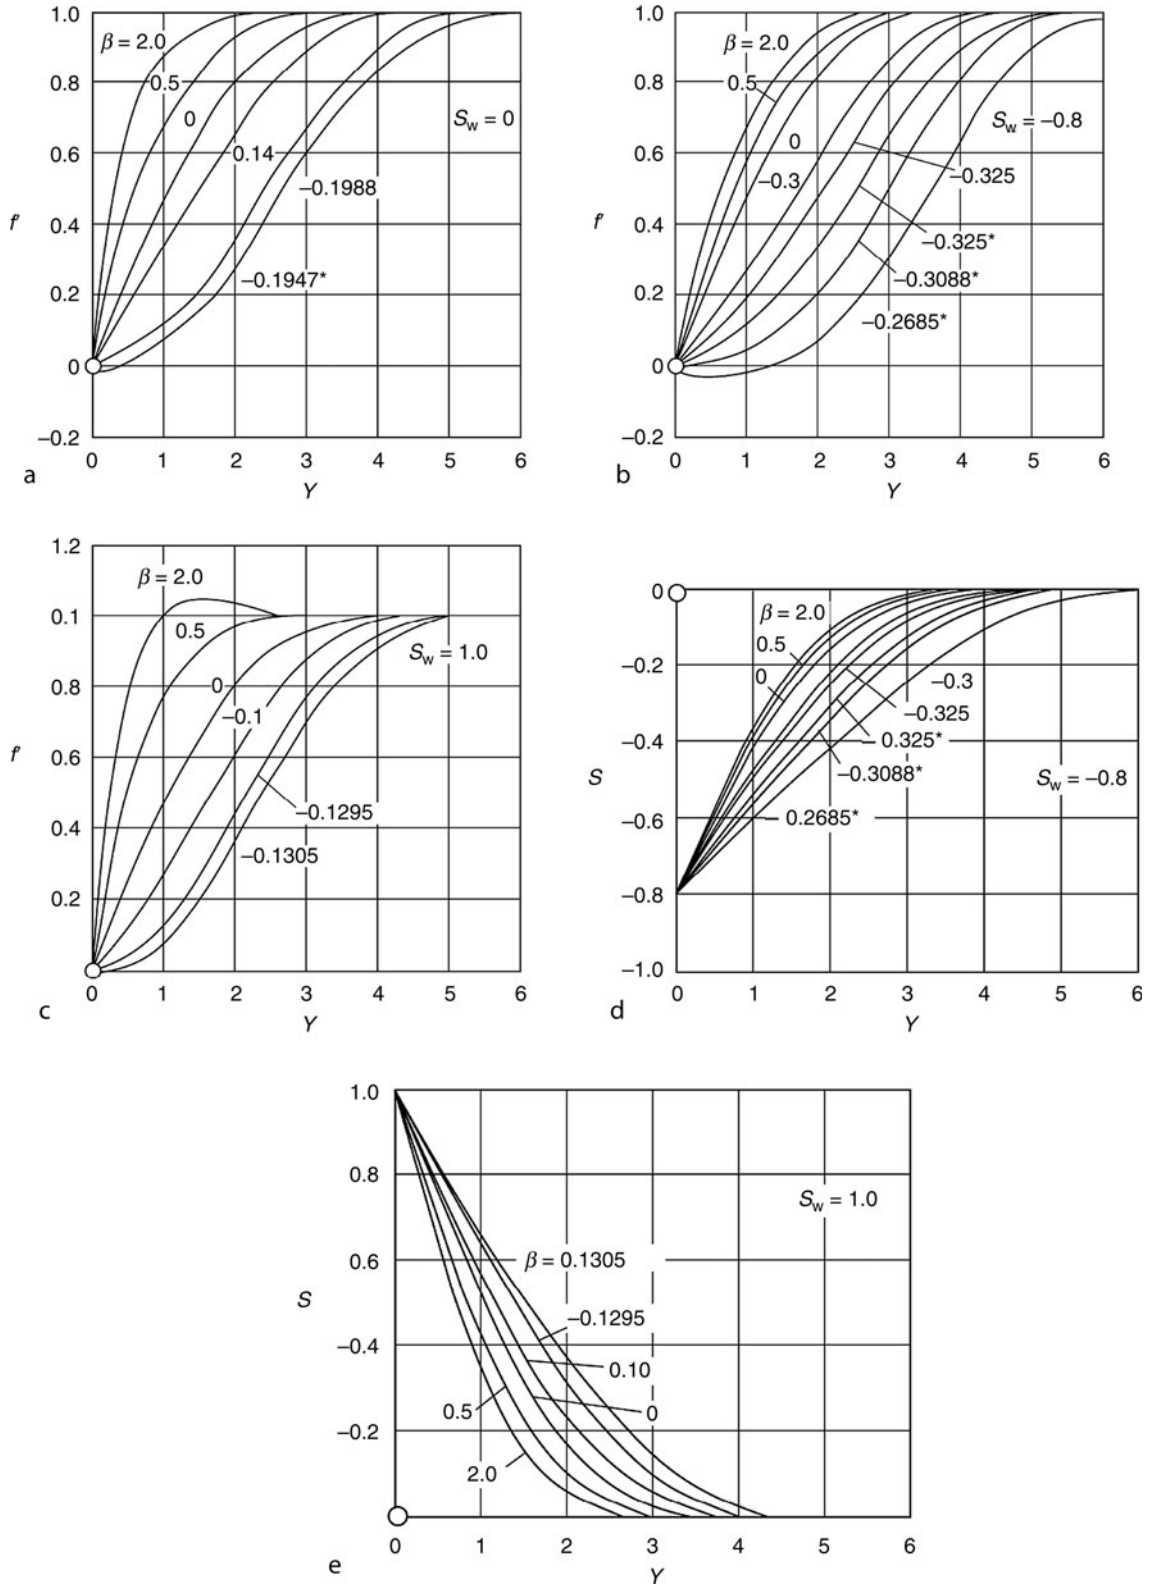
$$\mathrm{St} = B_1\,\mathrm{Pr}^{-2/3}\sqrt{\tilde{w}'_{x\delta}/\mathrm{Re}_{2r_0}} \tag{42}$$

where $B_1 = 0.354$ for a cylinder and $B_1 = 0.5$ for a sphere. One sees from Eqs. (41) and (42) that in Lees equation the Stanton number depends on the Prandtl number by the exponent (−2/3), while in Fay and Riddle's equation this dependence is (−0.6).

Comparing the Stanton number for a sphere with a cylinder, one obtains that

$$\frac{\mathrm{St}_{Sphere}}{\mathrm{St}_{Cylinder}} \approx \sqrt{2} \tag{43}$$

Figure 9 shows the Stanton number as a function of the Reynolds number Re_{2r_0} [13]. The measurements, which have



M9. Fig. 8. Velocity and enthalpy profiles for laminar compressible flows with different pressure gradients [6].

been taken at different values of the Mach number, ranging from 8 to 21, show a nearly linear behavior in the logarithmic diagram. Eckert [7] provides an empirical equation for the Stanton number, which is based on reference conditions

$$\mathrm{St} = B_2 / \left(\mathrm{Pr}_{\mathrm{ref}}^{2/3} \sqrt{\mathrm{Re}_{x,\mathrm{ref}}} \right) \tag{44}$$

In Eq. (44), the constant $B_2 = 0.5$ for the planar stagnation point and $B_2 = 0.7$ for the axis-symmetric stagnation point.

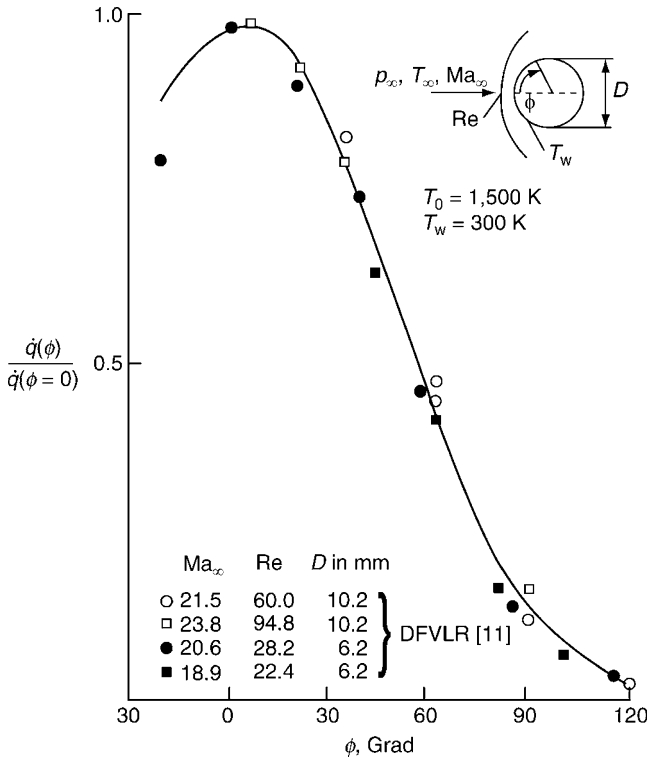
M9. Fig. 9. Stanton number as a function of the Reynolds number for a stagnation flow [13].



M9. Fig. 10. Heat flux ratio for the heat transfer around a cylinder [13].

2.4.2 Flow Around a Cylinder

Figure 10 shows measurement data for the heat flux ratio around a cylinder [13]. As indicated in Fig. 10, ϕ denotes the circumferential coordinate. For $\phi = 0$, the heat flux $\dot{q}(\phi = 0)$ at the stagnation point is obtained. The Reynolds number is

based on the diameter D of the cylinder and the flow conditions in front of the shock wave. Beckwith and Gallagher [22] provide an empirical correlation for the Stanton number distribution around the cylinder. The equation is based on experimental data and is given by

$$\mathrm{St}/\mathrm{St_S} = 0.7(\cos\phi)^{2/3} + 0.3 \tag{45}$$

In the equation, $\mathrm{St_S}$ is the value of the Stanton number at the stagnation point.

2.4.3 Flow Around a Cone

For the supersonic flow around a cone with an attached shock, a conical flow exists outside the boundary layer. The boundary layer flow can be transformed into a flow along a flat plate by using the Mangler transformation [6]. Friction coefficient and Stanton number for the flat plate solution simply have to be multiplied by a factor of $\sqrt{3}$ in order to obtain the values for the cone [7].

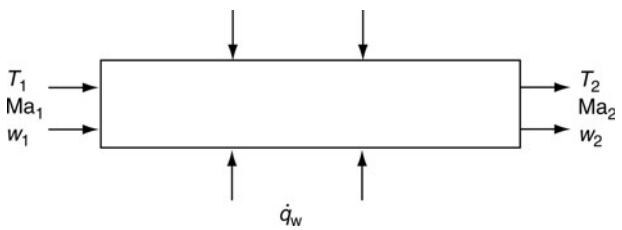
3 Heat Transfer for Internal Flows

Flow and heat transfer for internal flows in ducts play an important role e.g., in rocket engine and Ram and Scramjet design [23, 24]. The heat addition to duct flows can be analyzed approximately by 1D models. From the first law of Thermodynamics for an open system (shown in Fig. 11) with the assumption of a constant c_p and the assumption of one incoming and one outgoing mass flow, one obtains [3]

$$\dot{M}c_pT_{02} = \dot{M}c_pT_{01} + \dot{Q}_\mathrm{w},\ \dot{Q}_\mathrm{w} = \int_{\text{Surface}} \dot{q}_w \mathrm{d}S \tag{46}$$

In this equation $\dot{Q}_\mathrm{w}$ is the heat flux from the wall into the fluid. This quantity can be obtained by integrating the heat flux density $\dot{q}_w$ over the whole surface which is in contact with the fluid. For an ideal, caloric perfect gas the conditions at pipe exit can be calculated from the following Eq. [18]

$$\begin{aligned} T_{01}/T_{02} &= \mathrm{Ma}_2^2\left(1+\kappa\mathrm{Ma}_1^2\right)^2/\left(\mathrm{Ma}_1^2\left(1+\kappa\mathrm{Ma}_2^2\right)^2\right) \\ &\quad\cdot\left(1+((\kappa-1)/2)\mathrm{Ma}_2^2\right)^2/\left(1+((\kappa-1)/2)\mathrm{Ma}_1^2\right)^2 \\ T_2/T_1 &= \mathrm{Ma}_2^2/\mathrm{Ma}_1^2\left(1+\kappa\mathrm{Ma}_1^2\right)^2/\left(1+\kappa\mathrm{Ma}_2^2\right)^2 \end{aligned} \tag{47}$$



M9. Fig. 11. Duct with heat addition from the wall [3].

If the flow enters the channel with subsonic speed, $\mathrm{Ma}_1 < 1$, the Mach number in the flow increases in case of heat addition, so that $\mathrm{Ma}_2 > \mathrm{Ma}_1$. For a constant area duct, the Mach number can reach in case of heat addition in steady state the maximum value of $\mathrm{Ma}_2 = 1$ at the exit of the duct and the duct is chocked. Further heat addition to the flow is only possible unsteadily with strong variations in the inlet conditions. For an adiabatic flow, the Mach number at exit will also increase, because of the friction effects in the pipe and the resulting heat dissipation within the flow. For an isothermal wall, the flow will approach a value of the Mach number of $1/\sqrt{\kappa}$ at the exit of long pipes [25]. If the incoming flow into the pipe has a Mach number larger than one, $\mathrm{Ma}_1 > 1$, heat addition will decrease the outlet Mach number of the flow, so that $\mathrm{Ma}_2 < \mathrm{Ma}_1$.

Equation (47) assumes a one-dimensional, compressible, inviscid flow with heat addition. For 1D viscous, nonisothermal flows, there are no simple equations, which enable to calculate the flow conditions at the exit of the duct. Shapiro [25, 26] provides differential equations for the 1D viscous duct flow with heat addition, area changes in flow direction and mass addition. These equations can only be solved numerically. However, most of the commercial flow-net solver available today have these equations implemented (e.g., Miller [27]).

For the simple case of a pipe with constant area and a constant mass flow and by assuming the validity of the Reynolds analogy and further that $T_\mathrm{aw} \approx T_0$ (which is correct if Pr = 1 or for arbitrary Pr if the Mach number is small) Shapiro [25, 26] gives the following equations

$$\mathrm{d}T_0/\mathrm{d}x = 2c_\mathrm{f}(T_\mathrm{w} - T_0)/D, \tag{48}$$

$$\begin{aligned} &\mathrm{dMa}^2/\mathrm{d}x = (F_{T0}/T_0)\mathrm{d}T_0/\mathrm{d}x + 4F_\mathrm{f}c_\mathrm{f}/D, \\ &F_{T0} = \mathrm{Ma}^2\left(1+\kappa\mathrm{Ma}^2\right)\left[1+((\kappa-1)/2)\mathrm{Ma}^2\right]/\left(1-\mathrm{Ma}^2\right), \\ &F_\mathrm{f} = \kappa\mathrm{Ma}^4\left[1+((\kappa-1)/2)\mathrm{Ma}^2\right]/\left(1-\mathrm{Ma}^2\right). \end{aligned} \tag{49}$$

If the wall temperature $T_\mathrm{w} = \text{const.}$, Eq. (48) can be integrated analytically between the inlet (x_1) and exit (x_2) of the pipe. This results in

$$\frac{4c_\mathrm{f}(x_2 - x_1)}{2D} = \ln\left[\frac{T_\mathrm{w} - T_{01}}{T_\mathrm{w} - T_{02}}\right] \tag{50}$$

Unfortunately, Eq. (49) has to be solved numerically, because of the strong nonlinear nature of this equation. In the excellent book of Shapiro [25, 26] the reader can find a lot of other calculated cases and also several approximation solutions for 1D compressible flows.

3.1 Pipe Flow

The analysis of the flow field and the heat transfer in a pipe for compressible flows at high velocities requires the solution of the Navier–Stokes equations or the boundary layer equations. In literature a lot of these calculations can be found for laminar flows. A lot of these cases can be treated by solving the boundary layer equations. The reader is referred to Cebeci and Bradshaw [8] and Kays et al. [5] for more details.

For turbulent, subsonic flows in a pipe, the friction coefficient can be calculated, as for incompressible flow, by using the Karman-Nikuradse equation

$$1/\sqrt{4c_f} = -0.8 + 2\log\left(\mathrm{Re}\sqrt{4c_f}\right) \tag{51}$$

For a viscous turbulent subsonic flow with heat transfer, Shapiro [26] recommends the following equation for the friction factor in the pipe

$$c_f = 0.079\mathrm{Re}^{-0.25} \tag{52}$$

Assuming the Reynolds analogy, an empirical equation for the Nusselt number can be derived, which agrees well with measurements for air for values of the Reynolds number up to 10^5 and for Mach numbers between zero and one [26]:

$$\mathrm{Nu} = 0.0364(\mathrm{Re}\,\mathrm{Pr})^{0.75} \tag{53}$$

3.2 Laval Nozzle

In a Laval nozzle a compressible internal flow is obtained, which has a lot of different applications in aerospace as well as in wind tunnel testing. The flows in such nozzles are basically characterized by the fact that the Mach number can range from subsonic to hypersonic speeds. The flow acceleration, characterized by the pressure gradient, increases from the entrance to the throat area and decreases from there on. The axial distribution of the heat transfer coefficient is qualitatively similar to the axial distribution of the pressure gradient. Figure 12 shows schematically the geometry and typical distributions of the Mach number, the temperature and the heat transfer coefficient in the Laval nozzle [3].

The flow in the Laval nozzle can be predicted by using the Navier–Stokes equations or the boundary layer equations. Because of the strong acceleration of the core flow, interactions between boundary layer and core flow need to be taken into account. Back [28] analyzed the laminar flow in a Laval nozzle with local similarity methods. Carden [29] gives a simple method for determining the local heat transfer coefficients.

For the turbulent flow in a Laval nozzle, Bartz [30] provides the following empirical equation

$$\alpha = \left[\left(0.026/D^{*0.2}\right)\left(\eta_0^{0.2}c_p/\mathrm{Pr}^{0.6}\right)\left(p_0c^*\right)^{0.8}\right] \cdot \left(D^*/r_e\right)^{0.1}\left(A/A^*\right)^{0.9}\sigma \tag{54}$$

In this equation $c^* = p_0A^*/\dot{M}$ is a characteristic velocity, D^* is the throat diameter and $\sigma = (\rho_{\mathrm{ref}}/\rho_\delta)^{0.8}(\eta_{\mathrm{ref}}/\eta_0)^{0.2}$ considers the influence of changing fluid properties. The fluid properties $\rho_{\mathrm{ref}}, \eta_{\mathrm{ref}}$ should be taken at the reference temperature

$$T_{\mathrm{ref}} = 0.5(T_0 + T_w) + 0.22\,\mathrm{Pr}^{1/3}(T_0 - T_w) \tag{55}$$

The density ρ_δ can be calculated from a 1D isentropic nozzle flow analysis and r_e is the radius of curvature of the throat. Bartz [30] also provides a modified expression for σ

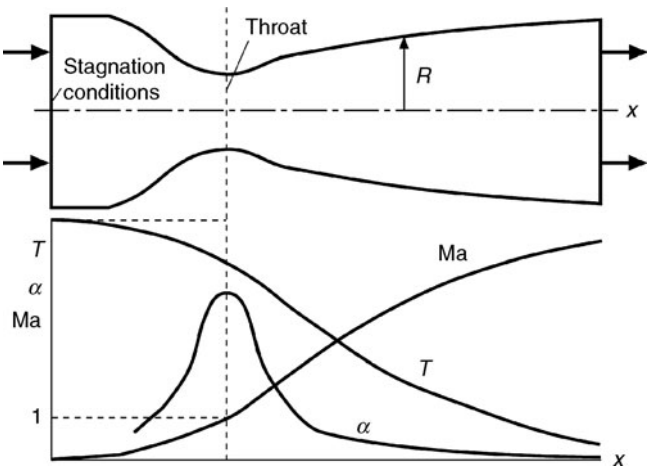
$$\sigma = \left[\left(0.5T_w/T_0\left(1 + \mathrm{Ma}^2(\kappa-1)/2\right) + 0.5\right]^{0.8-\omega/5} \cdot \left[1 + \mathrm{Ma}^2(\kappa-1)/2\right)^{\omega/5}\right]^{-1} \tag{56}$$

The local Mach number in Eq. (56) can be calculated from a 1D isentropic flow analysis of the nozzle. Another equation, which has been recommended by Back et al. [31], shows better agreement with measurements as Eq. (54). This equation is given by

$$\mathrm{St} = \frac{c_f/2}{\sqrt{c_f/2}(5\ln(5\,\mathrm{Pr}+1) - 14 + \sqrt{2c_f})} \tag{57}$$

The friction coefficient c_f can be taken from the flat plate solution. Equation (57) can be further improved by using a correction method given in Back et al. [31].

A simple calculation method for the skin-friction and the heat transfer in rocket nozzles has been given by Mastanaiah [32]. The method is based on the simultaneous solution of the integral form of momentum and energy equations. The turbulent flow has been modelled via the mixing length approach. The numerical results presented have been compared with experimental data in 10°–10° and 30°–15° convergent-divergent nozzles, and N_2H_4–N_2O_4 rocket nozzle with an 15° half-angle of divergence.



M9. Fig. 12. Schematic distributions of Mach number, temperature, and heat transfer coefficient in a Laval nozzle [3].

4 Related Aspects

4.1 Flow Separation

Flow separation can be caused by an increase in pressure in flow direction or sudden changes in geometry. With this, density differences are associated, which might cause shocks in supersonic or hypersonic flows. Typical examples are the heat transfer on blunt bodies and cones, flat surface with a step in geometry, concave surface elements or shock impingement regions. Vortices and reattachment induces at the body surface locally extremely high heat transfer coefficients, whose positions and values are still a challenge for numerical methods. Many experimental and numerical investigations of flow separation for high speed flows have been done in the past. A nice summary, including

several correlations for the heat transfer, are given by Merzkirch et al. [33]. The reader is also referred to Holden [34, 35] concerning further detailed information on this topic.

4.2 Transition

The equations, which have been provided above, are only valid if the flow is either laminar or turbulent. However, in a lot of applications, the flow (either external or internal) will undergo flow transition from a laminar to a turbulent state. This effect can change dramatically the heat transfer on the surface under consideration. The reader is referred to White [16] and Hirschel [12] who give two quite comprehensive overviews on this effect.

4.3 Roughness

Surface roughness for a turbulent flow will increase the friction factor and to a smaller extend also the heat transfer. Roughness can also strongly influence the position for which laminar to turbulent transition takes place. The reader is referred to Schlichting [6] and Schneider [36] for some literature on roughness effects in compressible flows.

Specific Heat Transfer Devices

N1 Heat Transfer in Regenerators

Helmuth Hausen[2,†] (*Revised by Wolfgang Bender*)[1]
[1]VDEh-Betriebsforschungsinstitut GmbH, Düsseldorf, Germany
[2]Hannover, Germany

1 Operating Principle of Regenerators

The term "regenerator" denotes a heat transfer device which comprises a packing through which two different gases are alternately passed. The amount of heat to be transferred is temporarily stored in this heat-storing packing through which the gas stream is directed, and which is also variously referred to as the regenerator's checker (work), matrix, grating, bed, heat store, or storage mass. The regenerative heat transfer involves locally non-steady-state subprocesses which are generally referred to as "heating" or "cooling." Depending on the viewpoint, these terms apply either to the storage mass or to the different gas flows.

The function of a regenerator is illustrated in Fig. 1 which, by way of example, shows a regenerator pair as used in cryogenic applications. The cylindrical tanks contain heat-storing masses which may be porous, interspersed with passages, or of a checkerwork structure. The two different gases are alternately routed through these storage masses in opposite directions to obtain a gas counterflow offset in time. As a result of this cyclic reversal, the temperature of the storage mass varies upward and downward periodically, i.e., the packing temporarily absorbs a certain amount of heat during the "hot cycle" before releasing it to the colder gas again during the "cold cycle." The regenerative heat transfer process is characterized by a locally alternating non-steady-state heat transfer, which takes place initially between the gas stream 1 and the storage mass and, subsequently, between the storage mass and the gas stream 2. In the course of this process, the two gas streams pass over the same heating surface of the storage mass in succession. The function of a regenerator pair as used in hot industrial furnace applications is shown in Fig. 2, the so-called regenerator burner system. The regenerative heat transfer process follows the same proceedings as with the cryogenic application.

2 Regenerator Design and Application

In terms of apparatus engineering, regenerators can be classified into two groups:

- Fixed-matrix regenerator system (Siemens/Cowper patent): A regenerator of this type is cycled discontinuously between heating and cooling. Thus, to achieve a continuous heat transfer, at least two separate regenerators (i.e., a regenerator pair) are required so that the first gas stream can be cooled while the other is being heated at the same time, as shown in Figs. 1 and 2. The temperature of the exiting gas streams is not constant with this design.
- Moving-matrix regenerator system (Ljungström patent): In this regenerator design, a continuous changeover between heating and cooling takes place. Only a single packing is used to ensure an uninterrupted heat transfer from one gas stream to the other. This packing may either be a rotating storage mass which is exposed, in turn, to one or the other gas stream, or a stationary storage mass onto which the incoming gas streams are directed via rotating vaned hoods. Here again, hot or cold gas can be passed alternately through one and the same section of the storage mass. The temperature of the outlet gas flows can be kept constant in this case.

In terms of functional engineering, regenerators can also be classified in two groups:

- Central regenerator system: Two or more fixed-matrix regenerators work together to heat or cool one gas stream to the required conditions. To achieve a gas stream of constant temperature a special control system is necessary, as described next.
- Decentralised regenerator system: Normally, this system is used for heat recovery at high temperature plants. Many regenerators e.g., 10 – 40 are installed at the plant, and each sucks a part of the waste gas. The temperature of the heated gas stream is not constant, and the control system controls the energy balance of the whole plant.

Examples of classic central high-temperature regenerator applications include the hot-blast stoves (Cowper) associated with blast furnaces and the regenerative chambers on glass melting furnaces. Examples of decentral applications include the

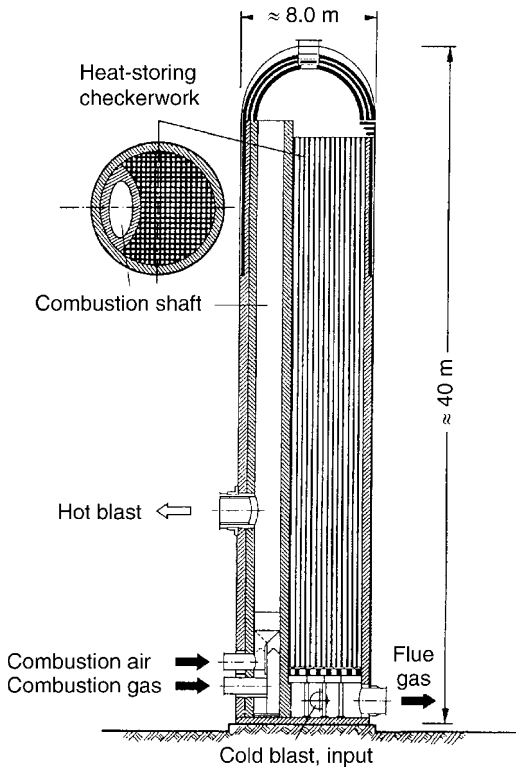
N1. Fig. 2. Operating principle of a regenerator burner for industrial furnaces.

regenerative chambers on coke ovens, and in recent years this regenerator principle has also been used in the so-called regenerator burners on industrial heating furnaces.

In the hot-blast stove (Cowper) according to Fig. 3, most of the interior space is filled by the heat-storing packing referred to



N1. Fig. 3. Hot-blast stove as Cowper.

as checkerwork, which consists of refractory bricks. In addition, each Cowper possesses a combustion shaft (Fig. 3, left-hand side) in which, e.g., the blast furnace gas is burnt to produce a hot flue gas. This flue gas is then blown through the checkerwork from the top downward, transferring its heat to the storage mass (i.e., the checkerwork). After flow reversal, air (referred to as "blast" in metallurgical terminology) is passed through the checkerwork from the bottom up and is thereby heated to a high temperature. The resulting "hot blast" is then injected into the blast furnace.

The hot blast is often required to exhibit not only a high temperature, but also one that remains as constant as possible. This can be achieved by ducting a progressively decreasing portion of the total airflow, which in itself remains unchanged, past the Cowper stove via a bypass line during the blast heating period, then mixing it with the hot air as it exits the stove. Therefore, the airflow through the Cowper stove must be heated to the point where its (decreasing) outlet temperature, at the end of the hot period, is still as high as, or slightly higher than, the required constant temperature of the mixed blast. Methods for calculating this process have been developed by Hausen [1, p. 387–392; 2], Willmott [3], and Razelos and Benjamin [4]. Another approach for producing a hot blast of maximum temperature constancy is to run four or more Cowpers simultaneously, on a regime which ensures that two of them deliver hot air at any given time. In an arrangement of this type, one Cowper has always been "on blast" for longer than the other. As a result, two gas flows of different temperatures are always available for mixing, and the mixed blast temperature can be maintained as constant as possible. Calculation equations for this technique can be found in the work by Schmidt and Willmott [5].

Nowadays one main application of regenerators is the heat recovery and preheating of combustion media at high

temperature heating plants (e.g., heating and melting furnaces in the metal, ceramic, chemical, and glass industry) and waste gas past combustion plants [6, 7]. The thermal power of these regenerators is less than the well-known hot-blast stoves or coke over regenerative chambers. They also must fulfill the actual demands:

- handling of gas temperature above 1,300°C,
- high load of dust and aggressive components,
- media preheating up to more than 1,000°C,
- longer operating time with low maintenance effort.

These requirements lead to some general principles of smaller regenerator design, especially for the application as regenerator burner:

- the regenerator and the burner(s) are connected with a short piping to avoid heat losses and the operation of valves at the hot side,
- the entire regenerator inside walls and packages must be made of ceramic materials,
- the flow direction should be vertical to avoid dust congregation,
- uncontrolled flow must be tied up.

Figure 4 shows an example of a switching regenerator unit, with a fixed storage mass, installed at a reheating furnace in a forging plant. The hot gas, about 1,200°C, from the furnace is sucked through the burner and the regenerator unit. The heat is stored in the ceramic mass and after reversing the flow the combustion air is heated up to 1,000°C. The function of burning – cooling the regenerator – and sucking – heating the regenerator – changes periodically. The usual time period is about 10 s up to 90 s. For the energy and temperature control of the whole furnace exist several methods, which have different impact on the single regenerator and burner unit.

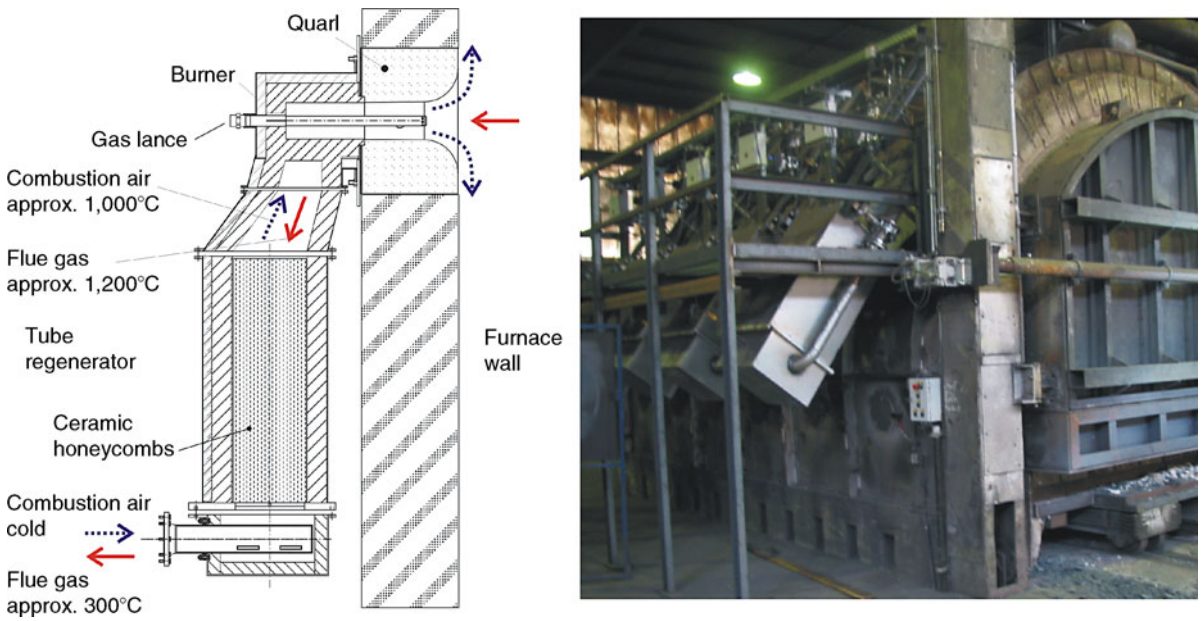
Another regenerator system has a rotating heat storage mass (Fig. 5). The hot gas from the furnace streams through the right area and heats the storage mass. By continuous rotation the hot mass is transported to the combustion air side (left), where the air is preheated. The average temperature of the whole air stream is nearly constant. The disadvantage of this system is a permanent leakage flow about 5–15% between air and gas. The problems of tightening systems for moving elements at high temperature are not solved yet.

In both cases – switching and rotating regenerators – the heat recovery works well and a decrease in gas consumption at industrial furnaces to about 30% is reached.

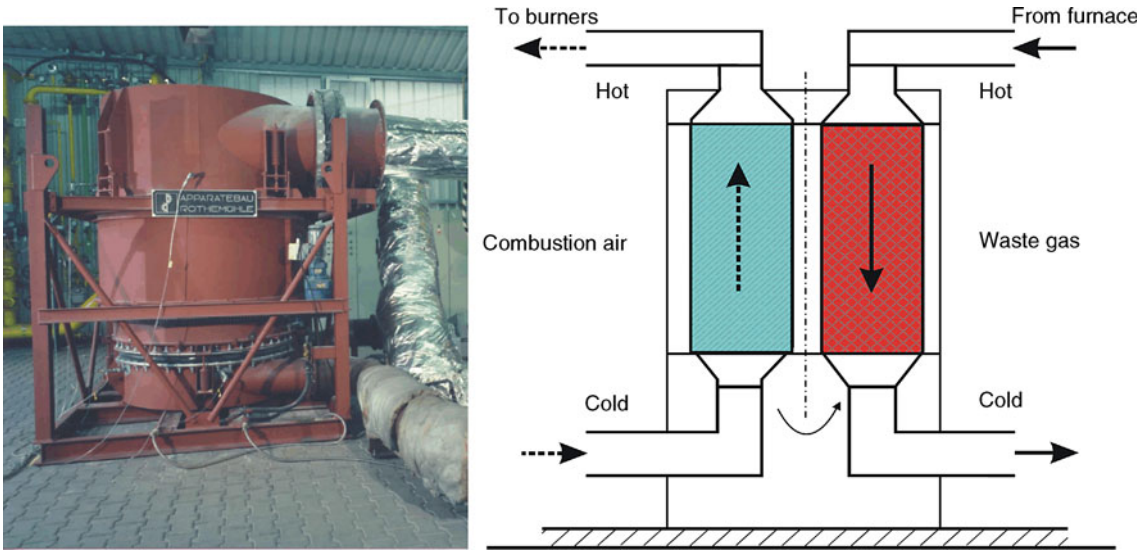
3 Geometry and Material of Storage Masses

The heat storage masses employed in high-temperature sections of big regenerators, e.g., of a Cowper, consist of refractory bricks measuring approx. 200 mm in original thickness. The time between two flow reversals is about 1–2 h in a unit of this type. Brick thickness has been progressively reduced to about 40 mm or less, especially in regenerators for the chemical industry. This has permitted a decrease in reversal times to less than a quarter hour. As shown in Fig. 6a, rectangular bricks can be arranged into a packing, providing smooth shafts, or into a more checkerwork-type configuration. It is also possible to build the packing of molded bricks, Fig. 6b–d. The previously employed method of changing the cross section of vertical passages over their linear length by installing filler bricks of varying size and shape is no longer common.

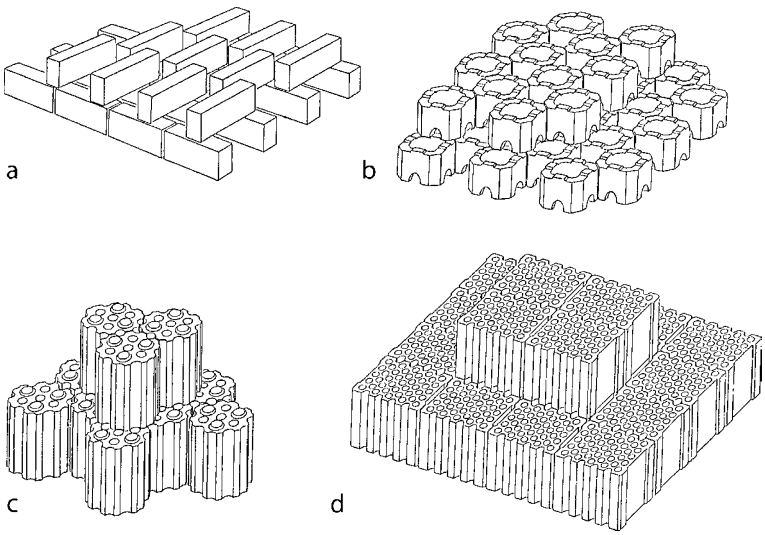
The time between the flow reversals in regenerator systems for heat recovery at industrial furnaces is shorter, less than 180 s. According to this, the thickness of the storage mass is smaller, about 1–5 mm. Figure 7 shows pictures of a storage mass for a hot-blast stove and three different masses for small regenerators: honeycombs, balls, and RASCHIG rings. Honeycombs are less sensitive to dust and they have little pressure drop. Balls and rings have a higher heat transfer coefficient, but they are sensitive to blocking by dust and the pressure drop is very high.



N1. Fig. 4. Fixed-matrix regenerator system at a forging furnace.



N1. Fig. 5. Moving-matrix regenerator system.



N1. Fig. 6. Bricks for large regenerators.

In the case of low or only moderately high temperature, the heat storage mass can be made of metal, e.g., steel or aluminum, so that narrower gas flow passages are obtained (Fig. 8). In cryogenics, obliquely corrugated strips of sheet aluminum were originally used. These were placed on top of each other with their corrugation directions alternating, so that a system of fine criss-crossing passages was produced. This costly packing design was later replaced successfully with gravel or stone chippings. Metal panel-type heating elements as shown in Fig. 8 are today used mainly in regenerators based on the Ljungström in Fig. 8 patent which operate as combustion air preheaters or flue gas heaters in boiler installations. The thickness of the sheet metal is about 0.5–1 mm. The hydraulic diameter of the gas passages amounts to between 4 and 9 mm. Extremely small dimensions were adopted for the regenerators in the Philips cryocooler developed for cryogenic applications; their packing consists of thin, wound copper wire.

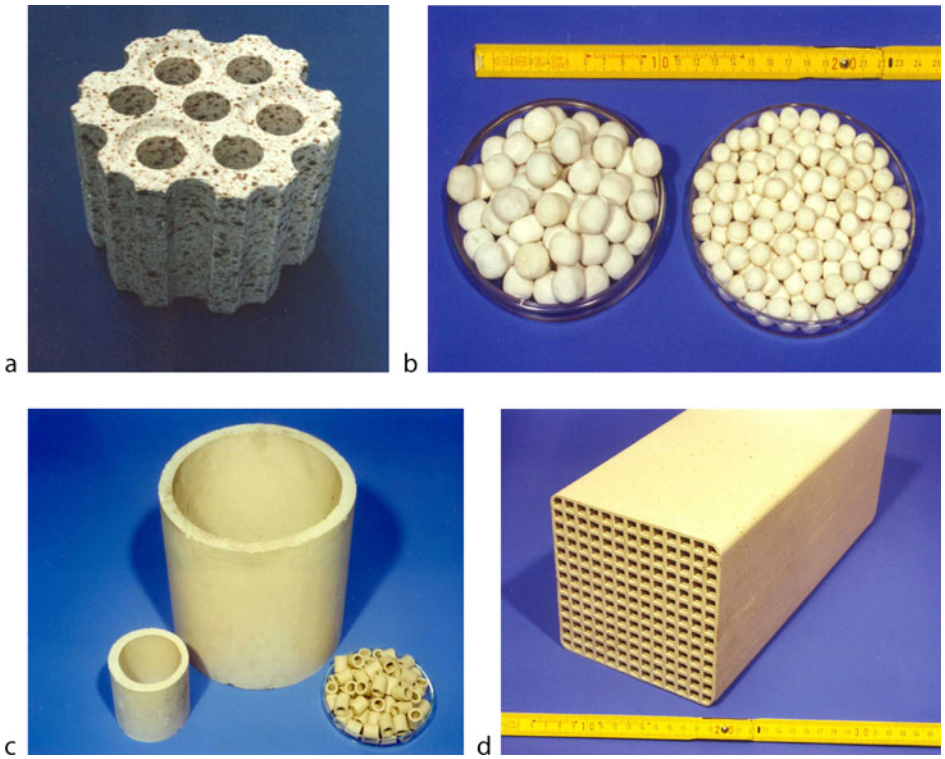
The geometrical properties of a checkerwork packing can be described in terms of the following four parameters:

- hydraulic diameter of the flow passage d_h,
- portion of free cross section of flow φ,
- specific heating surface area of checkerwork f_v,
- equivalent wall thickness δ_{gl} of a storage mass assembled from plates.

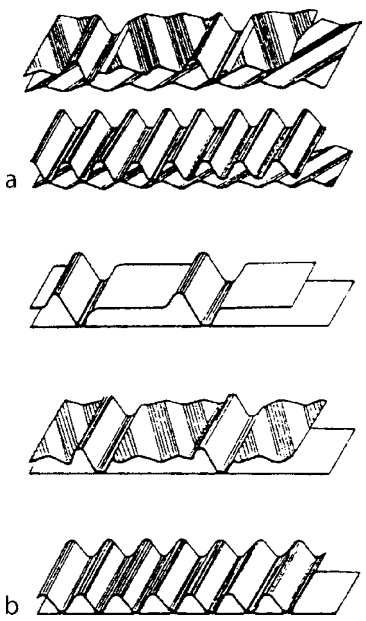
It has been shown by Heiligenstaedt [8] that the interrelationships between these four variables are such that selecting of any two of them will suffice to determine the two others. The following equations apply:

$$f_v = \frac{4\varphi}{d_h} \tag{1}$$

$$\delta_{gl} = \frac{d_h \cdot (1-\varphi)}{2\varphi} \tag{2}$$



N1. Fig. 7. Ceramic storage mass for smaller regenerators.



N1. Fig. 8. Metallic profiles for low-temperature regenerators.

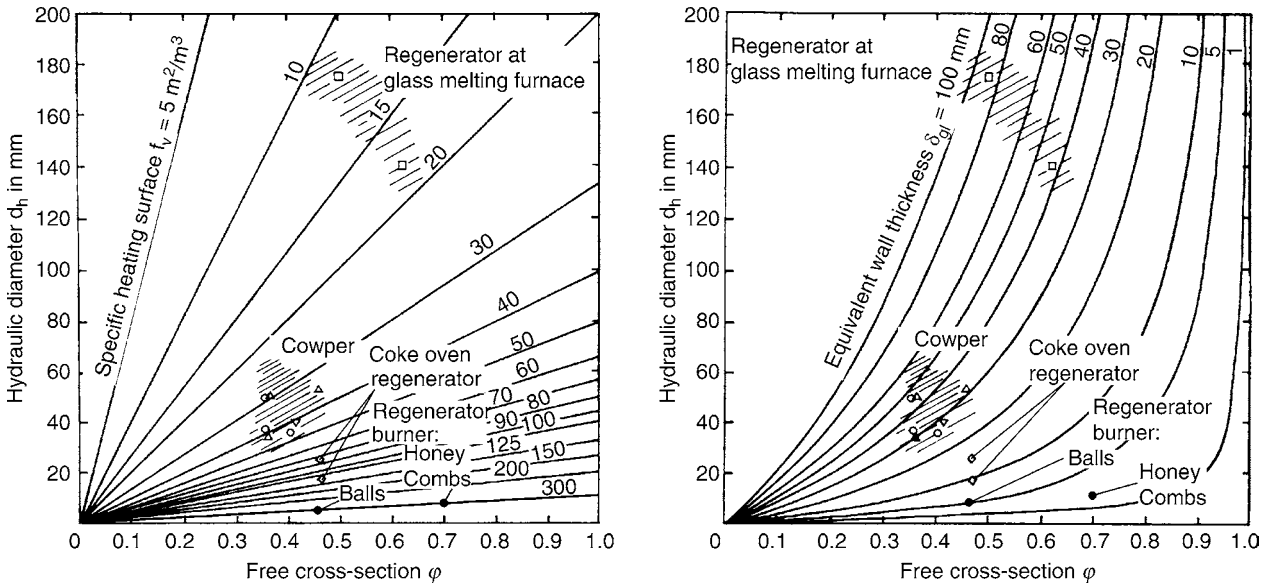
The two diagrams in Fig. 9 plot common packing data for a variety of regenerators. It emerges that the checkerworks employed differ quite substantially in terms of their geometry, according to the different operating conditions of the individual regenerator units.

4 Temperature Distribution and Heat Storage in Regenerators

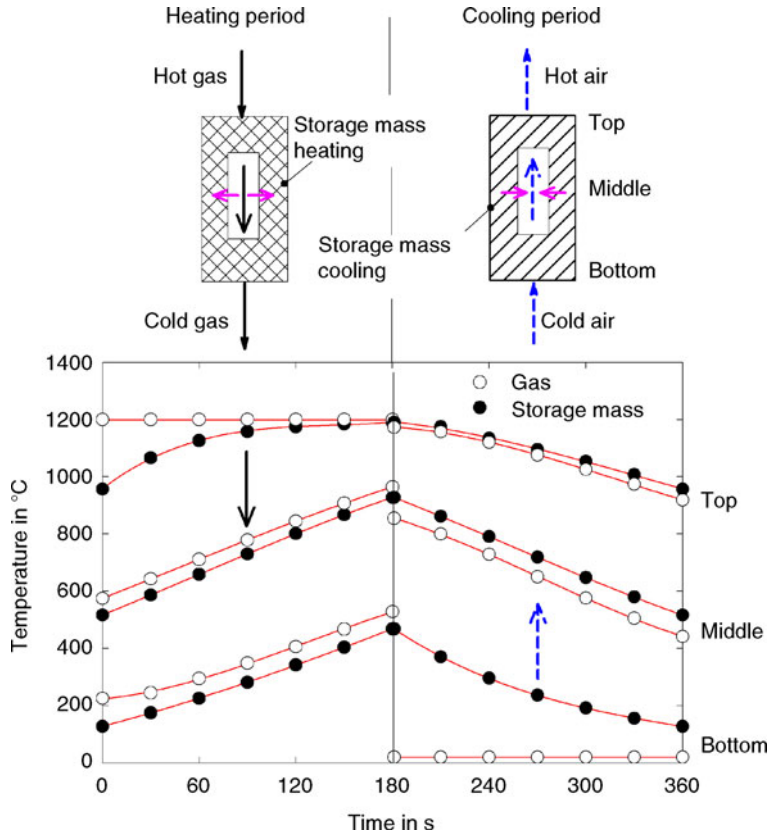
In regenerators with cycling function, the temperature of gas and storage mass changes periodically. Figure 10 shows the calculated temperature distribution of a regenerator during heating and cooling periods in three plains top, middle, and bottom.

The hot gas enters the regenerator with constant temperature of 1,200°C, the average temperature of the storage mass in this plain rises from 950°C up to nearly 1,200°C at the end of the heating period. In the middle plain the temperature curves of gas and storage mass are nearly parallel and they rise from about 550–600°C up to 900–950°C. At the bottom the gas outlet temperature rises up to 450°C at the end of the heating period. In the cooling period the cold air enters the regenerator in the bottom with a temperature of 20°C, the hot air leaves the regenerator at 1,200°C at the beginning and about 900°C after 180 s.

The gas outlet temperature in the heating period has a great impact on the construction of the waste gas system. Due to high temperature the material of piping and valves is expensive. The maximum temperature can be reduced by shortening the heating periods. Also the gas outlet temperature in the cooling period is important to the connected process, especially, a great temperature decrease can be avoided by shortening the time period, too. On the other side, the shortening of the time period reduces the regenerator efficiency by raising the leakage losses and decreasing the overall working time. Therefore, the integration of the regenerator system in the whole plant has a great influence on the layout and construction of the regenerator itself.



N1. Fig. 9. Comparison of geometric parameters of different storage masses.



N1. Fig. 10. Temperature distribution in a regenerator storage mass.

5 Calculation of Regenerators

For the general layout and the construction of a regenerator, usually it is not necessary to possess an accurate knowledge of local and time-dependent temperature distributions. For this task, it is normally sufficient to determine the heat transfer coefficient by the method of Hausen [1].

5.1 Calculation by Heat Transfer Coefficient

The heat transfer coefficient k for steady regenerators can be calculated with the equation:

$$k = \frac{Q_{Per}}{A \cdot (t_1 + t_2) \cdot \Delta T_m}; \qquad (3)$$

Q_{Per} is the heat amount, which is stored in the storage mass, A is the transfer area, t_1 and t_2 are lengths of time of heating and cooling periods, respectively, and ΔT_m is the average temperature difference between the two gas streams.

Further on the stored heat amount is transferred from the gas stream 1 to the gas stream 2

$$Q_{Per} = \dot{M}_1 \cdot \bar{c}_{p1} \cdot t_1 \cdot \Delta T, \tag{4a}$$

$$Q_{Per} = \dot{M}_2 \cdot \bar{c}_{p2} \cdot t_2 \cdot \Delta T_2, \tag{4b}$$

$\dot{M}$ is the mass flow, $\bar{c}_p$ the average heat capacity, t the period time, and ΔT the difference between entry and exit temperatures. With the assumption that the values of heat capacity are not temperature dependent, this is the logarithmic average value of the temperature differences at both ends of the regenerator. This heat transfer coefficient includes the heat transfer on the surface and the heat conduction inside the storage mass. It is calculated in two steps, first is the calculation of k_0:

$$\frac{1}{k_0} = (t_1 + t_2) \cdot \left[\frac{1}{\alpha_1 \cdot t_1} + \frac{1}{\alpha_2 \cdot t_2} + \left(\frac{1}{t_1} + \frac{1}{t_2} \right) \frac{\delta}{\lambda_s} \Phi \right]. \tag{5}$$

Hereby Φ is a function of $\frac{\delta^2}{2a}\left(\frac{1}{t_1} + \frac{1}{t_2}\right)$ which can be taken from Fig. 11, with δ as thickness of the storage material.

A normally sufficient approximation value δ_{gl} for thickness can be calculated by

$$\delta_{gl} = \frac{\delta}{2} + \frac{V_s}{A}. \tag{6}$$

To obtain the real heat transfer coefficient k of the regenerator, one has to calculate the relation of k/k_0. In this way one has to calculate the reduced regenerator length Λ and the reduced regenerator time Π:

$$\Lambda = 2 \cdot \frac{k_0 \cdot (t_1 + t_2) \cdot A}{C_{Per}} \tag{7}$$

$$\Pi = 2 \cdot \frac{k_0 \cdot (t_1 + t_2) \cdot A}{C_s} = \frac{C_{Per}}{C_s} \cdot \Lambda. \tag{8}$$

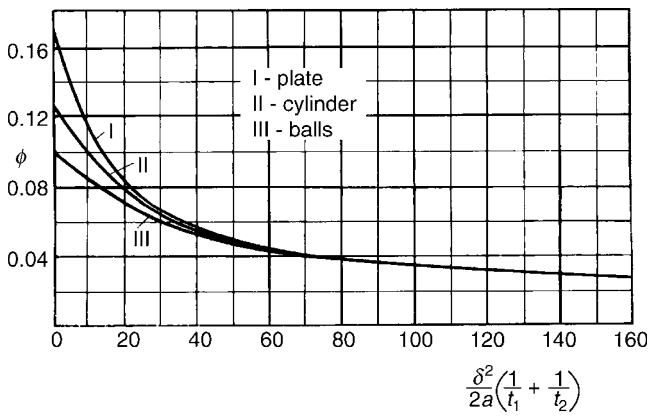
with $C_{Per} = \frac{1}{2}\left(\dot{M}_1 \cdot \bar{c}_{p1} \cdot t_1 + \dot{M}_2 \cdot \bar{c}_{p2} \cdot t_2\right)$ and C_s as the heat capacity of the storage mass. With these values for Λ and Π, we can determine the relation k/k_0 from Figs. 12 and 13. With the value for the heat transfer coefficient k, a regenerator can be calculated as well as a recuperator. Note that the temperature dependence of the heat capacity of gas and storage mass is not included.

5.2 Step-based Method

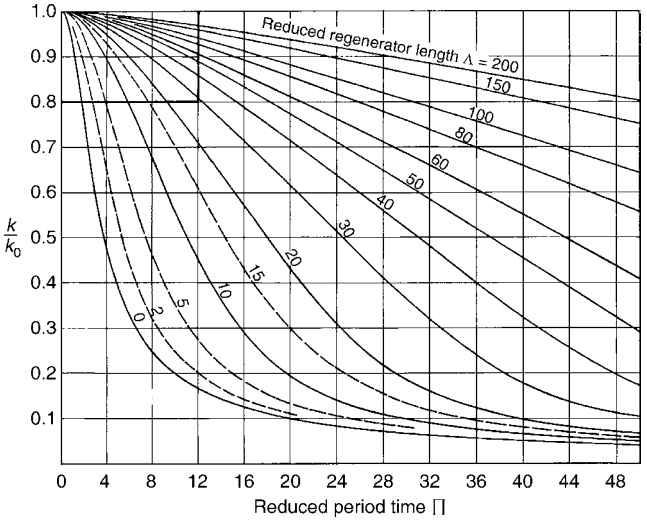
Nevertheless, some notes are included here for the event that a precise determination of the temperature distribution is desired. The former calculations are performed using the local mean brick temperature T_{sm} in the given regenerator cross section considered. The heat transfer coefficient, too, should then preferably be related to the difference between the gas temperature and the mean brick temperature T_{sm}. This heat transfer coefficient α_m is calculated from the true heat transfer coefficient α, the thickness δ, and the heat conductance λ_s of the brick material using the equation

$$\frac{1}{\alpha_m} = \frac{1}{\alpha} + \frac{\delta}{\lambda_s} \Phi, \tag{9}$$

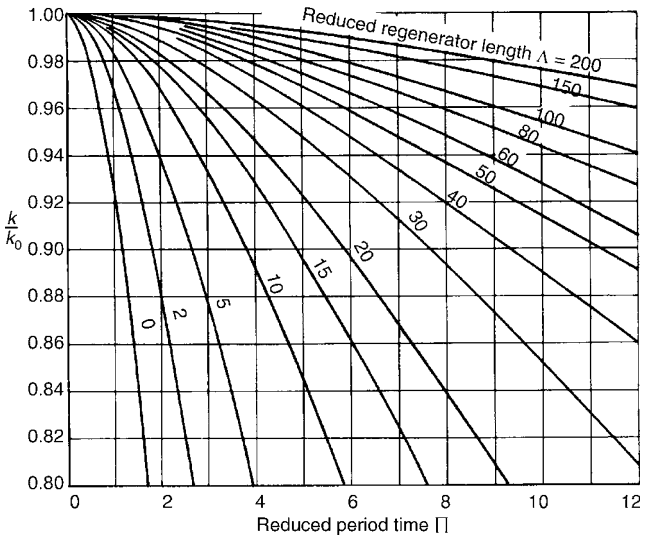
where Φ is the function determined from Fig. 11.



N1. Fig. 11. Function Φ for the calculation of the heat transfer coefficient.



N1. Fig. 12. Relation k/k_0 depending on Λ and Π.



N1. Fig. 13. Enlarged part of Fig. 12.

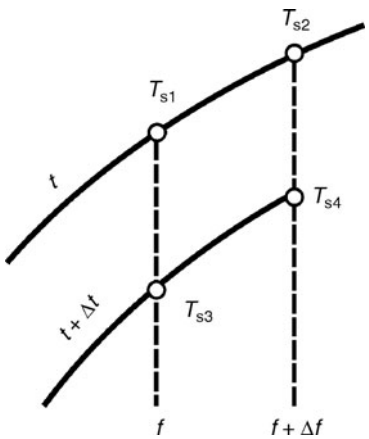
For calculating the temperature distribution in the longitudinal regenerator direction as a function of time, several approaches are known. Emphasis is placed here on those using the finite difference method, i.e., which proceed in steps and are therefore particularly suitable for computer-based execution as described, e.g., by Kuhn and Sucker [9, 10].

Two methods are explained, both of which are based on a transformation of the original graphic technique developed by Hausen [1, 11] into an all-numerical equation system. According to method I, which was given its numerical form by Willmott [12], the storage mass and the gas temperature are alternately determined at each step. Method II, on the other hand, which lent itself to numerical use virtually unchanged from the outset, initially involves calculation of the storage mass temperature only.

First, the space–time mesh on which the calculation process is based is explained with reference to Fig. 14. The longitudinal coordinate in the flow direction is assumed to be the heat-transferring surface area f of that portion of the heat storage mass which extends between the gas inlet point and the given regenerator point considered. It is further assumed, considering the example of a cold period in Fig. 14, that the temperatures T_{s1} and T_{s2} of the storage mass at points f and $f + \Delta f$ are known for time t, and that the temperature T_{s3} at point f is known for time $t + \Delta t$. The data sought is the storage mass temperature T_{s4} at point $f + \Delta f$ at time $t + \Delta t$. All storage mass temperature values represent local mean temperatures. For clarity's sake, the index m for the storage mass temperature has been omitted in the following equations. The corresponding gas temperature values T_{g1}, T_{g2}, T_{g3}, and T_{g4} are not shown in Fig. 14.

Step-based method I: Using the step-based method I according to Willmott [12], the desired temperatures T_{s4} of the storage mass and T_{g4} of the gas can be obtained by means of the following equations:

$$T_{s4} = \frac{\left(\frac{2\dot{W}}{\alpha_m \cdot \Delta f} + 1\right) \cdot \left[T_{g2} + \left(\frac{2}{\alpha_m \cdot \Delta t} \frac{dC_s}{df} - 1\right) T_{s2}\right] + \left(\frac{2\dot{W}}{\alpha_m \cdot \Delta f} - 1\right) \cdot T_{g3} + T_{s3}}{\left(\frac{2\dot{W}}{\alpha_m \cdot \Delta f} + 1\right) \cdot \left(\frac{2}{\alpha_m \cdot \Delta t} \frac{dC_s}{df} + 1\right) - 1}, \quad (10)$$



N1. Fig. 14. Calculation steps to investigate the storage mass temperature.

$$T_{g4} = T_{g3} + \frac{T_{s3} + T_{s4} - 2T_{g3}}{\frac{2\dot{W}}{\alpha_m \cdot \Delta f} + 1}. \quad (11)$$

In the foregoing Eqs. (10) and (11), $\dot{W}$ is the heat flow capacity of the flowing gas volume, C_s is the heat capacity of the storage mass, and dC_s denotes that part of the latter which corresponds to a very small portion df of its surface area. The value of α_m is determined by Eq. (9). For very thin or metal heat-storing elements, $\alpha_m = \alpha$. The iterative application of this step-based method I is best performed by means of computing software.

(This is discussed in more detail in the calculation in Example 3 at the end of Part N. The resulting temperature curves of the gas and packing are also presented for hot and cold periods.)

Step-based method II: In the method proposed by Hausen [11], which is also referred to as the step-based method II, only the temperature of the storage mass is determined initially.

$$T_{s4} = T_{s1} + \frac{(T_{s2} + T_{s3} - 2T_{s1}) + \frac{\alpha_m}{2}\left[\frac{\Delta f}{\dot{W}} - \frac{df}{dC_s}\Delta t\right] \cdot (T_{s2} - T_{s3})}{1 + \frac{\alpha_m}{2}\left[\frac{\Delta f}{\dot{W}} + \frac{df}{dC_s}\Delta t\right]}. \quad (12)$$

The symbols used are the same as in Eqs. (10) and (11). A simplification of Eqs. (10) and (12) is obtained if the position and time value at each step are selected such that $\frac{1}{\dot{W}}\Delta f = \frac{df}{dC_s}\Delta t$. This is particularly true for Eq. (12), which can then be expressed in the following simplified form:

$$T_{s4} = T_{s1} + \frac{T_{s2} + T_{s3} - 2T_{s1}}{1 + \frac{\alpha_m \Delta f}{\dot{W}}}. \quad (13)$$

In the step-based method II, the gas temperature associated with the calculated packing temperature curve is usually determined at the end of the computing process only, e.g., once the system has reached its equilibrium state. For calculating the gas temperature, Eq. (11) can be used in the same way as in step-based method I.

Evaluation notes on the two step-based methods I and II: The two step-based methods permit a calculation of the entire temperature curve at time $t + \Delta t$ (and, accordingly, for other increments) via Eqs. (10), (11), and Eq. (12) or (13), by iterating from f to $f + \Delta f$, $f + 2\Delta f$, etc. Both step-based methods can also be used with variable – and in particular, time-dependent – values of α_m, $\dot{W}$, and C_s by inserting slightly different values for these variables at each step. It is recommended to work with the α_m, $\dot{W}$, and C_s values applicable in each case to the temperature T_{s1} or $1/2\,(T_{s2} + T_{s3})$. With constant values of α_m, $\dot{W}$, and C_s one additionally obtains the required storage mass temperature T'_s at the gas inlet point, using the equation

$$T'_s = T'_g + \left(T'_{s0} - T'_g\right) \cdot e^{-\frac{\alpha_m \cdot df}{dC_s} t}. \quad (14)$$

Further to the known variables in Eq. (14), T'_g denotes the constant gas inlet temperature and T'_{s0} is the storage mass temperature at time $t = 0$. If one intends to compute the temperature values for multiple successive periods, it should be noted that the local temperature distribution of the storage mass determined at the end of one period will be equal to the

initial distribution at the start of the next period. To obtain the periodic equilibrium condition of the regenerator, the step-based methods must be applied for as many successive periods as are necessary until the temperature distributions remain unchanged at the end of the full period.

Both step-based methods yield a rather accurate determination of the changes in mean brick temperature over time. Time-related changes in gas temperature, however, are accurately rendered on a time-average basis only. This is due to the use of α_m according to Eq. (9). As a result, the rapid changes over time to which the gas temperature (and similarly the brick surface temperature) are subject immediately after the reversal are not taken into account. If a good numerical approximation of these rapid transients is desired, reference should be made to the publications by Willmott [3] and Hausen [1, p. 312].

The accuracy of the step-based methods I and II can be evaluated as follows, according to Hausen [13]. If identical lengths in space and time are adopted for the computing steps in both methods, then step-based method I will be more accurate than method II for the region near the regenerator's gas inlet point. However, the same accuracy in this region can also be achieved with step-based method II if the space and time steps are each set to one-half of the value used in method I. Slightly further away from the inlet, but at least starting from the position coordinate $(\alpha_m/\dot{W})f = 5$, both step-based methods yield the same very high accuracy with identical step sizes, and the calculation may therefore be based on large steps, e.g., $(\alpha_m/\dot{W})\Delta f = 3$. Step-based method II has one advantage here, in that it permits calculation of the storage mass temperature only, without any loss of accuracy. This reduces the computing time significantly, because only the simple Eq. (13) needs to be solved in this case.

5.3 Notes on Additional Calculation Methods

Besides the step-based methods, which are particularly suitable for implementation in computer software, other authors have attempted to give more analytical descriptions of the temperature distribution inside a regenerator. Thus, Anzelius [14] expressed the cooling and heating behavior of a storage mass of constant initial temperature by means of Bessel functions. Nußelt [15, 16], Schneidler [17], and Ackermann [18] proposed analytical approaches which also address quick temperature changes in the heat-storing material. However, any attempt to evaluate these analytical approaches leads back to numerical difference methods. The calculation method developed by Schack [19, 20] derives the calculation of regenerators from that of recuperators by introducing empirical elements for the checkerwork temperature distribution into the computing equations. Relying on Laplace transformation, Nahavandi and Weinstein [21] as well as Sandner [22] arrive at calculation equations which essentially coincide with Nußelt's integral equations. A more easily manageable approximation method for solving the integral equations was published by Iliffe [23]. Another approach to solve the regenerator equations has been presented by Vortmeyer and Le Mong [24, 25]. These authors use an equivalence relation between single- and two-phase fixed bed models. This method yields a quasi-homogeneous equivalence equation for the two-phase gas/brick system which, following mathematical transformation, becomes a partial differential equation analogous to the non-steady-state heat conduction equation and can thereupon be solved analytically. This interesting calculation variant abandons the concept of gas/brick heat transfer and instead considers the fictitious heat conductance merely in a brick phase. Willmott [26] and Schellmann [27] have disclosed implicit difference methods which make it possible to calculate not only the local mean brick temperature T_{sm}, but also local temperature differences within a brick cross section. The two methods are based on three-dimensional mathematical models. Especially, the calculation of smaller regenerators requires the operation of three-dimensional models, hence the influence of the transient effects is very high. The analytical solutions give just an approach of the real state.

Example 1

The first example shows the calculation of the true heat transfer coefficient with the equations in Sect. 5.1 of this chapter, to determine the average exit temperature values $\bar{T}_1''$ and $\bar{T}_2''$ by given entry temperature values.

A group of hot-blast stoves with two equal regenerators is used for the preheating of hot blast for the blast furnace. During the heating period hot combustion gas flows through the checkerwork, and during the cooling period cold air flows. The checkerwork consists of bricks with a thickness of $\delta = 0.03$m. The values of the storage material are $\rho_s = 1.800\ \mathrm{kg/m^3}$, $c_s = 1.200\ \mathrm{J/(kg \cdot K)}$, and $\lambda_s = 1\mathrm{W/(m \cdot K)}$. The temperature conductivity is

$$a = \frac{\lambda_s}{\rho_s \cdot c_s} = \frac{1}{1{,}800 \cdot 1{,}200}\ \mathrm{m^2/s} = 0.463 \cdot 10^{-6}\ \mathrm{m^2/s}.$$

The heat transporting surface of the storage mass is $A = 40.000\ \mathrm{m^2}$ and the volume of the solid mass is $V_s = 900\ \mathrm{m^3}$. The resulting heat capacity of the storage mass is

$$C_s = V_s \cdot \rho_s \cdot c_s = 900 \cdot 1.800 \cdot 1.200\ \mathrm{J/K} = 1.944 \cdot 10^9\ \mathrm{J/K}.$$

The mass flow through the regenerator in the course of the heating period is $\dot{M}_1 = 31\ \mathrm{kg/s}$ with an average specific capacity of $\bar{c}_{p1} = 1.000\ \mathrm{J/(kg \cdot K)}$, an air stream of $\dot{M}_2 = 28\ \mathrm{kg/s}$ and $\bar{c}_{p2} = 1.040\ \mathrm{J/(kg \cdot K)}$ flows in the cooling period. The heat capacity streams are

$$\dot{W}_1 = \dot{M}_1 \cdot \bar{c}_{p1} = 31 \cdot 1.000\ \mathrm{J/(s \cdot K)} = 31.000\ \mathrm{J/(s \cdot K)},$$
$$\dot{W}_2 = \dot{M}_2 \cdot \bar{c}_{p2} = 28 \cdot 1.040\ \mathrm{J/(s \cdot K)} = 29.120\ \mathrm{J/(s \cdot K)}.$$

The time of heating and cooling periods are equal, $t_1 = t_2 = 1\ \mathrm{h} = 3.600\ \mathrm{s}$. Thereby results the average heat capacity of both gas streams:

$$C_{Per} = \frac{1}{2} \cdot \left(\dot{W}_1 \cdot t_1 + \dot{W}_2 \cdot t_2\right)$$
$$= \frac{1}{2} \cdot (31.000 \cdot 3.600 + 29.120 \cdot 3.600)\ \mathrm{J/K} = 108.2 \cdot 10^6\ \mathrm{J/K}.$$

The hot combustion gas enters the regenerator with the temperature $T_1' = 1{,}250°\mathrm{C}$, and the cold blast with the temperature $T_2' = 100°\mathrm{C}$. The heat transfer coefficients are $\alpha_1 = 31\ \mathrm{W/(m^2 \cdot K)}$ and $\alpha_2 = 22\ \mathrm{W/(m^2 \cdot K)}$.

The true heat transfer coefficient k and the average exit temperature values $\overline{T}_1''$ and $\overline{T}_2''$ shall be calculated.

$$\frac{\delta^2}{2a}\cdot\left(\frac{1}{t_1}+\frac{1}{t_2}\right)=\frac{0.03^2}{2\cdot 0.463\cdot 10^{-6}}\cdot\frac{2}{3.600}=0.54.$$

By using Fig. 11 you get

$$\Phi=\frac{1}{6}-0.00556\cdot 0.54=0.1636.$$

Furthermore is

$$\frac{\delta}{\lambda_s}\Phi=\frac{0.03}{1}\cdot 0.1636\ \mathrm{m^2\cdot K/W}=0.00491\ \mathrm{m^2\cdot K/W}.$$

Set in Eq. (5) delivers

$$\frac{1}{k_0}=(3.600+3.600)\cdot\left[\frac{1}{31\cdot 3.600}+\frac{1}{22\cdot 3.600}+\frac{2}{3.600}\cdot 0.00491\right]\mathrm{m^2\cdot K/W}$$
$$=0.175\ \mathrm{m^2\cdot K/W},$$
$$k_0=5.71\ \mathrm{W\cdot(m^2\cdot K)}.$$

This delivers with Eqs. (7) and (8):

$$\Lambda=2\cdot\frac{5.71\cdot(3.600+3.600)\cdot 40.000}{108.2\cdot 10^6}=30.4,$$
$$\Pi=2\cdot\frac{5.71\cdot(3.600+3.600)\cdot 40.000}{1.944\cdot 10^9}=1.69.$$

With these values one get by using Fig. 12:

$$\frac{k}{k_0}=0.99$$

and finally the true heat transfer coefficient:

$$k=0.99\cdot 5.71\ \mathrm{W/(m^2\cdot K)}=5.65\ \mathrm{W/(m^2\cdot K)}.$$

The required values of exit temperatures $\overline{T}_1''$ and $\overline{T}_2''$ can be estimated by the combination of Eqs. (3) and (4).

$$Q_{\mathrm{Per}}=k\cdot A\cdot(t_1+t_2)\cdot\Delta T_m=\dot{W}_1 t_1\left(T_1'-\overline{T}_2''\right)=\dot{W}_2 t_2\left(T_2''-T_2'\right)$$
$$=5.65\cdot 40.000\cdot 2\cdot\Delta T_m=31.000\cdot 1\cdot\left(1.250-\overline{T}_1''\right)$$
$$=29.120\cdot 1\cdot\left(T_2''-100\right).$$

This means for ΔT_m when the specific heat capacity of the gas does not depend on the temperature:

$$\Delta T_m=\frac{\left(T_1'-\overline{T}_2''\right)-\left(\overline{T}_1''-T_2'\right)}{\ln\dfrac{\left(T_1'-\overline{T}_2''\right)}{\left(\overline{T}_1''-T_2'\right)}}=\frac{\left(1.250-\overline{T}_2''\right)-\left(\overline{T}_1''-100\right)}{\ln\dfrac{1.200-\overline{T}_2''}{\overline{T}_1''-100}}$$

By "testing" one will get from the last two equations:

$$\overline{T}_1''=210^\circ\mathrm{C}\quad\text{and}\quad\overline{T}_2''=1.207^\circ\mathrm{C}.$$

This means that the hot combustion gas is cooled in the regenerator down to 210°C and the cold blast is heated up to 1,207°C as average values.

Example 2

Reversal of the equation of Example 1: Which heat transfer surface do you need for heating the hot blast up to $\overline{T}_2''=900^\circ\mathrm{C}$? The other conditions and values remain constant as in Example 1. With these conditions the heat balance follows as:

$$T_1'-\overline{T}_1''=\frac{\dot{W}_2 t_2}{\dot{W}_1 t_1}\cdot\left(\overline{T}_2''-T_2'\right)=\frac{29.120}{31.000}\cdot(900-100)^\circ\mathrm{C}$$
$$=751.5^\circ\mathrm{C}$$

and the average exit temperature $\overline{T}_1''$ of combustion gas:

$$\overline{T}_1''=(1.250-751.5)^\circ\mathrm{C}=498.5^\circ\mathrm{C}.$$

With these values you can calculate the average temperature difference:

$$\Delta T_m=346.9^\circ\mathrm{C}$$

Out of the heat balance

$$k\cdot A\cdot(t_1+t_2)\cdot\Delta T_m=\dot{W}_1 t_1\left(T_1'-\overline{T}_1''\right)$$

follows with $t_1=t_2$

$$k\cdot A=\frac{31.000\cdot 751.5}{2\cdot 346.9}\ \mathrm{W/K}=33.578\ \mathrm{W/K}.$$

By using the approach value for $k=5.65\ \mathrm{W/(m^2\cdot K)}$ – as in example 1 – you get

$$A=\frac{33.578}{5.65}\mathrm{m^2}=5.943\,\mathrm{m^2}.$$

With this approach value of A, a constant relation of A/V_s, a reduced heat capacity $C_s=0.149\cdot 1.944\cdot 10^9$ and $k_0=5.71$ you get the following preliminary values:

$$\Lambda=2\cdot\frac{5.71\cdot(3.600+3.600)\cdot 5.943}{108.2\cdot 10^6}=4.52,$$
$$\Pi=2\cdot\frac{5.71\cdot(3.600+3.600)\cdot 5.943}{0.149\cdot 1,944\cdot 10^9}=1.69.$$

Furthermore you get out of Fig. 13 the relation k/k_0=0.95, which is used to obtain more exactly:

$$k=5.71\cdot 0.95\ \mathrm{W/(m^2\cdot K)}=5.42\ \mathrm{W/(m^2\cdot K)}$$

and following the required heat transfer surface:

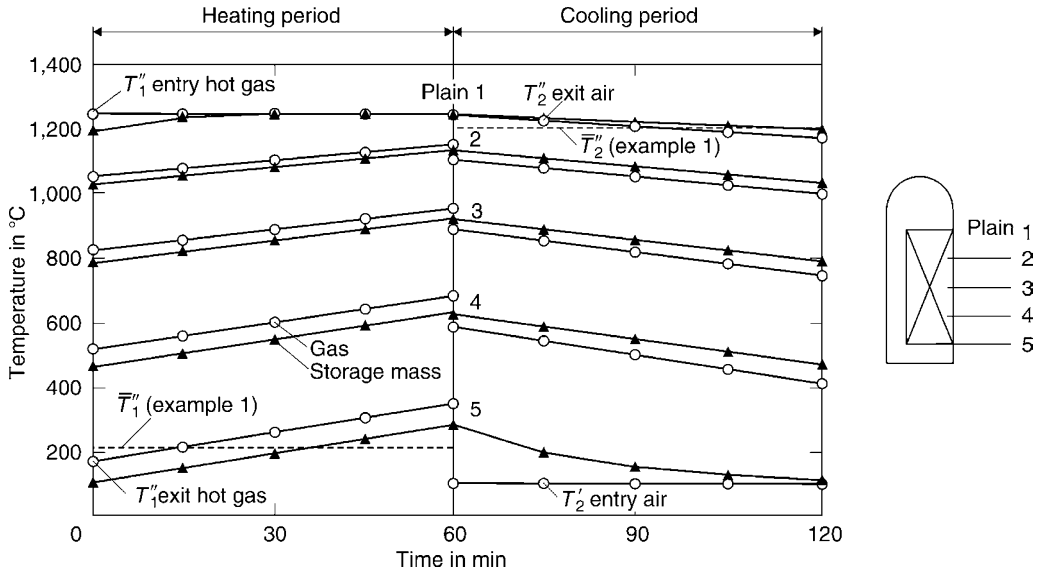
$$A=6.195\ \mathrm{m^2}.$$

With this more exact value of A normally Λ and Π must be calculated again: The results would be $\Lambda=4.71$ and $\Pi=1.69$. With these values the relation of $k/k_0=0.95$ would remain constant, therefore a repetition of the calculation is not necessary.

Remark: The calculations as in Examples 1 and 2 give sufficient and usable results. For more detailed information e.g., about the time-dependent and local temperature profiles you must use the step-based method or another extensive calculation method, see following Example 3.

Example 3

The temperature profile of the checkerwork can be calculated with e.g., the step-based method (Sect. 5.2 in this chapter). To execute the parameter studies the use of a computational model is helpful. Kuhn and Sucker [9, 10] presented this for selected



N1. Fig. 15. Calculated storage mass and gas temperature profiles.

cases. The following results are discussed in the example of Fig. 15. The used computational model involves temperature-dependent material values. Figure 15 shows the respective temperatures of hot combustion gas and air as well as the average temperature of storage mass, depending on the time of the heating and cooling periods, at five selected plains in the storage mass. The filled triangles characterize the storage mass temperature. The temperature profile is continuous in all plains, which can be recognized at the switching point. The gas temperature – open circles – has a jump at this point. In Fig. 15 the calculated average exit temperature values $\overline{T}_1''$ and $\overline{T}_2''$ are also drawn. The comparison shows the differences between the results of Examples 1 and 3 as well as the used calculation methods. For simple layout calculations the method described in Sect. 5.1 in this chapter gives quickly a sufficient result. To get more information about local and time-dependent temperature profiles in the regenerator, one must use a more detailed step-based method.

N2 Combined Heat and Mass Transfer in Rotating Regenerators

Gerd Gaiser
Reutlingen, Germany

1 Setup of Rotating Regenerator Systems

The previous section dealt with regenerators with non-moving heat storage media, where hot and cold gas alternately flow through the static regenerator. The outlet temperatures of both media vary during the operation (during the heating and cooling phases). For a continuous operation, two parallel devices are required. Each of the devices is passed through by the hot and the cold gas flux alternately.

The regenerators with moving heat storage medium, considered in this section, show a relative movement of the heat storage medium in relation to the gas fluxes. The first type of these regenerators consists of a rotating heat storage medium, while the inlet of the hot and cold gas is static (Ljungström system, see Fig. 1). The second type consists of a static heat storage medium while the gas inlet and outlet distributors rotate synchronously (Rothemühle system).

Figure 2 shows a Ljungström regenerator for a power plant application. The Rothemühle system for a comparable application is shown in Fig. 3.

With both systems the continuous rotation results in an alternating flow of the hot and cold gas through the heat storage medium. Each virtual segment of the storage medium of a rotating regenerator (shown as hatched segment in Fig. 1) undergoes a continuous heating-up on the warm gas side and a continuous cooling-down on the cold gas side during one rotation. During the warm gas phase the hot gas enters the segment with a constant temperature. The volume element undergoes a continuous heating-up. The changeover of the volume element to the cold gas side corresponds to the switching of the gas fluxes in a static regenerator. This analogy is valid under the assumption that no heat flux occurs in circumferential direction from one segment to an adjacent one. This condition will apply for most of the storage media used in these applications. So, a regenerator with one moving heat storage medium in its functionality performs like a pair of interconnected regenerators with static heat storage media.

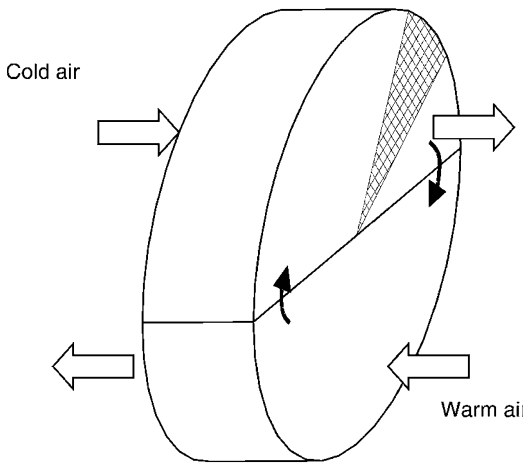
With static regenerators the outlet temperatures vary with time but are locally constant. In contrast, rotating regenerators show locally different outlet temperatures in circumferential direction. In case of constant inlet conditions and a constant rotational speed, the local outlet temperatures are constant with time. Therefore in this case the average value of the outlet temperatures is constant with time. In order to homogenize the local temperature differences in practical applications, a mixing of the outlet gas fluxes should be aimed at, especially in the case of regenerators with large diameters. In air conditioning applications, this is often done by arranging the fan behind the regenerator.

The benefits of rotating regenerators consist in the uniform and continuous operation without interruption of the gas fluxes, as well as in the temporally constant average outlet temperatures, and in the shorter cycle times which allow a more compact installation size. These benefits have led to a broad application of rotating regenerators in the power plant technology as well as in the ventilation and air conditioning technology and for air conditioning in the process technology. An additional benefit for applications in ventilation and air conditioning technology

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_62,

consists in the continuously adjustable efficiency by varying the rotational speed of the rotating regenerator.

In contrast to recuperative heat exchangers, regenerative heat exchangers show the following additional benefits: as already shown by Hausen [1], using regenerative heat exchangers the same amount of heat can be transferred at a three-times smaller temperature difference as in the case of recuperative heat exchangers. Also regenerative heat exchangers are less sensitive to fouling, especially in the case of straight flow channels as used in applications for ventilation and air conditioning technology. This is supported by a certain self-cleaning effect by the alternating flow direction. In addition, potential deposits have significantly less effects on the thermal efficiency in the case of regenerators than in the case of recuperators: the heat transfer and subsequently the thermal efficiency are affected only to a minor extent by deposits since deposits also act as heat storage medium. In contrast, in the case of recuperative heat exchangers deposits significantly reduce the overall heat transfer. Furthermore, regenerators can be more easily cleaned as the heat transferring surfaces are better accessible for cleaning.

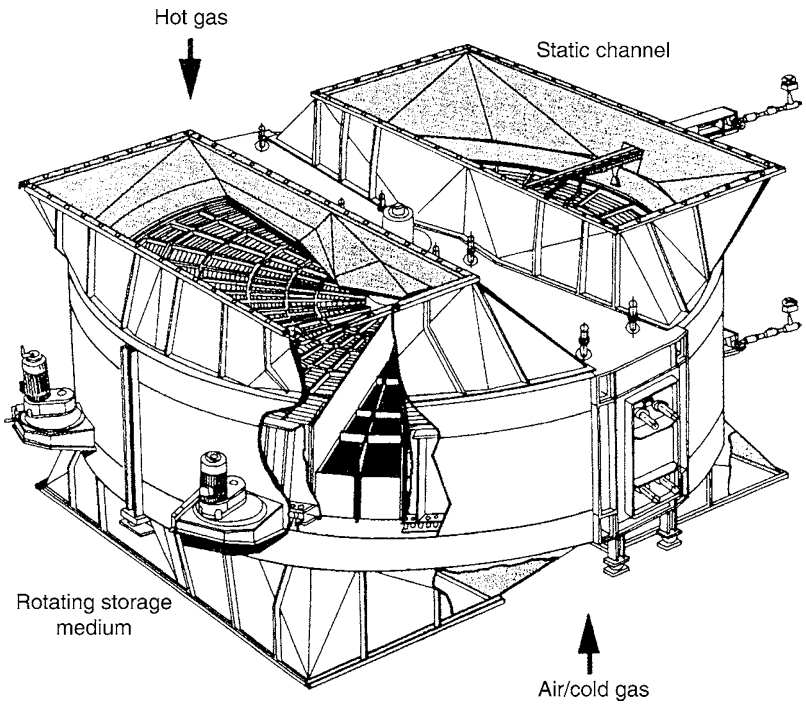


N2. Fig. 1. Scheme of a regenerator with rotating heat storage medium.

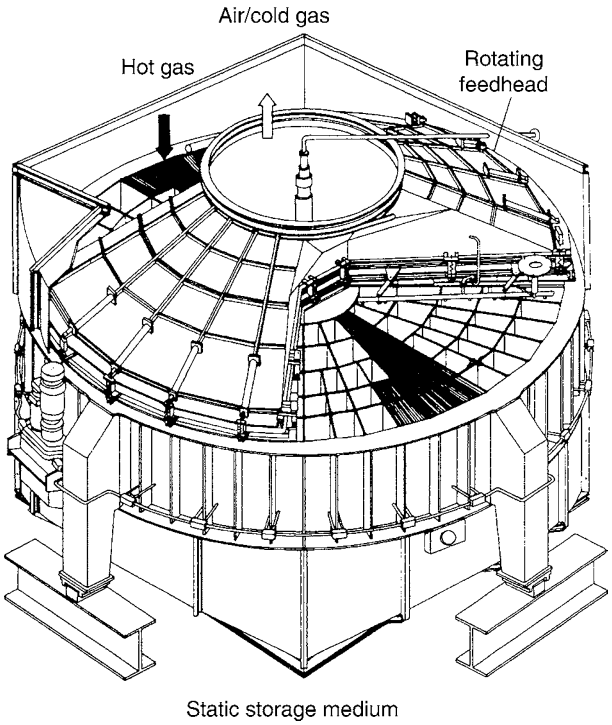
2 Rotating Regenerator Systems in Power Plant Applications

The preheating of the combustion air in the power plant technology is a common application for rotating regenerators. The warm-up of the combustion air is done using heat from the hot flue gas. On the flue gas side, the inlet temperatures are in the range of 320–350°C; the outlet temperatures are about 120°C. The preheating of the combustion air happens from an inlet temperature of 50°C to an outlet temperature of 300°C. Typical flow velocities are in the range of 12–15 m/s in the single channels of the storage medium. When calculating the design it has to be considered that the mass fluxes of air and exhaust gas are different and the proportions depend on the type of fuel. Regenerators for these applications are designed for volume fluxes up to 1.5 Mio Nm^3/h and for diameters up to 20 m. The rotating mass is up to 1,000 tons [2, 3]. For these applications, the heat storage medium is divided into several segments. The rotational speed for these applications is about 0.5–2 rotations per minute.

Besides the preheating of the combustion air, rotating regenerators in the power plant technology are also used for cooling and reheating of the exhaust gas in connection with wet desulphurization systems and with DENOx Systems. A further field of application is their use with gas turbines. The technique of sealing leakage and leakage reduction as well as the preheating of different gas fluxes in the same apparatus is reported by Allgäuer and Dietrich [2].



N2. Fig. 2. Regenerator with continuously rotating storage medium (Ljungström system).

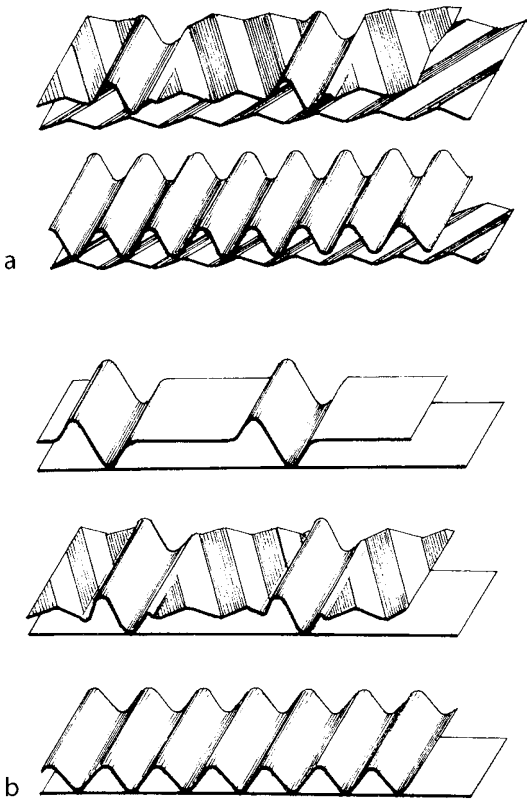


N2. Fig. 3. Regenerator with static storage medium and continuously rotating gas distribution system (Rothemühle system).

2.1 Design of the Storage Medium

For power plant applications storage media formed of rolled sheet metal plates are commonly used. Figure 4 shows some characteristic sheet designs. The sheet thickness usually is in between 0.5 and 1 mm. The average channel height for these applications in exhaust technology is in the range of 5 and 15 mm. In flow direction, different sheet designs can be arranged consecutively to achieve desired temperature profiles.

Requirements for the design of the storage medium are a low pressure drop and a low sensitivity toward fouling effects. Therefore, the heat storage plates commonly used show fluid channels oriented in main flow direction, where these channels may be formed of various cross sections. The dust in the exhaust gases may result in deposits on the heat storage plates which are periodically cleaned during operation using steam or pressurized air. To avoid a stream expansion in these cases usually "closed" profiles (as shown in Fig. 4b) are used. These closed profiles consist of alternating layers of flat plates and profiled plates. For applications with little risk of deposits "open" profiles (as shown in Fig. 4a) are used. The profile of both adjacent plates results in a lateral permeability and as a consequence of this to thinner boundary layers and to a higher heat transfer. For applications with gas turbines ceramic storage media are used. Recent designs consist of adjacent layers of each a flat and a corrugated ceramic foil in a rolled setup. This kind of setup



N2. Fig. 4. Metallic plate profiles for regenerators for power plant applications: (**a**) open profiles for high heat transfer and (**b**) closed profiles for good cleaning efficiency.

allows the setup of channels with extra small width, resulting in a high heat transfer and a high heat transferring surface. Thereby the required very high thermal efficiencies can be achieved.

For most of the power plant applications the major part of the storage medium consists of steel plates. In cases where a passing below the dew point at the cold end cannot be excluded, enameled plates are used in this zone to avoid the risk of corrosion. For difficult applications storage media made of plastic material, e.g., fluoride-based plastics, are used [4]. The storage plates are consecutively exposed to air and exhaust gases and thereby are exposed to a perpetual temperature cycling. Therefore, the calculation of the passing below the dew point must not be performed with the average temperature at the cold end of the regenerator, but must be performed considering the minimum storage medium temperature occurring in one cycle.

Due to the small thickness of the heat storage plates a uniform temperature distribution across the plate thickness may be assumed [4], as also has been proved by Kumpf [5] in simulation studies.

3 Rotating Regenerator Systems for Air Conditioning Applications and Process Applications

Regenerators with rotating storage medium are state of the art for heat recovery in ventilation and air conditioning technology. In the most common air ventilation application in winter, the fresh air is preheated by the exhaust air, while in summer the fresh air is precooled by the exhaust air which helps in reducing cooling power. Particularly for treatment of high air fluxes, regenerators with rotating storage medium have become state of the art for a long time. Examples for applications are ventilation and air conditioning devices for office buildings, department stores, production facilities, etc.

For the application in ventilation and air conditioning two different designs are used: the first one without systematic moisture recovery and the second one with systematic moisture recovery. With the first application sensible heat is transferred by the storage medium. Only after the exhaust air in the rotor has been cooled below the dew point, a humidity transfer occurs by condensation on the exhaust gas side (winter operation) and evaporation on the fresh gas side. The humidity transfer thereby varies depending on the temperatures and the humidity of both the fresh air and the exhaust air. A disadvantage is the formation of condensate on the heat transferring surfaces since this on the one hand promotes fouling on humid surfaces and on the other hand may result in icing of the channels during cold inlet temperatures.

In summer, the fresh air often is warmer and more humid than the exhaust air. In this case an uncoated regenerator reduces only the temperature of the incoming air while their water content remains constant. In this case, the incoming air achieves even a higher relative humidity.

For a systematic humidity transfer in ventilation and air conditioning technology regenerators are commonly designed with a water-vapor-adsorbing coating of the heat storage medium. Thereby, in the warm-cycle during the cooling of the exhaust air, an adsorption of the water vapor occurs at the sorptive surface. During the preheating of the incoming air in the cold-cycle, a desorption of the water vapor occurs and the incoming air is humidified thereby. This configuration can transfer both sensible and latent heat throughout the year. In winter besides the heat recovery an additional humidity recovery is achieved. In summer, both a precooling and a dehumidification of the incoming air is achieved. This assembly is also called sorption regenerator. By the simultaneous transfer of humidity a passing of the dew point and thereby the formation of condensate on the heat transferring surfaces can be effectively avoided. The recovery of humidity is also of economic benefit as in winter the latent heat fraction linked to the air humidity may achieve values of up to 40% of the entire enthalpy of the exhaust air.

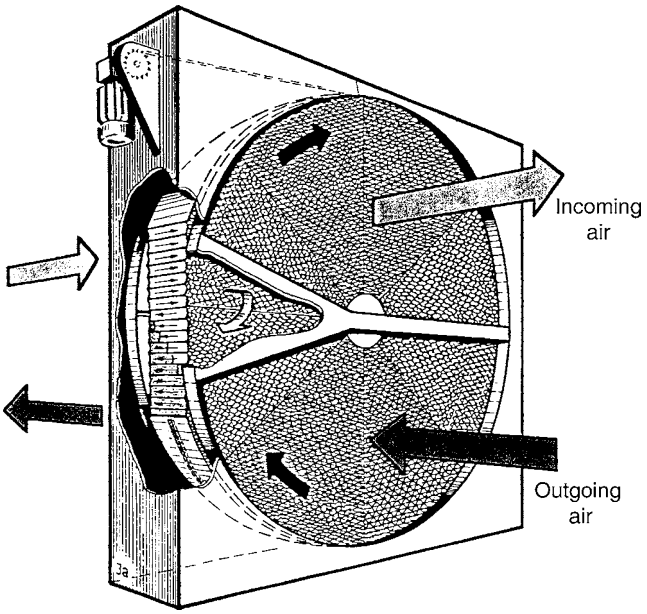
Regenerators with rotating storage medium also find a wide field of applications in heat recovery in industrial equipment as well as in process technology. In cases where a conditioning of the incoming air is desired in addition to the heat recovery (e.g., with paint finishing systems) sorption regenerators with simultaneous humidity transfer are used. Regenerators for ventilation and air conditioning applications are designed in diameters from 0.5 up to 5 m for air fluxes between 1,500 and 150,000 m^3/h. For air conditioning in paint spray lines, air fluxes up to 10^6 m^3/h are treated in parallel regenerators.

Figure 5 shows the scheme of a regenerator for ventilation applications [6]. At the intersection of the exhaust air segment to the fresh air segment a part of the air contained in the channels of the storage medium is moved to the fresh air side by the rotation of the storage medium. Depending on the rotational speed the amount of this leaking air may be 1.3–3% [7, 8]. To avoid this leaking air a purge segment can be arranged between the exhaust air segment and the fresh air segment. By the arrangement of such a purge segment as shown in Fig. 6, the amount of leakage air can be reduced to values of less than 0.05% [7]. Details on the hygienic rating of this measure have been composed by Beckert and Dehli [7].

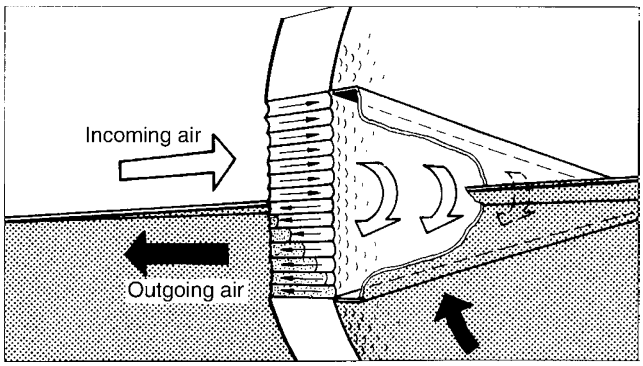
3.1 Design of the Storage Medium

The storage medium of regenerators for ventilation and air conditioning applications commonly shows a rolled setup by a pair of each a flat and a corrugated layer of thin material. Thereby, straight, sinusoidally shaped channels oriented parallel to the main flow direction are formed. The height of the layers are designed in between 1.5 and 4 mm, resulting in a laminar flow. In ventilation applications, the storage medium usually consists of a corrosion-resistive aluminum alloy. In process applications for the transfer of latent heat in the condensation range often plastic-coated aluminum alloy sheets are used. The thickness of the sheets used varies between 60 and 120 μm depending on the height of the corrugation. Therefore, a uniform temperature distribution across the layer thickness may be assumed in these cases. Figure 7 shows the typical setup of such a rolled storage medium for applications in ventilation and air conditioning.

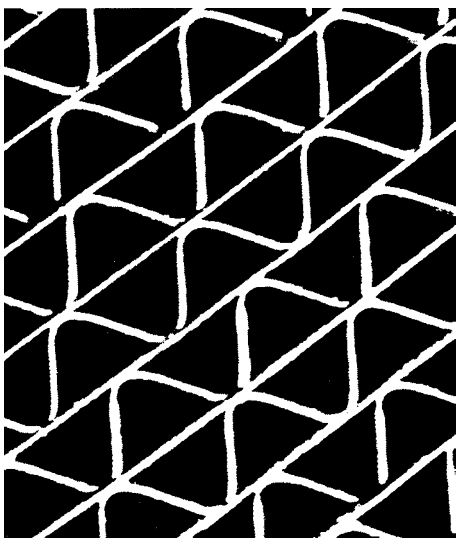
For simultaneous transfer of humidity with sorption regenerators the storage medium is coated with a water-vapor-adsorbing material. While former regenerators usually had a



N2. Fig. 5. Regenerator with rotating storage medium for ventilation and air conditioning applications (from [6]).



N2. Fig. 6. Purge segment to avoid exhaust air leakage from the exhaust air segment into the fresh air segment (from [6]).



N2. Fig. 7. Storage medium for regenerators in ventilation and air conditioning applications.

coating of lithium chloride, nowadays silicagel or in case of the process technology zeolithes are increasingly used as the sorptive layer. For applications in ventilation and air conditioning only thin layers are needed with respect to the high rotational speeds.

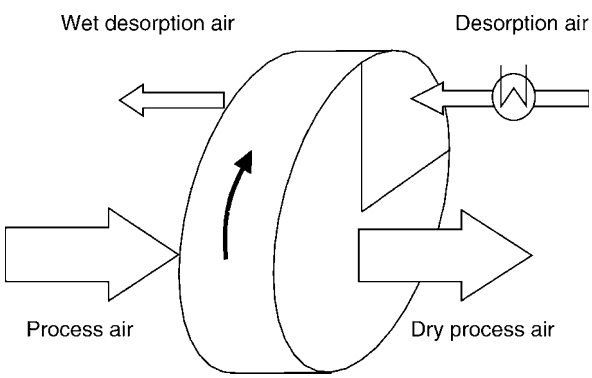
3.2 Air Dehumidification with Sorption Regenerators

Sorption regenerators can be used for systematic dehumidification of process air (see also Chap. M8). Thereby, the major part of the coated storage medium is flown through by the process air to be dried (Fig. 8). The humidity is adsorbed at the coated surface. In a smaller segment of the rotor the adsorbed humidity is desorbed with hot air. The rotating storage medium results in a continuous dehumidification of the process gas flux. For this application low rotational speeds in between 5 and 10 revolutions per hour are used. In addition for this application, the storage medium consists of a higher specific adsorptive mass of the coating.

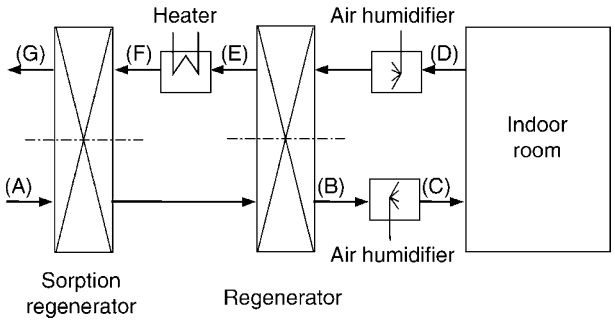
For coating of the storage medium different adsorbents are used. The coating with silicagel as often used is insensitive to surface humidity and therefore can be used even into the dew point range. The coating with lithium chloride allows a high loading capacity due to the different bonding mechanisms. In addition, coatings of lithium chloride show a bacteriostatic behavior [7]. Thereby, even during elongated standstill of the regenerator a reproduction of bacteria on the rotor can be excluded. Coatings with zeolithes are used when especially low air humidities are aimed at.

3.3 Cooling with Sorption Regenerators

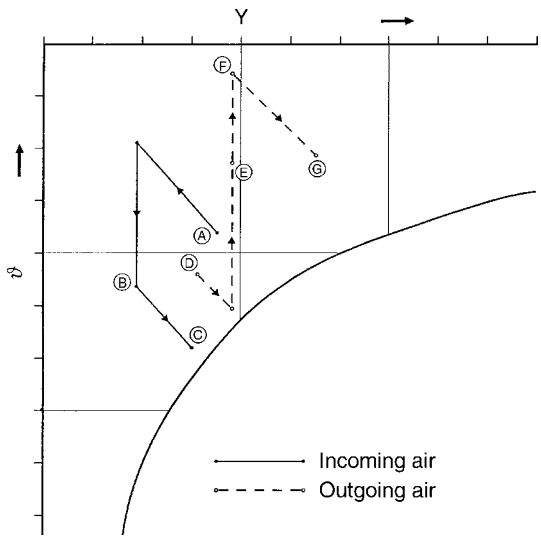
A sorptive cooling system [9], in the literature also known as "Desiccant Evaporative Cooling" (DEC), consists of a sorption regenerator in combination with a non-sorption regenerator and two moistening devices. Figure 9 shows the scheme of such a system. The corresponding constitutional changes of the air are shown in the h,Y diagram in Fig. 10. The function is as follows: outside air (A) enters the sorption regenerator, which adsorbs a part of the humidity from the air. Due to the



N2. Fig. 8. Air dehumidification with a sorption regenerator.



N2. Fig. 9. Scheme of an adsorptive cooling system with a sorption regenerator and a non-sorption regenerator.



N2. Fig. 10. Constitutional changes of the incoming air and the outgoing air in an adsorptive cooling system.

sorption the temperature of the dehumidified air rises. In the subsequent non-sorption regenerator, the air is cooled down to the state (B). In the subsequent moisturizer, the air is humidified and its temperature decreases further to the state (C). The air, conditioned to that target state (C) is then released into the room. The air in the room is warmed up to state (D). The outgoing air from the room (D) flows through a moisturizer in which it is cooled down due to the humidification. The outgoing air then enters the non-sorption regenerator in which it is warmed up to the state (E). In the subsequent heater, the outgoing air is heated up to desorption temperature (F) and then enters the sorption regenerator as desorption air. After the desorption of the sorption regenerator the outgoing air leaves the system with the state (G). Alternatively, only a part of the outgoing air may be used as desorption air.

For a high cooling power of the system a high efficiency of the regenerators is required as well as a sufficient desorption of the sorption regenerator. This leads to the required desorption temperature. If waste heat with sufficient temperature, e.g., from a production process, is available it may be used for the heater. The system in the cooling operation works with 100% fresh air and therefore is especially suitable for cases where a high air change ratio is required besides the cooling. In winter, the system acts as a sorption regenerator. In this case, heat recovery and humidity recovery can be controlled separately by the independent control of the two regenerators.

4 Calculation of Heat and Mass Transfer

4.1 Calculation Methods

The calculation of the heat transfer in regenerators traces back to Nußelt [10, 11] and Hausen [12–14]. The calculation of the heat transfer and the temperature profile according to the step method I of Hausen or step method II of Willmott [15, 16] have been described in detail in the previous Chap. N1. Vortmeyer and Le Mong [17] have reduced the separate calculation of air temperature and storage medium temperature to a single-phase model by means of an equivalence model. Hausen [18, 19] has also considered the effects of temperature-dependent properties as well as time-dependent mass fluxes. Kuhn and Sucker [20] used a mathematical model for their calculation of regenerators. Bahnke and Howard [21] considered the effect of longitudinal heat conduction on the performance of regenerators. Further calculation procedures have been described in the previous section.

At the beginning the analogy between regenerators with rotating storage medium and regenerators with static storage medium has been discussed. So the calculation methods described in the previous section can also be applied for calculation of the pure heat transfer.

For applications in ventilation and air conditioning as well as in the process technology, however, a simultaneous mass transfer occurs due to the moisture in the air. As described in Sect. 3, at non-adsorbing storage media the moisture transfer happens by condensation and evaporation of the moisture. Hausen [22] has already examined the condensation and evaporation of moisture in regenerators. Kruse and Vauth [23] as well as Vauth [24] have experimentally investigated the condensation of the moisture and the problem of the icing of the regenerator at cold outside temperatures. Vauth [24] has calculated the coupled mass transfer using a finite difference method. Further, calculation models and numerical solving procedures for the combined heat and mass transfer by condensation and evaporation have been published by Holmberg [25], van Leersum and Banks [26], Klein [27], and Frauhammer et al. [28]. All authors use numerical methods for the solving of the resulting system of differential equations.

The operation behavior of regenerators with adsorbing storage media has been investigated experimentally by Spahn and Gnielinski [29]. Maclaine-Cross and Banks [30] have calculated the heat transfer and the mass transfer separately but using a single film transfer coefficient. The simultaneous heat and mass transfer in regenerators with adsorptive storage medium have been calculated by Holmberg [31], Klein [27], and Gutermuth [32] by using a finite difference method.

A simple handmade calculation procedure is described in Chap. M8 (Humidifying and Drying of Air). This procedure

however requires additional empirical data on the operation behavior of the sorption regenerator.

4.2 Balance Model for the Heat Transfer in Regenerators

The design of regenerators may be done according to the step calculation procedures mentioned above and described in Chap. M8. However, considering todays PCs and the widespread use of established mathematical software (e.g., Maple™, Mathcad™, Matlab™, Mathematica™, or similar) the calculation by numerical solution of the system of differential equations resulting from the model suggests itself. By that, additional parameters like different storage media designs in axial direction can be considered easily. In particular, this modeling can easily be extended to the calculation of the combined heat and mass transfer in sorption regenerators for the ventilation and air conditioning technology.

The following paragraph will at first consider the pure heat transfer model. Later on, the model will be extended to the simultaneous heat and mass transfer in air conditioning applications.

Thereby, the following assumptions are made: the temperature is considered to be constant in radial direction (from the center to the outer diameter). With regard to the thin metal sheets and the channels oriented straight in main flow direction the heat transport in tangential direction is neglected. In addition, heat losses to the ambience are not considered here. In view of the thin metal sheets being >0.1 mm thick, the temperature across the sheet thickness is considered to be uniform. Kumpf [5] has shown that this is valid even for the thicker plates as used for power plant applications. The heat conduction of the heat storage medium in axial direction however has to be considered.

Thereby, the equation for the energy balance of the streaming air results as follows:

$$A \cdot \rho_L \cdot \varepsilon \cdot c_{p_L} \cdot \frac{\partial \vartheta}{\partial t} = \mp \dot{m}_L \cdot c_{p_L} \cdot \frac{\partial \vartheta}{\partial z} + A \cdot \lambda_L \cdot \varepsilon \cdot \frac{\partial^2 \vartheta}{\partial z^2} + \alpha \cdot A \cdot a_v \cdot (\vartheta_{Sp} - \vartheta). \quad (1)$$

The negative sign is valid for the warm-air cycle, the positive sign is valid for the cold-air cycle.

The corresponding energy balance for the storage medium results as follows:

$$A \cdot (1-\varepsilon) \cdot \rho_{sp} \cdot c_{sp} \cdot \frac{\partial \vartheta_{sp}}{\partial t} = A \cdot (1-\varepsilon) \cdot \lambda_{sp} \cdot \frac{\partial^2 \vartheta_{sp}}{\partial z^2} + \alpha \cdot A \cdot a_v \cdot (\vartheta - \vartheta_{sp}). \quad (2)$$

Thereby z means the flow direction, ϑ is the temperature of the gas flux, and ϑ_{Sp} is the temperature of the heat storing medium in the particular cycle. The values for the flow cross section A, the heat transfer coefficient α, and the mass flux also refer to the actual cycle. They may be different for the warm-air cycle and the cold-air cycle. The temperature-dependence of the thermophysical properties is accounted for.

The resulting system of differential equations is solved according to the finite volume discretization method. A variable local step size may be considered. For calculation of the steady-state profiles, the equation systems for the cold-air cycle and those for the warm-air cycle are solved alternately. The calculation of the alternating cycles is repeated until the quasi-steady-state (cyclic-steady-state) is achieved. Thereby, the initial condition for the heat storing medium in each cycle results from the corresponding temperature of the heat storing medium at the end of the previous cycle. For the cold-air cycle, the boundary condition results from the temperature of the incoming air at the cold rotor inlet side.

$$z = 0 : \vartheta = \vartheta_2'.$$

For the heat storing medium, the boundary condition

$$z = 0 : \partial \vartheta_{Sp} / \partial z = 0$$

is used.

For the warm-air cycle, the boundary condition results from the temperature of the outgoing room air at the warm rotor inlet side:

$$z = L : \vartheta = \vartheta_1'.$$

For the heat storing medium, the boundary condition

$$z = L : \partial \vartheta_{Sp} / \partial z = 0$$

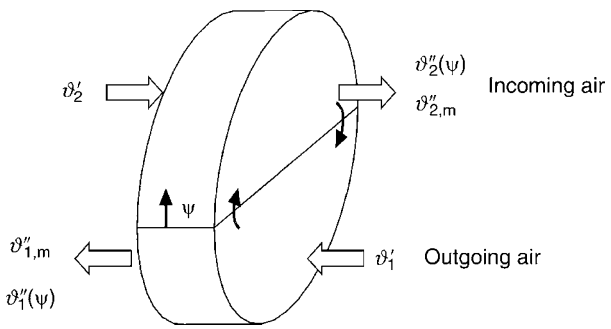
is used accordingly.

As mentioned in the beginning, the calculated chronological profiles of the temperatures in one cycle correspond to the temperature profiles across the circumferential angle ψ of the corresponding regenerator segment. Results of the calculations will be discussed in Sect. 5. Figure 11 illustrates the terms for the individual air streams. The relation between the circumferential rotor angle ψ and the time is

$$\psi = 360^\circ \cdot n \cdot t. \quad (3)$$

In regenerators with rotating heat storing medium the air streams flow in countercurrent flow direction. However, the heat storing mass moves transverse to the corresponding air stream. Therefore, the heat storing medium at any circumferential location sees the same air inlet temperature. This results in a cross-countercurrent flow as already has been descriptively shown by Martin [33].

As already shown by Hausen [1], a theoretical cycle duration of 0, in the case of the rotating regenerator corresponding to an infinite high rotational speed would correspond to the characteristics of a countercurrent heat exchanger. So, with increasing rotational speed the temperature profile averaged over one



N2. Fig. 11. Denomination of the air streams in the regenerator model.

period approaches the profile of the countercurrent heat exchanger. The explanations in Sect. 5 show that this is already valid in good approximation for higher rotational speeds as used in some technical applications.

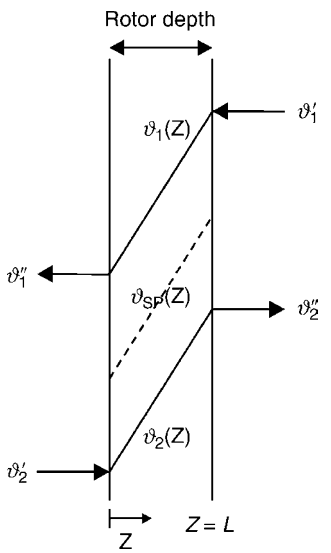
For these applications the simplified solution as a countercurrent heat exchanger may be used, which gives a significant saving in calculation time. The balance equations for this simplified consideration are described in Sect. 4.3. The terms are shown in Fig. 12. Results with this model will be described in Sect. 5.

4.3 Balance Model for the Combined Heat and Mass Transfer in Sorption Regenerators

For applications in ventilation and air conditioning the calculation of the simultaneous transfer of heat and moisture is of significant importance. With regard to the widespread use of sorption regenerators in ventilation, air conditioning, and process industry applications, the simultaneous heat and mass transfer in these apparatus will be considered. The following additional assumptions are made for the moisture transfer: the sorptive coating of the heat transferring medium is considered to be thin, so that pore diffusion effects within the sorptive coating layer can be neglected compared to the laminar mass transfer. With regard to the thin coating layers typically used this assumption is considered to be valid.

As shown by Frauhammer et al. [28] and Holmberg [31], the assumption can be made that the moisture of the air passes the phase boundary with the state of the streaming air and the sorption enthalpy only contributes to the energy balance of the heat storing medium. By that the energy balance of the streaming air results as follows:

$$A \cdot \rho_L \cdot \varepsilon \cdot c_{p_L} \cdot \frac{\partial \vartheta}{\partial t} = \mp \dot{m}_L \cdot c_{p_L} \cdot \frac{\partial \vartheta}{\partial z} + A \cdot \lambda_L \cdot \varepsilon \cdot \frac{\partial^2 \vartheta}{\partial z^2} + \alpha \cdot A \cdot a_v \cdot (\vartheta_{Sp} - \vartheta). \quad (4)$$



N2. Fig. 12. Approximated case of high rotational speeds. Approximation toward the solution of the countercurrent heat exchanger.

With regard to the high flow velocities in these applications the axial diffusion of the water vapor in the air has been neglected. With the discretization method of finite volumes used here this assumption has no negative effects on the convergence.

The energy balance of the storing medium results as follows:

$$A \cdot (1-\varepsilon) \cdot \rho_{sp} \cdot c_{sp} \cdot \frac{\partial \vartheta_{sp}}{\partial t} = A \cdot (1-\varepsilon) \cdot \lambda_{sp} \cdot \frac{\partial^2 \vartheta_{sp}}{\partial z^2} + \alpha \cdot A \cdot a_v \cdot (\vartheta - \vartheta_{sp}) + \beta \cdot A \cdot a_v \cdot \Delta h_{ads} \cdot \rho_L \cdot (Y - Y^*). \quad (5)$$

The mass balance of the moisture in the air in this case results in:

$$A \cdot \rho_L \cdot \varepsilon \cdot \frac{\partial Y}{\partial t} = \mp \dot{m}_L \cdot \frac{\partial Y}{\partial z} + \beta \cdot A \cdot a_v \cdot \rho_L \cdot (Y^* - Y). \quad (6)$$

The mass balance for the moisture loading of the adsorbent on the heat storing medium in this case results in:

$$A \cdot (1-\varepsilon) \cdot \rho_{sp} \cdot f_s \cdot \frac{\partial X}{\partial t} = \beta \cdot A \cdot a_v \cdot \rho_L \cdot (Y - Y^*). \quad (7)$$

The diffusion of the moisture within the adsorbent coating layer has been neglected as mentioned before.

For the moisture of the entering air fluxes, the following additional boundary conditions are valid:

$$z = 0 : Y = Y_2', \quad z = L : Y = Y_1'.$$

Analogue to the case of the pure heat transfer, the calculation of the steady state is done by calculating the systems of equations for the warm-air cycle and those for the cold-air cycle alternately. The calculation of the alternating cycles is repeated until the quasi-steady-state (cyclic-steady-state) is achieved. The initial condition for the moisture load of the sorptive layer in each cycle results from the moisture load of the sorptive layer at the end of the previous cycle. For the sorption of the moisture a sorption isotherm described by Holmberg [31] for silicagel-coated sorption regenerators is used. Likewise the sorption enthalpy is used according to Holmberg [31].

For the case of very high rotational speeds also in the case of combined heat and mass transfer an approximative modeling may be done according to the model of a (hypothetical) countercurrent heat and mass exchanger. This simplified modeling implies that the heat transferring walls show an unlimited high permeability for the moisture.

For this case the energy balance for the outgoing air is as follows:

$$A_1 \cdot \rho_L \cdot \varepsilon \cdot c_{p_L} \cdot \frac{\partial \vartheta_1}{\partial t} = -\dot{m}_{L1} \cdot c_{p_L} \cdot \frac{\partial \vartheta_1}{\partial z} + A_1 \cdot \lambda_L \cdot \varepsilon \cdot \frac{\partial^2 \vartheta_1}{\partial z^2} + \alpha_1 \cdot A_1 \cdot a_v \cdot (\vartheta_{Sp} - \vartheta_1). \quad (8)$$

In analogy the energy balance for the incoming air is given by

$$A_2 \cdot \rho_L \cdot \varepsilon \cdot c_{p_L} \cdot \frac{\partial \vartheta_2}{\partial t} = \dot{m}_{L2} \cdot c_{p_L} \cdot \frac{\partial \vartheta_2}{\partial z} + A_2 \cdot \lambda_L \cdot \varepsilon \cdot \frac{\partial^2 \vartheta_2}{\partial z^2} + \alpha_2 \cdot A_2 \cdot a_v \cdot (\vartheta_{Sp} - \vartheta_2). \quad (9)$$

According to the regenerator model for the thin metal sheets the assumption is made that the wall temperature is uniform across the thickness of the metal sheets. In the simplified

countercurrent model, the wall is in contact with both air streams. Thereby, the energy balance of the wall results in

$$\begin{aligned} A_{ges}\cdot(1-\varepsilon)\cdot\rho_{sp}\cdot c_{sp}\cdot\frac{\partial\vartheta_{sp}}{\partial t} &= A_{ges}\cdot(1-\varepsilon)\cdot\lambda_{sp}\cdot\frac{\partial^2\vartheta_{sp}}{\partial z^2} \\ &+\alpha_1\cdot A_1\cdot a_v\cdot(\vartheta_1-\vartheta_{sp}) \\ &+\alpha_2\cdot A_2\cdot a_v\cdot(\vartheta_2-\vartheta_{sp}) \\ &+\beta_1\cdot A_1\cdot a_v\cdot\Delta h_{ads}\cdot\rho_L\cdot(Y_1-Y^*) \\ &+\beta_2\cdot A_2\cdot a_v\cdot\Delta h_{ads}\cdot\rho_L\cdot(Y_2-Y^*). \end{aligned} \tag{10}$$

The moisture balance of the outgoing air is

$$A_1\cdot\rho_L\cdot\varepsilon\cdot\frac{\partial Y_1}{\partial t}=-\dot{m}_{L1}\cdot\frac{\partial Y_1}{\partial z}+\beta_1\cdot A_1\cdot a_v\cdot\rho_L\cdot(Y^*-Y_1). \tag{11}$$

The moisture balance of the incoming air correspondingly results in

$$A_2\cdot\rho_L\cdot\varepsilon\cdot\frac{\partial Y_2}{\partial t}=\dot{m}_{L2}\cdot\frac{\partial Y_2}{\partial z}+\beta_2\cdot A_2\cdot a_v\cdot\rho_L\cdot(Y^*-Y_2). \tag{12}$$

The mass balance of the adsorbent moisture load correspondingly results in

$$\begin{aligned} A_{ges}\cdot(1-\varepsilon)\cdot\rho_{sp}\cdot f_s\cdot\frac{\partial X}{\partial t} &= \beta_1\cdot A_1\cdot a_v\cdot\rho_L\cdot(Y_1-Y^*) \\ &+\beta_2\cdot A_2\cdot a_v\cdot\rho_L\cdot(Y_2-Y^*). \end{aligned} \tag{13}$$

For the inlet temperatures of incoming air and outgoing air as well as for the storage medium the same assumptions are made as in the case of the dynamic regenerator model. The outlet temperatures of the air streams correspond to the averaged outlet temperatures in the dynamic regenerator model. The terms are shown in Fig. 12. Results obtained by this model will be discussed in Sect. 5.

In ventilation and air conditioning applications the effects of the rotational speed are of major importance. Therefore, the calculation of the dynamic model with the alternating cycles is discussed in the following. The system of differential equations is discretized according to the method of finite volumes and is solved with an implicit solver using the software tool Mathcad™. (Note: The calculation files, as used here, can be provided by the author.)

5 Calculation Examples for the Transfer of Heat and Moisture in Sorption Regenerators for Ventilation and Air Conditioning Technology

The operation behavior of sorption regenerators with simultaneous heat and mass transfer will be regarded in the following using the simulation model as described above. Experimental investigations for this application have been performed by Spahn and Gnielinski [29]. Simulation studies using a finite difference method have been performed by Gutermuth [32]. Both articles have considered a storage medium setup of undulated asbestos with a sorptive coating of lithium chloride.

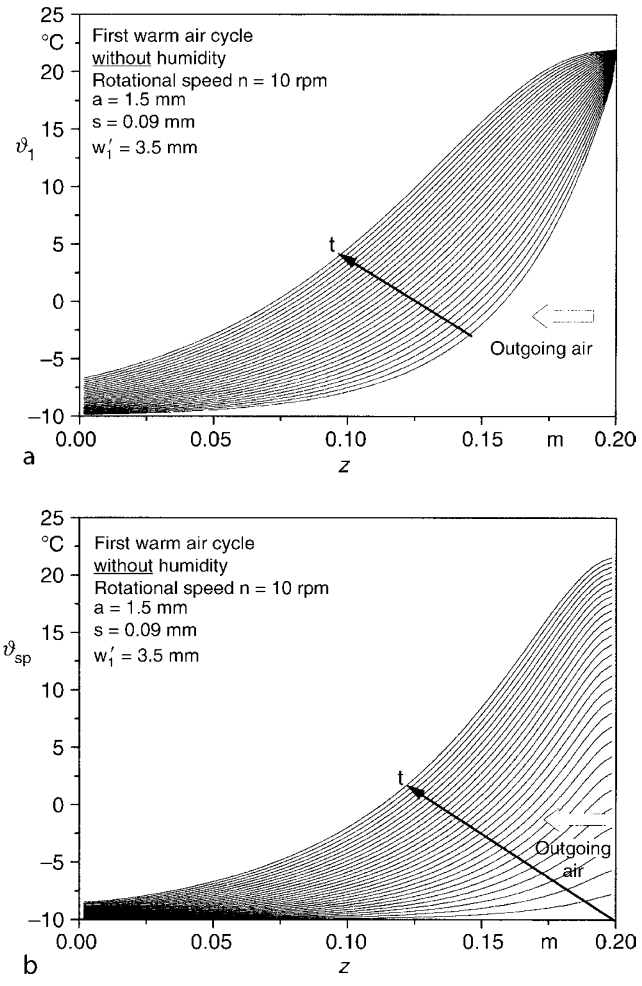
In the following, a regenerator consisting of a rolled setup of pairs of each a corrugated and a flat thin metal sheets as shown in Fig. 7 is considered. Values for the heat transfer in sinusoidally shaped channels have been published by Shah and London [34] as a function of the channel geometry. A ratio λ/a of the wavelength λ of the corrugated sheet in relation to its amplitude a of $\lambda/a = 3.5$ results in a Nu number of Nu = 3.3. The heat conduction of the aluminum alloy of the heat storage sheets considered here is $\lambda_{Sp} = 209$ W/m K. Void fraction ε, hydraulic diameter d_h, and specific surface area a_V of the storage medium are calculated according to the corrugation shape, corrugation height, and thickness of the layers.

The effects of the sorption of the moisture on the temperature profile in the sorptive regenerator become evident already at the heat-up of the sorption regenerator. Figure 13 shows the local and time-dependent temperatures of air and storage medium during the warm-up of the sorption regenerator in the first warm-air cycle. At the beginning the storage medium has the temperature of the cold ambient. The outgoing air has a temperature of $\vartheta_1' = 22°C$. The outgoing air enters the regenerator with a velocity of $w_1' = 3.5$ m/s. Figure 13 thereby shows the (hypothetic) case of dry air. The flow direction is from right to left. The storage medium is heated up from the indoor side. Figure 14 shows the warm-up in the case of real humid outgoing air with a relative moisture of $\varphi_1' = 40\%$ when entering the regenerator. Comparing the figures demonstrates explicitly the effects of the moisture transfer on the temperature profiles of air and storage medium. During the sorption of the moisture at the adsorbing surface of the storage medium, the sorption enthalpy is set free at the surface. This contributes additionally to the warm-up of the storage material. Thereby in the range where the moisture is adsorbed, higher temperatures of both storage medium and air occur.

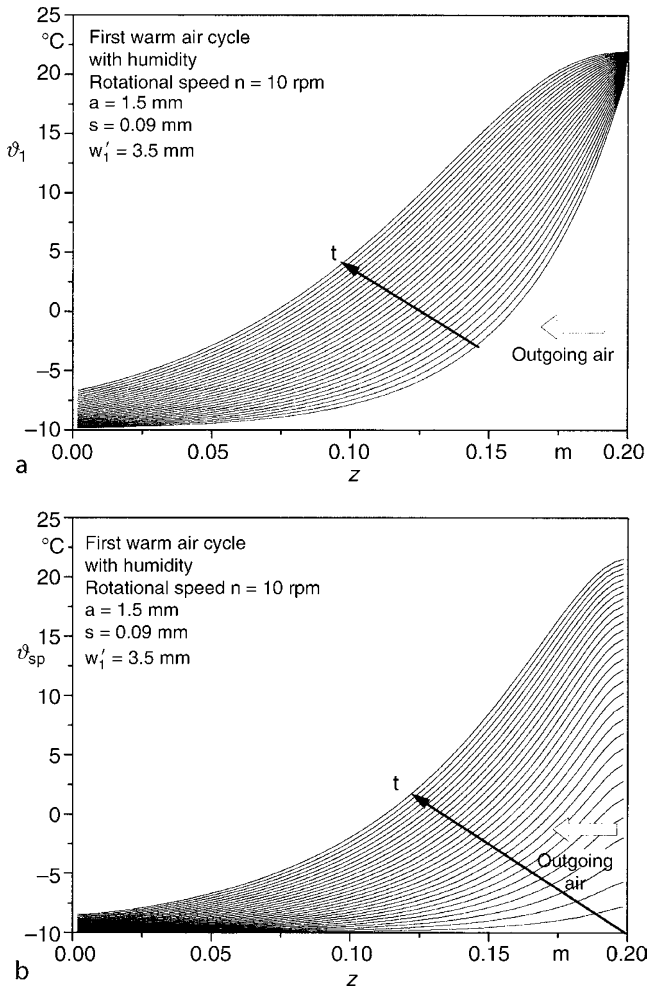
In the following example the effects of different rotational speeds on the quasi-steady-state temperature profiles in the regenerator will be considered. The following conditions are considered in the simulation according to a winter operation in the ventilation technology: the outgoing air has a temperature of $\vartheta_1' = 22°C$, the incoming air has a temperature of $\vartheta_2' = -10°C$. The outgoing air enters the regenerator with a velocity of $w_1' = 3.5$ m/s. The mass flux of the outgoing air and the mass flux of the incoming air are the same. The flow cross section of the warm-air segment and the cold-air segment are the same in the case considered here so that both streams show the same mass flux density. The length of the regenerator is $L = 200$ mm. The corrugation height of the sheets is 2 mm which corresponds to an amplitude of the corrugation of $a = 1$ mm.

The outgoing air has a relative humidity of $\varphi_1' = 40\%$, the incoming air has a relative humidity of $\varphi_2' = 90\%$. Figure 15 shows the temperature profiles in the quasi-steady-state for a rotational speed of $n = 10$ revolutions per minute.

The profile of the air temperature in the cold-air cycle is shown on top in Fig. 15a. Below that the temperature profile of the storage medium in the cold-air cycle is shown (Fig. 15b). The profile of the air in the warm-air cycle is shown in Fig. 15c, while Fig. 15d shows the temperature profile in the storage medium in the warm-air cycle. At the high rotational speed of 10 rpm a relative moderate change in temperature occurs during the cycle. The temperature profiles at a low rotational speed of 3 rpm are shown in Fig. 16. All other conditions are kept the same.



N2. Fig. 13. Temperature profiles during the warm-up of the regenerator during the first warm-air cycle in the case of dry air. (**a**) outgoing air (**b**) storage medium.



N2. Fig. 14. Temperature profiles during the warm-up of the regenerator during the first warm-air cycle in the case of humid air. (**a**) outgoing air (**b**) storage medium.

As shown in Fig. 15 in this case the outlet temperatures of the incoming air vary between $\vartheta''_{2,a} = 19°C$ at the beginning of the cycle and $\vartheta''_{2,e} = 12.5°C$ at the end of the cycle. Based on the circumferential angle of the regenerator on the one side ($\psi = 0$) an outlet temperature of $\vartheta''_{2,a} = 19°C$ results. With an increasing angle ψ, the outlet temperature decreases to $\vartheta''_{2,e} = 12.5°C$. In the application in the ventilation technology the air flux is fed into the air-guiding channel resulting in an average air temperature $\vartheta''_{2,m}$. This average air temperature results from the area-based average of the individual air temperatures over the segment. In the case considered here the averaged temperature of the incoming air results in $\vartheta''_{2,m} = 16.2°C$.

The outgoing air in the warm-air cycle behaves analogous. Here at the beginning of the cycle the outgoing air is cooled down to a temperature of $\vartheta''_{1,a} = -0.3°C$. At the end of the cycle this outlet temperature moves down to $\vartheta''_{1,e} = -7.5°C$.

At the low rotational speed of 3 rpm as shown in Fig. 16, the differences in temperature are much bigger. At the beginning of the cold-air cycle the incoming air is warmed up to a temperature of $\vartheta''_{2,a} = 20.4°C$. At the end of the cold-air cycle this temperature sinks to $\vartheta''_{2,e} = 6.8°C$. As a consequence the averaged temperature of the incoming air is $\vartheta''_{2,m} = 12.4°C$. This is significantly lower than in the case of the higher rotational speed.

The corresponding moisture profiles of the incoming air and the outgoing air as shown in Figs. 17 and 18 also show considerably bigger differences at the low rotational speed. At the higher rotational speed of 10 rpm a higher recovered humidity of $Y''_{2,m} = 5.96$ g/kg is achieved, compared to a recovered humidity of $Y''_{2,m} = 4.68$ g/kg in the case of the low rotational speed of 3 rpm. The results illustrate how the efficiency of the sorption regenerator depends on the variation of the rotational speed.

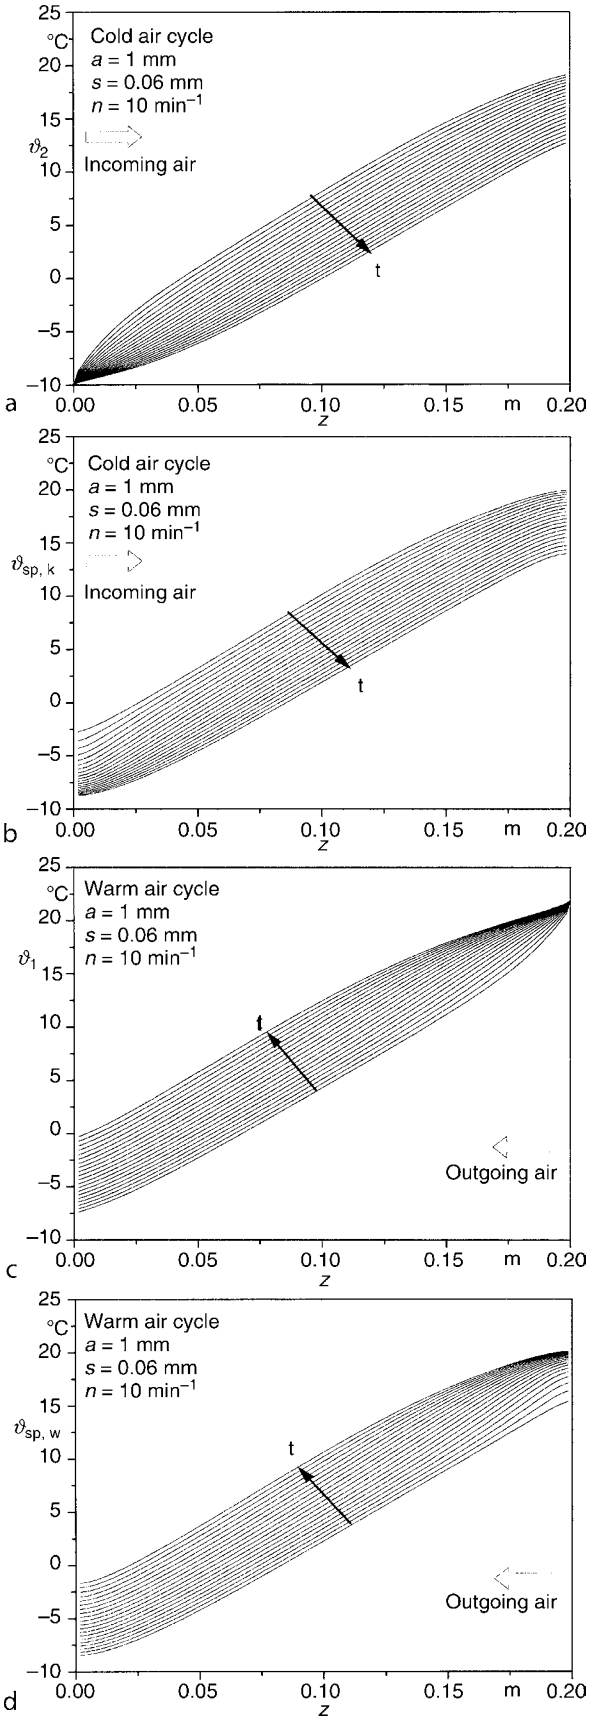
Figure 19 shows the thermal efficiency η_{Th}

$$\eta_{\vartheta,1} = \frac{\vartheta'_1 - \vartheta''_1}{\vartheta'_1 - \vartheta'_2} \tag{14}$$

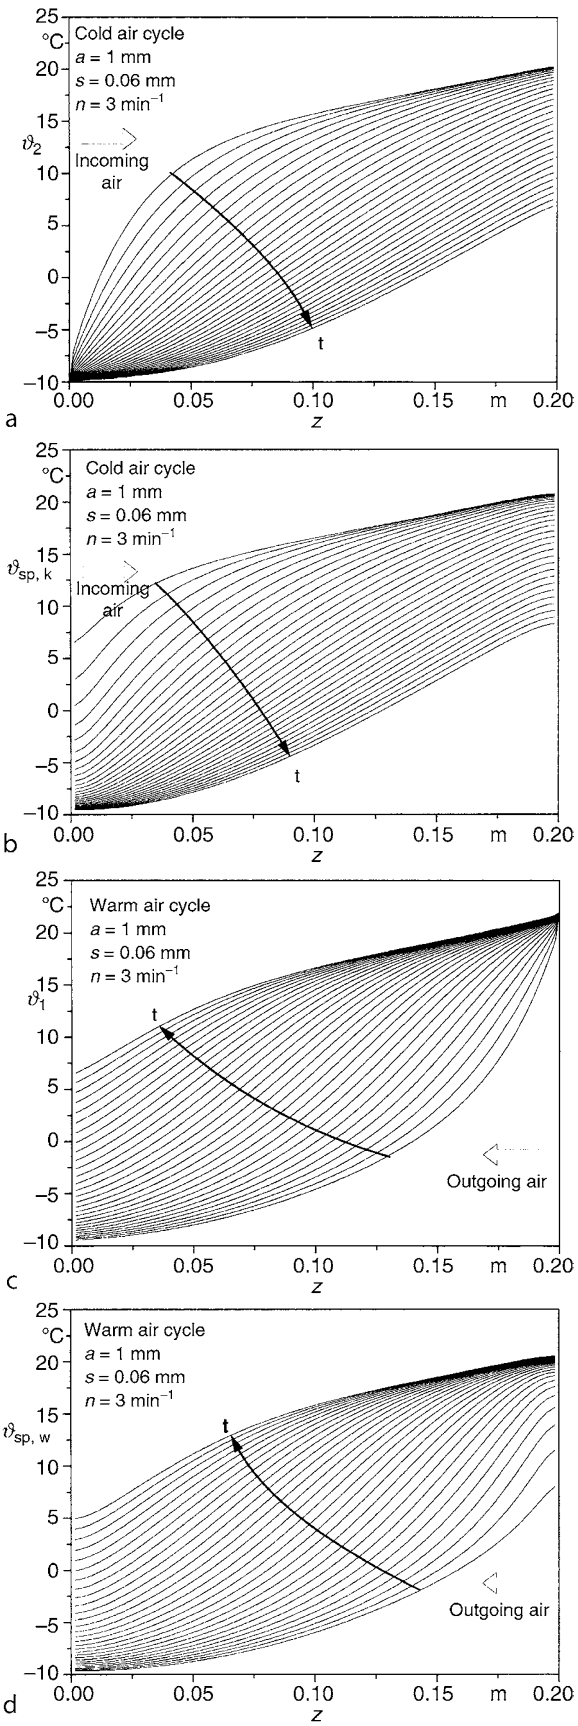
as a function of the regenerators rotational speed. In a similar way an efficiency for the humidity recovery can be defined.

$$\eta_{Y,1} = \frac{Y'_1 - Y''_1}{Y'_1 - Y'_2} \tag{15}$$

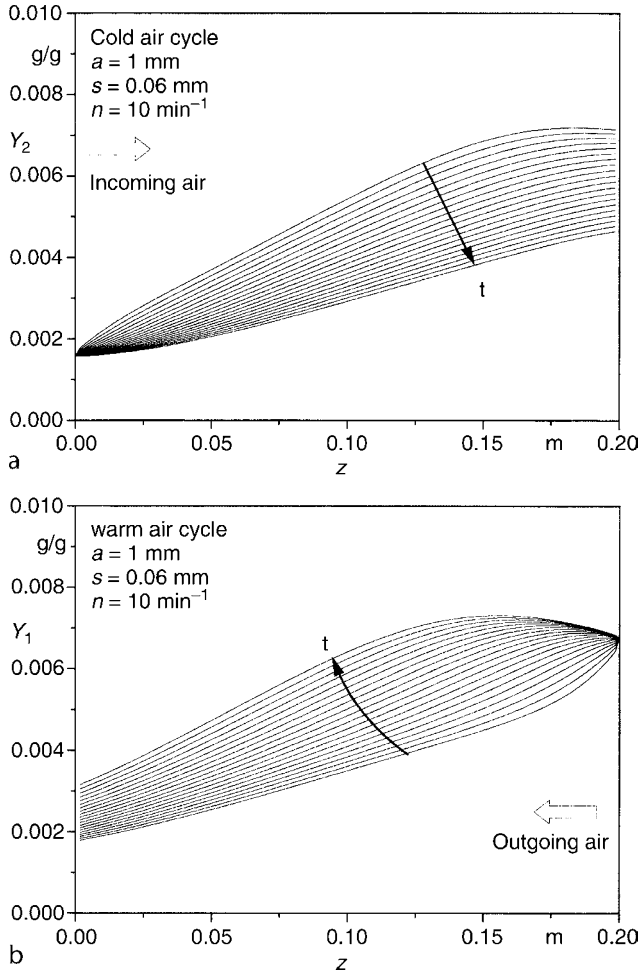
Figure 19 shows that the thermal efficiency increases with increasing rotational speed. For high rotational speeds it approaches the limiting value of the hypothetical counter current heat and moisture exchanger, which is shown as a dashed line in Fig. 19. Higher efficiencies can be achieved in the case of higher



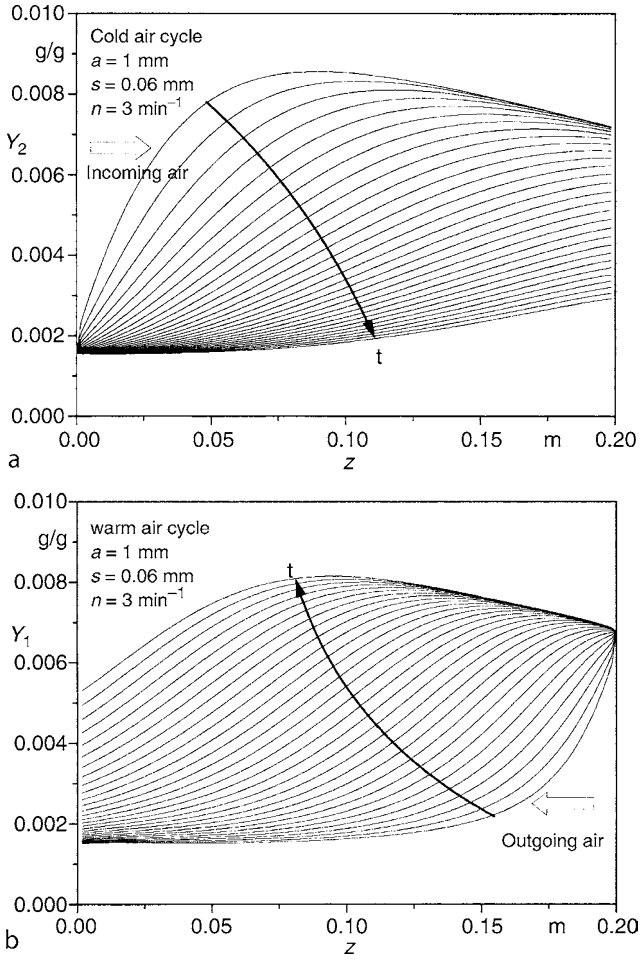
N2. Fig. 15. Temperature profiles in the quasi-steady-state for a rotational speed of n = 10 rpm. (**a**) incoming air (**b**) storage medium in cold air cycle (**c**) outgoing air (**d**) storage medium in warm air cycle.



N2. Fig. 16. Temperature profiles in the quasi-steady-state for a rotational speed of n = 3 rpm. (**a**) incoming air (**b**) storage medium in cold air cycle (**c**) outgoing air (**d**) storage medium in warm air cycle.



N2. Fig. 17. Moisture profiles in the quasi-steady-state at a rotational speed of n = 10 rpm. (**a**) incoming air (**b**) outgoing air.

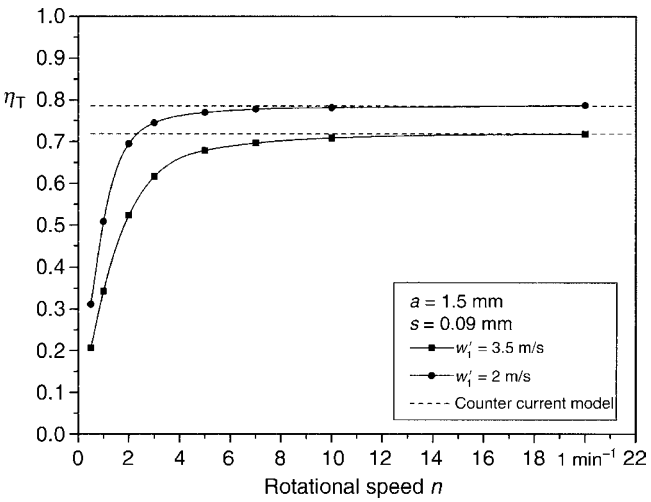


N2. Fig. 18. Moisture profiles in the quasi-steady-state at a rotational speed of n = 3 rpm. (**a**) incoming air (**b**) outgoing air.

rotational speeds. In the case of high rotational speeds of 10 rpm, as commonly used in air conditioning applications, the efficiency closely approaches the efficiency of the hypothetical counter current heat and moisture exchanger. Therefore, such applications may also be calculated approximately using the simplified model described by Eqs. (7)–(12).

The effect of the rotational speed on the efficiency for humidity recovery of the regenerator is shown in Fig. 20. This efficiency also increases with increasing rotational speed. Comparing Figs. 19 and 20 shows that at low rotational speeds the efficiency of moisture recovery is lower than the thermal efficiency. The operation characteristics at low rotational speeds below 0.5 rpm will be discussed in Sect. 6 where the sorption regenerator is used for air-dehumidification.

In the case of high rotational speeds the efficiency can be increased by the use of corrugated sheets with a small corrugation height resulting in a higher heat transfer. Figure 21 shows a comparison between sheets with amplitudes of 1 and 1.5 mm. Low rotational speeds result in similar efficiencies. This is due to the high cycle duration where the temperatures of air and storage medium approach each other. In this case a higher heat transfer does not benefit the efficiency. In the case of higher rotational speeds, however, a clear benefit of the higher heat



N2. Fig. 19. Effects of the rotational speed on the thermal efficiency of the regenerator.

transfer in the case of the smaller channel height is clearly visible from Fig. 21.

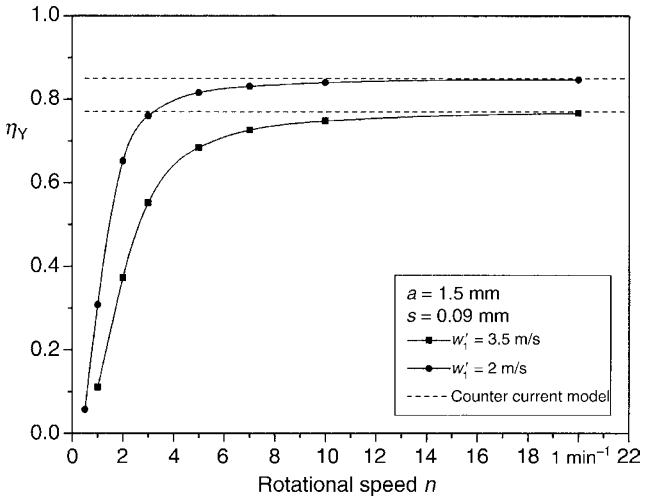
For technical applications, it has to be considered that the outlet temperature of the air significantly varies across the

circumferential rotor angle ψ, especially in the case of low rotational speeds. Figure 22 shows the outlet temperatures of the incoming air at the warm side of the regenerator as a function of the circumferential rotor angle ψ for different rotational speeds.

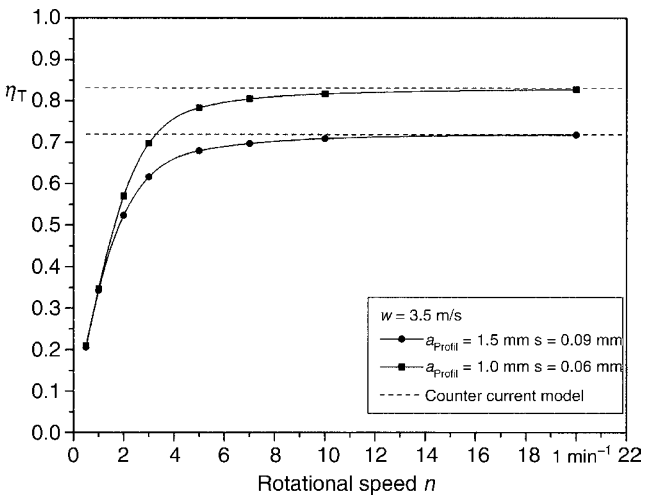
6 Calculation Examples for the Heat and Mass Transfer in Sorption Regenerators for Air Dehumidification

The balance model shown in Sect. 4 can be used in the same way for calculation of sorption regenerators for air dehumidification. As an example, process air having a temperature of $\vartheta_2' = 22°C$ and a relative humidity of $\varphi_2' = 70\%$ shall be dehumidified in a sorption regenerator. The storage medium of the regenerator is considered to consist of corrugated metal sheets having a layer height of 3 mm corresponding to an amplitude of $a = 1.5$ mm and a sheet thickness of 0.09 mm. The sorptive coating consists of silicagel. Sorption enthalpy and sorption isotherm are used according to Holmberg [31]. The segment for the process air comprises 75% of the rotor cross section; the segment for the desorption air comprises 25% of the rotor cross section. The flow velocity of the process air is $w_2' = 1$ m/s. The desorption is done with ambient air, which is preheated to a temperature of $\vartheta_1' = 115°C$ before entering the desorption segment. The amount of desorption air is designed to have the same mass flux density g_z as the process air. The rotational speed of the rotor is $n = 7.5$ revolutions per hour.

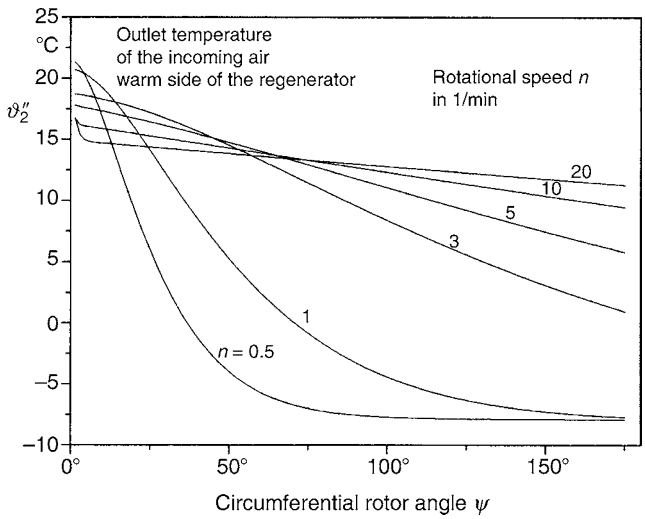
Figure 23 shows the temperature profiles for the dehumidification cycle in the quasi-steady-state. The storage medium has been warmed up in the previous desorption cycle and is now being cooled by the process air during the dehumidification cycle. Accordingly at the beginning of the cycle the process air is being warmed up by the storage medium being still warm from the previous desorption cycle. Due to the higher temperatures of storage medium and process air and the unfavorable sorption equilibrium resulting therefrom, a minor dehumidification of the process air occurs at the beginning of the cycle. During the cycle the water content $Y_2''(t)$ of the process air decreases at first. In the further part of the cycle the water content $Y_2''(t)$ of the process air increases continuously due to the increasing moisture load of the storage medium. This results in the moisture profile of the outgoing process air as shown in Fig. 24 as a function of the circumferential rotor angle ψ. In the case of higher rotational speeds the moisture of the outgoing process air increases at the beginning of the cycle (corresponding to a small circumferential rotor angle ψ). At higher rotational speeds the moisture of the outgoing process air increases toward the end of the cycle (Fig. 24). The high moistures of the process air at the beginning of the cycle could be avoided if the storage medium would be cooled in a separate purge segment after the desorption segment.



N2. Fig. 20. Effects of the rotational speed on the efficiency for humidity recovery of the regenerator.



N2. Fig. 21. Thermal efficiency of the regenerator at different channel sizes of the storage medium.

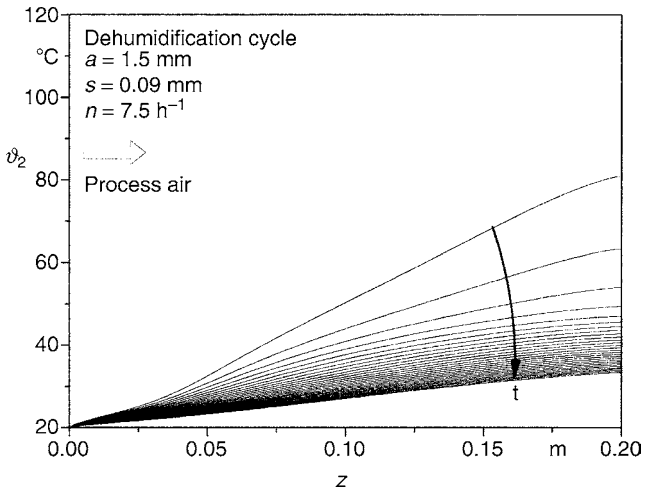


N2. Fig. 22. Outlet temperatures of the incoming air at the warm side of the regenerator as a function of the circumferential rotor angle ψ.

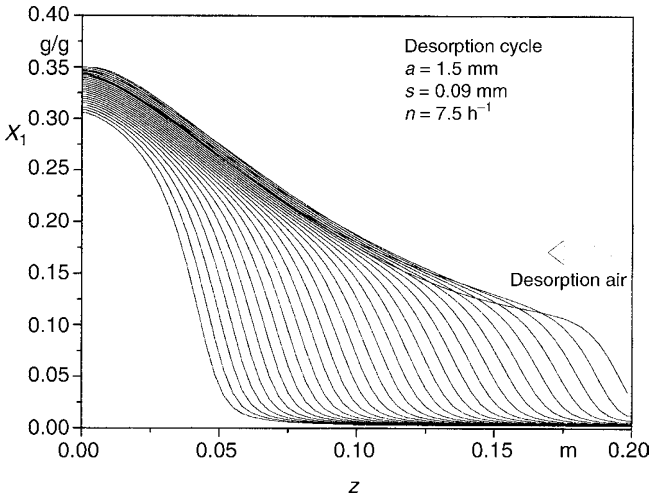
The sorption enthalpy released during the dehumidification warms up the storage medium. As a consequence this results in a warming of the process air in flow direction. During the desorption cycle the moisture desorbs from the storage medium and is carried away by the desorption air. The storage medium is warmed up by the hot desorption air. Figure 25 shows the profile of the moisture load of the storage medium during the desorption cycle. At first the moisture desorbs at the side where the desorption air enters the regenerator. Then the desorption air in flow direction passes the colder parts of the storage medium and cools down there. Therefore, a part of the moisture having been desorbed upstream is then adsorbed again downstream (smaller z-coordinate in Fig. 25). By that the moisture load increases there initially (as can be seen by the intersecting lines in Figs. 25 and 27). In the further desorption process the temperature profiles move in flow direction and the downstream zones also warm up. The desorption proceeds.

At the conditions (concerning segment partitioning, flow velocity, and rotational speed) considered in Fig. 25 the desorption takes place only to a certain extent of the rotor depth z. Figure 26 shows the moisture load of the sorptive layer in the case of a lower rotational speed of $n = 5$ rph with the rest of the conditions being the same. The profiles show that by a longer period a complete desorption occurs across the entire rotor depth. However, during the longer period the storage medium is heated up by the hot desorption air to high temperatures almost across the entire rotor depth. These high temperatures of the storage medium result in a worse sorption equilibrium in the beginning of the following dehumidification cycle and thereby to a minor dehumidification of the process air.

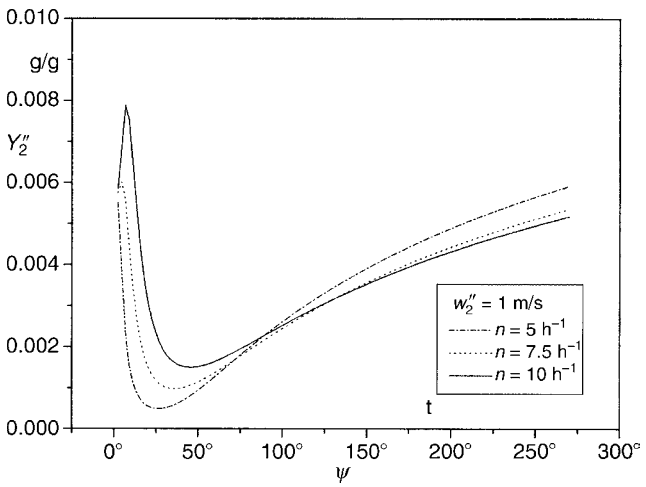
The profiles of the moisture load during the desorption cycle in the case of a higher rotational speed of $n = 10$ rph is shown in Fig. 27. At this short duration of the desorption cycle,



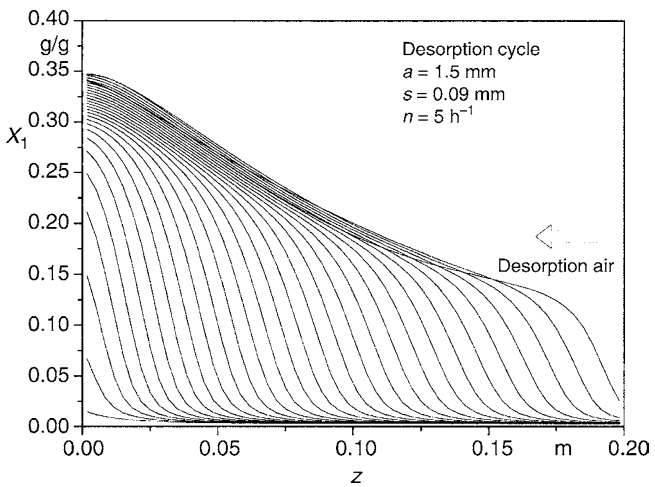
N2. Fig. 23. Temperature profiles during the dehumidification cycle (rotational speed n = 7.5 revolutions per hour).



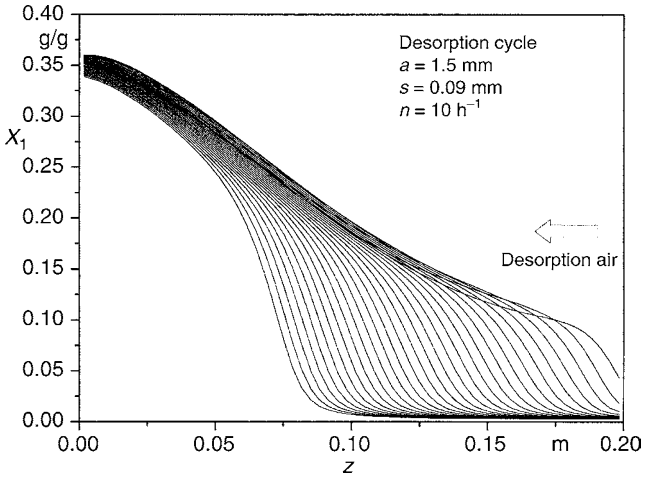
N2. Fig. 25. Moisture load of the sorptive layer during the desorption cycle at a rotational speed of n = 7.5 revolutions per hour.



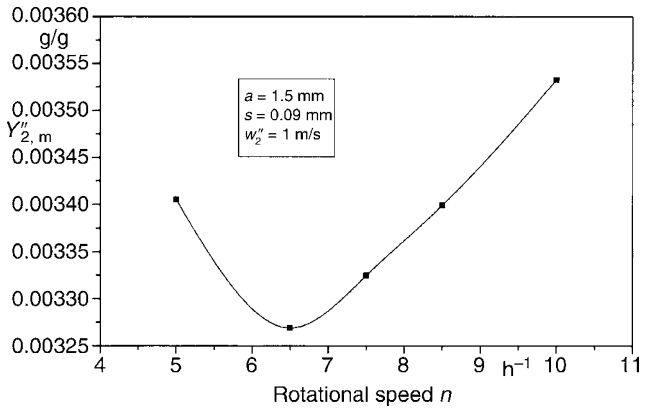
N2. Fig. 24. Water content of the process air at the outlet of the regenerator as a function of the circumferential rotor angle ψ.



N2. Fig. 26. Moisture load of the sorptive layer during the desorption cycle at a rotational speed of n = 5 revolutions per hour.



N2. Fig. 27. Moisture load of the sorptive layer during the desorption cycle at a rotational speed of $n = 10$ revolutions per hour.



N2. Fig. 28. Effects of the rotational speed on the residual moisture of the dehumidified process air.

however, only half of the storage medium (in depth) is desorbed completely. The remaining high moisture loads at small z-coordinates on the one hand side and the high temperatures after the desorption at high z-coordinates on the other hand side result in a lower desorption of the process air during the following dehumidification cycle.

Due to the effects described there is an optimum of the rotational speed with regard to the residual moisture load of the dehumidified process air as shown in Fig. 28. At the flow velocity considered in this example the optimum for the rotational speed is 6.5 rph. In the case of higher flow velocities this optimum moves toward higher rotational speeds. Analogue results obtained with a regenerator coated with lithium chloride have been reported by Gutermuth [32]. Gutermuth also has investigated different partition ratios of the dehumidification segment and the desorption segment.

The results prove that the operating characteristics in the technical application of sorption regenerators can only be calculated by simultaneously considering heat and mass transfer. The calculation files as used here can be provided by the author.

7 Symbols

A	flow cross section (m^2)
A_1	flow cross section outgoing air (m^2)
A_2	flow cross section incoming air (m^2)
a	amplitude of the corrugation of the storage medium (mm)
a_V	volumetric specific surface of the storage medium (m^2/m^3)
c_{Sp}	specific heat capacity of the storage medium (J/kg K)
c_{P_L}	specific heat capacity of air (J/kg K)
d_h	hydraulic diameter (m)
f_S	mass fraction of the adsorbent (silicagel) in relation to the entire storage medium (g/g)
g_z	mass flux density in flow direction (kg/m^2 s)
Δh_{ads}	adsorption enthalpy (kJ/kg)
L	length of the regenerator (also called depth of the rotor) (m)
m_L	mass flux of the dry air (kg/s)
n	rotational speed of thr sorption regenerator (application "heat recovery") (1/min)
n	rotational speed of thr sorption regenerator (application "air dehumidification") (1/h)
s	sheet thickness (mm)
t	time (s)
w	flow velocity (m/s)
w'_1	flow velocity of the outgoing air at the inlet of the regenerator (m/s)
w'_2	flow velocity of the incoming air at the inlet of the regenerator (m/s)
Y	moisture load of the air (g/g)
Y_1, Y_2	moisture load of the air fluxes 1 and 2 (g/g)
Y'_1, Y'_2	moisture load of the air fluxes 1 and 2 at the inlet (g/g)
Y''_1, Y''_2	moisture load of the air fluxes 1 and 2 at the outlet (g/g)
$Y_{1,m}$, $Y_{2,m}$	average moisture load of the air fluxes 1 and 2 (g/g)

N3 Heat Transfer and Power Consumption in Stirred Vessels

Edward S. Gaddis
Technische Universität Clausthal, Clausthal-Zellerfeld, Germany

1 Introduction

Stirred vessels are important equipments in process engineering, particularly in batch processes. They are used in

- Heating or cooling of liquids
- Mixing and temperature equalization in solutions and mixtures
- Intensifying mass transfer and carrying out chemical reactions in liquid mixtures and suspensions
- Aerating liquids and suspensions
- Dispersing and emulsifying processes
- Suspending of solids

In stirred vessels, various mechanisms take place either simultaneously or successively. Usually, the vessels are fitted from outside with jackets or welded coils of semicircular or circular cross section to heat or cool the contents of the vessels; if the heat transfer area is not sufficient, additional coils or plates may be inserted from inside (see Fig. 1). A stirred vessel is equipped from inside with an impeller, which can have – according to the requirements of the process – different shapes. Figure 2 shows some types of the impellers commonly used in the industry. Flat-blade turbines (Fig. 2a), pitched-blade impellers (Fig. 2b), and propellers (Fig. 2c) are high-speed impellers, which are generally used with low-viscosity liquids ($\eta \leq 1$ Pa s). While flat-blade turbines induce mainly a radial flow, pitched-blade impellers and propellers generate basically an axial flow. Paddles (Fig. 2d) belong to the low-speed impellers and are usually used with high viscous liquids ($\eta \leq 10$ Pa s). Other low-speed impellers such as anchor impellers (Fig. 2e, 1 Pa s $\leq \eta \leq 10^2$ Pa s) and helical impellers (Fig. 2f, 10 Pa s $\leq \eta \leq 10^3$ Pa s) operate usually with a close clearance to the inner surface of the vessel and are used basically to intensify heat transfer in high viscous liquids. Scraped-surface heat exchangers are double-tube heat exchangers that are used for heating, cooling, or freezing of highly viscous liquids and pastes; the heating or cooling medium flows through the external annular space, and the internal cylindrical space has a shaft fitted with a number of scraper blades that wipe the wall of the inner tube (see Fig. 8). High-speed impellers are fitted usually with baffles to suppress vortex formation (Fig. 3).

2 Heat Transfer

2.1 Heat Transfer in a Stirred Vessel

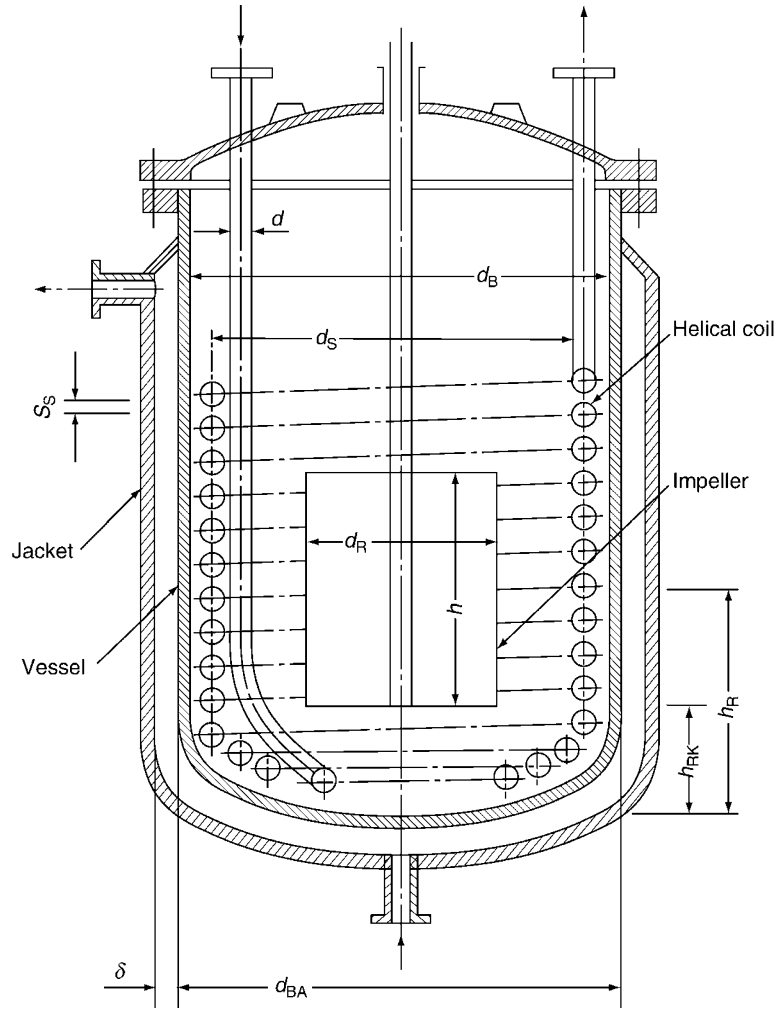
2.1.1 Single-Phase Systems

Newtonian Liquids

Heat Transfer from the Inner Surface of a Stirred Vessel Numerous studies [1] have revealed that heat transfer from the inner wall surface of a stirred vessel, for example, the type shown in Fig. 1, and a liquid inside the vessel can be described by dimensionless equations of the following form:

$$\mathrm{Nu} = C\mathrm{Re}^{a}\mathrm{Pr}^{b}\left(\frac{\eta}{\eta_{\mathrm{w}}}\right)^{e}, \qquad (1)$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_63,



N3. Fig. 1. A stirred vessel with a jacket, a coil, and a paddle.

with

Nusselt number $\mathrm{Nu} = \frac{\alpha d_B}{\lambda}$,

Reynolds number $\mathrm{Re} = \frac{n d_R^2 \rho}{\eta}$,

Prandtl number $\mathrm{Pr} = \frac{\nu}{a}$.

In analogy with the flow through tubes, the exponents of the Reynolds number, the Prandtl number, and the viscosity ratio in Eq. (1) have in the turbulent range approximately the following numerical values:

- Exponent of the Reynolds number $a \approx \frac{2}{3}$,
- Exponent of the Prandtl number $b \approx \frac{1}{3}$,
- Exponent of the viscosity ratio $e \approx 0.14$.

The constant C in Eq. (1) takes into account all the geometrical effects. Unless otherwise stated, the physical properties (a, η, υ, λ, *and* ρ) are to be evaluated at mean liquid temperature and η_w at mean wall temperature. The empirical correlations for heat transfer prediction are derived from experimental measurements carried out with stirred vessels having, in many cases, a standard geometry. Customarily, the standard geometry is defined as follows:

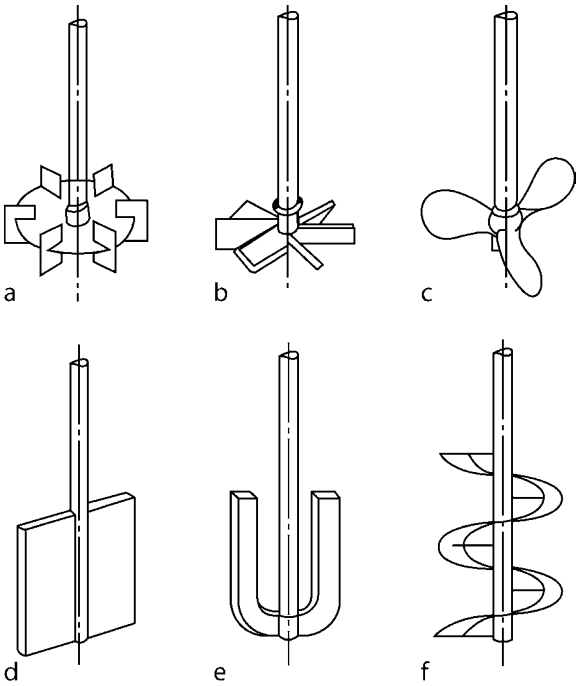
- Ratio of impeller diameter to vessel diameter $\frac{d_R}{d_B} = \frac{1}{3}$
- Ratio of liquid height to vessel diameter $\frac{h_L}{d_B} = 1$
- Ratio of height of impeller above bottom to height of liquid $\frac{h_R}{h_L} = \frac{1}{3}$
- Ratio of baffle width to vessel diameter $\frac{b_S}{d_B} = \frac{1}{10}$
- Number of baffles (if present) $n_S = 4$

The standard geometrical parameters mentioned above are valid for high-speed impellers; they do not apply for close-clearance impellers (e.g., anchor impellers and helical impellers) and for other low-speed impellers.

Many authors examined the influence of the individual geometrical parameters of the stirred vessel and the impeller on heat transfer and included these effects in their correlations through dimensionless parameters in the form

$$C = C^* \pi_1^f \pi_2^p \cdots \tag{2}$$

$\pi_1, \pi_2, \ldots$ are geometrical ratios and C^* is a constant. A list of a large number of published correlations is found in the work of R. Poggemann et al. [2]. The Nusselt numbers calculated by means of the correlations presented in this chapter are mean values and are based, in many cases, on measurements carried



N3. Fig. 2. Some commonly used impellers: (**a**) flat-blade turbine, (**b**) pitched-blade impeller, (**c**) marine-type propeller, (**d**) paddle, (**e**) anchor impeller, (**f**) helical impeller.

out under steady state conditions. In batch operation, heat transfer is primarily transient, at least in the early operation period. However, in the turbulent range, the heat transfer in batch operation can be regarded as quasi-steady state, and the equations developed under steady state conditions may still be used. In the laminar range, to reach steady state conditions, a fairly long operation period is required. Thus, heat transfer is transient during an appreciable part of the process or during the entire process with pronounced temperature gradients. This chapter is primarily devoted to heat transfer in the transition and the turbulent ranges ($\mathrm{Re} > 10$). Investigations related to heat transfer with laminar flow in stirred vessels are presented in various works [3–5]. The validity ranges given for the empirical correlations presented in this chapter are the ranges of the Reynolds number, the Prandtl number, and the important geometrical parameters $\pi_1, \pi_2, \ldots$ examined by the investigators presenting the correlations. Strictly speaking, the correlations should only be used within the given ranges. However, it might be reasonable to assume that small deviations from the examined ranges will not lead immediately to much higher deviations between actual measurements and predictions.

Flat-blade turbine or pitched-blade impeller

According to Nagata et al. [6], the following equations give the Nusselt number for a stirred vessel fitted with a flat-blade turbine or a pitched-blade impeller (Fig. 2a and b, respectively):
For an unbaffled vessel:

$$\mathrm{Nu} = 0.54\left(\frac{d_\mathrm{R}}{d_\mathrm{B}}\right)^{-0.25}\left(\frac{h}{d_\mathrm{B}}\right)^{0.15}\left(\frac{h_\mathrm{R}}{h_\mathrm{L}}\right)^{0.15} (\sin\gamma)^{0.5} Z^{0.15}\mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_\mathrm{w}}\right)^{0.14} \tag{3}$$

For a baffled vessel:

$$\mathrm{Nu} = 1.4\left(\frac{d_\mathrm{R}}{d_\mathrm{B}}\right)^{-0.3}\left(\frac{h}{d_\mathrm{B}}\right)^{0.45}\left(\frac{h_\mathrm{R}}{h_\mathrm{L}}\right)^{0.2}\left(\frac{h_\mathrm{L}}{d_\mathrm{B}}\right)^{-0.6} (\sin\gamma)^{0.5} Z^{0.2}\mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_\mathrm{w}}\right)^{0.14} \tag{4}$$

Validity ranges:

$$10^2 \le \mathrm{Re} \le 4\times 10^5,$$
$$2 \le \mathrm{Pr} \le 2\times 10^3,$$
$$0.035 \le \frac{h}{d_\mathrm{B}} \le 0.2,$$
$$0.15 \le \frac{h_\mathrm{R}}{h_\mathrm{L}} \le 0.5,$$
$$2 \le Z \le 16,$$
$$45^\circ \le \gamma \le 90^\circ.$$

Additional for an unbaffled vessel

$$0.3 \le \frac{d_\mathrm{R}}{d_\mathrm{B}} \le 0.6,$$
$$\frac{h_\mathrm{L}}{d_\mathrm{B}} \approx 1.0$$

and for a baffled vessel

$$0.3 \le \frac{d_\mathrm{R}}{d_\mathrm{B}} \le 0.4,$$
$$0.67 \le \frac{h_\mathrm{L}}{d_\mathrm{B}} \le 1.0.$$

For a multistage impeller, that is, a system with more than one impeller mounted on the shaft (with $\Delta h < 1.5 d_\mathrm{R}$), h and h_R in

Eqs. (3) and (4) should be replaced by $n_R h$ and $\sum_{i=1}^{n_R} \left(h_{R,i}/n_R\right)$, respectively. Equations (3) and (4) yield for the standard geometry of the stirred vessel and the impeller (i.e., $d_R/d_B = 1/3$, $h_R/h_L = 1/3$, $h_L/d_B = 1$, $h/d_R = 1/5$ and $Z = 6$) the following equations:

For an unbaffled vessel:

$$\mathrm{Nu} = 0.53(\sin\gamma)^{0.5}\mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_w}\right)^{0.14} \quad (5)$$

For a baffled vessel:

$$\mathrm{Nu} = 0.66(\sin\gamma)^{0.5}\mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_w}\right)^{0.14} \quad (6)$$

The width of a blade b_R (in axial direction) of a flat-blade turbine with a standard geometry amounts to one quarter of the impeller diameter. Flat-blade turbines create high shear forces; therefore, they are very suitable for dispersing processes. In the literature, different names are given for this type of impeller (e.g., "bladed-disc turbine," "disc impeller," and "Rushton turbine"). High-speed impellers are customarily denoted as turbines.

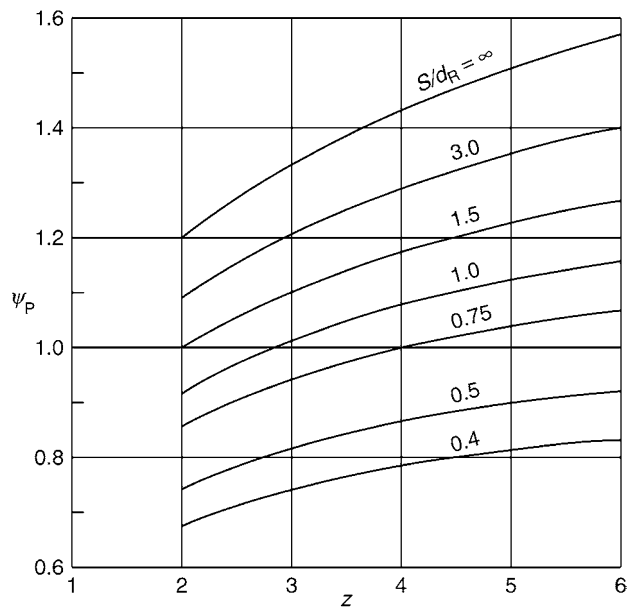
Propeller

Strek and Masiuk [7] proposed the following correlation for a propeller (Fig. 2c) in a stirred vessel with four baffles:

$$\mathrm{Nu} = 0.505\psi_p\mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_w}\right)^{0.14} \quad (7)$$

In Eq. (7), ψ_P is a function of the number Z of propeller blades and the pitch ratio (S/d_R), and can be calculated from Eq. (8) or from Fig. 4,

$$\psi_p = \exp(0.3\ln Z - 0.0144Z)\left\{\frac{0.278\exp[0.0469\exp(0.923\ln Z)]}{\frac{S}{d_R}} + 1\right\}^{-1} \quad (8)$$



N3. Fig. 4. ψ_p as a function of the number of propeller blades with the pitch ratio S/d_R as a parameter according to Eq. (8).

Validity ranges:

$$1.7 \times 10^4 \le \mathrm{Re} \le 9 \times 10^5,$$

$$1.9 \le \mathrm{Pr} \le 2.4,$$

$$0.4 \le \frac{S}{d_R} \le \infty \text{ commonly } 0.5 \le \frac{S}{d_R} \le 1.5,$$

$$1 \le Z \le 45 \text{ commonly } 2 \le Z \le 5.$$

Equation (7) was derived with water as a working medium in a narrow range of temperature. Generally, the axial flow of a propeller is directed toward the bottom of the vessel. The power consumption for propellers is lower than that for radial impellers (e.g., flat-blade turbines) with the same impeller diameter and the same speed of rotation. Propellers generate a high circulation rate and, therefore, are suitable for temperature equalization as well as for mixing.

Pfaudler impeller

Post [8] gives for a "Pfaudler" impeller, shown in Fig. 5a and b, the following equations:

For an unbaffled vessel

$$\mathrm{Nu} = 0.354\mathrm{Re}^{0.714}\mathrm{Pr}^{0.260}. \quad (9)$$

For a baffled vessel with one baffle according to Fig. 5b

$$\mathrm{Nu} = 0.349\mathrm{Re}^{0.719}\mathrm{Pr}^{0.264}. \quad (10)$$

For a baffled vessel with two baffles according to Fig. 5b

$$\mathrm{Nu} = 0.365\mathrm{Re}^{0.720}\mathrm{Pr}^{0.262}. \quad (11)$$

For a baffled vessel with four standard baffles as described previously

$$\mathrm{Nu} = 0.339\mathrm{Re}^{0.716}\mathrm{Pr}^{0.293}. \quad (12)$$

Validity ranges:

$$4.5 \times 10^3 \le \mathrm{Re} \le 5.7 \times 10^4,$$

$$8.4 \times 10^2 \le \mathrm{Pr} \le 6.3 \times 10^3$$

$$\frac{d_R}{d_B} = 0.575,$$

$$\frac{h_L}{d_B} = 1$$

$$\frac{h}{d_B} = 0.15,$$

$$\frac{h_i}{d_B} = 0.092,$$

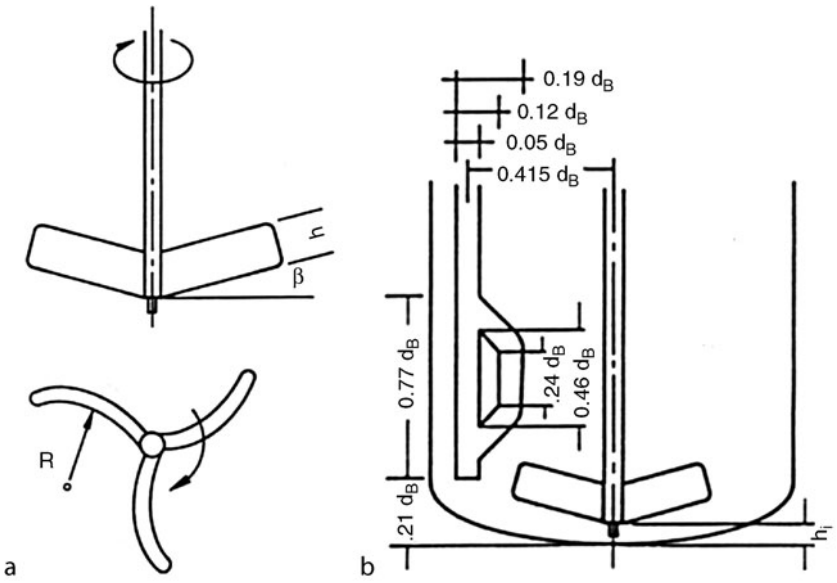
$$\frac{R}{d_B} = 0.4,$$

$$\beta = 15^\circ.$$

The difference in heat transfer between heating and cooling can be taken into consideration in Eqs. (9–12) by means of the correction factor $(\eta/\eta_w)^{0.14}$.

Paddle

Lichtenberg [9] gives the following equation for a baffled vessel with a paddle and four baffles (Fig. 2d):



N3. Fig. 5. Pfaudler impeller with dimensions considered in [8].

$$\mathrm{Nu} = 1.31\left(\frac{d_R}{d_B}\right)^{0.39}\left(\frac{h}{d_B}\right)^{0.34}\mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_w}\right)^{0.14}. \quad (13)$$

Validity ranges:

$$270 \le \mathrm{Re} \le 4.8 \times 10^5,$$
$$2.4 \le \mathrm{Pr} \le 1.1 \times 10^3,$$
$$0.25 \le \frac{d_R}{d_B} \le 0.6,$$
$$0.1 \le \frac{h}{d_B} \le 0.6,$$
$$\frac{h_L}{d_B} = 1.13,$$
$$0.22 \le \frac{h_R}{d_B} \le 0.47,$$
$$\frac{h_{RK}}{d_B} = 1/6,$$
$$\frac{b_S}{d_B} = 0.067.$$

According to Lichtenberg, the following limiting criterion must be observed for the geometrical ratios:

$$\left(\frac{d_R}{d_B}\right)^{0.39}\left(\frac{h}{d_B}\right)^{0.34} > 0.35 \rightarrow 0.4,$$

with the constant 0.35 valid for $(h/d_B) \approx 0.1$ and the constant 0.4 for $(d_R/d_B) \approx 0.25$.

Stein and Müller [10] examined a paddle in a stirred vessel with four baffles and the following geometrical ratios:

$$\frac{d_R}{d_B} = 0.471,$$
$$\frac{h}{d_B} = 0.471,$$
$$\frac{h_L}{d_B} = 1.263,$$
$$\frac{h_R}{d_B} = 0.690,$$
$$b_S/d_B = 0.1.$$

The ratios h_L/d_B, h_R/d_B, and b_S/d_B differ from those examined by Lichtenberg. Substituting $d_R/d_B = 0.471$ and $h/d_B = 0.471$, examined by Stein and Müller, in Eq. (13) gives the following equation:

$$\mathrm{Nu} = 0.76\mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_w}\right)^{0.14}. \quad (14)$$

The constant in Eq. (14) determined by Stein and Müller was 0.74 (deviation about 2.7%).

Anchor impeller

Zlokarnik [11] recommends the following equations for an Anchor impeller (Fig. 2e):
For cooling:

$$\mathrm{Nu} = 0.242\left(\mathrm{RePr}^{1/2} + 4000\right)^{2/3}\left(\frac{\nu}{\nu_w}\right)^{m}. \quad (15)$$

For heating:

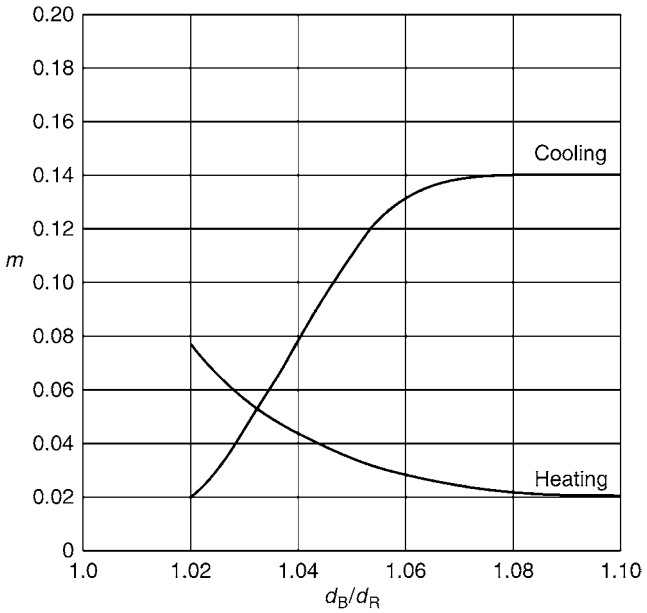
$$\mathrm{Nu} = 0.358\left(\mathrm{RePr}^{1/2} + 4000\right)^{2/3}\left(\frac{\nu}{\nu_w}\right)^{-m}. \quad (16)$$

Validity ranges:

$$1 \le \mathrm{Re} \le 10^5,$$
$$3 \le \mathrm{Pr} \le 3.6 \times 10^4,$$
$$1.02 \le \frac{d_B}{d_R} \le 1.1.$$

The numerical value of m, which depends on the ratio d_B/d_R, can be determined from Fig. 6. The dependence of m on d_B/d_R during heating given in Fig. 6 can be equally calculated from the following equation:

$$m = 2.2 \times 10^{-3}\left[\frac{d_B}{d_R} - 0.99\right]^{-1}. \quad (17)$$



N3. Fig. 6. The dependence of m in Eqs. (15) and (16) on d_B/d_R during heating or cooling.

For very small numerical values of the Reynolds number (Re < 10), the comments given at the beginning of Sect. 2.1.1 about laminar flow in stirred vessels have to be observed.

Helical impeller

Blasinski and Kuncewicz [12] recommend the following equations for a helical impeller (Fig. 2f):

$$\mathrm{Nu} = 0.248\left(\frac{S_B}{d_R}\right)^{-0.22}\left(\frac{S}{d_R}\right)^{-0.28}\mathrm{Re}^{0.5}\mathrm{Pr}^{0.33}\left(\frac{\eta}{\eta_w}\right)^{0.14} \quad (18)$$

$$\text{for } 34 \le \mathrm{Re} \le 130$$

and

$$\mathrm{Nu} = 0.238\left(\frac{S}{d_R}\right)^{-0.25}\mathrm{Re}^{0.67}\mathrm{Pr}^{0.33}\left(\frac{\eta}{\eta_w}\right)^{0.14} \quad (19)$$

$$\text{for } 130 \le \mathrm{Re} \le 6.89 \times 10^3.$$

In Eq. (18), $s_B = (d_B - d_R)/2$.
Validity ranges:

$$81 \le \mathrm{Pr} \le 1.1 \times 10^4,$$
$$0.0172 \le \frac{S_B}{d_R} \le 0.0556,$$
$$0.357 \le \frac{S}{d_R} \le 0.894,$$
$$0.0715 \le \frac{b_{WR}}{d_R} \le 0.143.$$

According to Blasinski and Kuncewicz, the width of the helical impeller b_{WR} has no effect on the Nusselt number in the examined range. The experimental measurements were made during unsteady heat transfer with a pseudoplastic fluid.

Stein [13] determined the heat transfer on the inner surface of a stirred vessel equipped with a helical impeller composed of an external helical ribbon, an internal screw, and a bottom blade as shown in Fig. 7a. The experimental results were correlated with the following equation:

$$\mathrm{Nu} = C_{WR}\mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_w}\right)^{0.14}. \quad (20)$$

Validity ranges:

$$20 \le \mathrm{Re} \le 2 \times 10^5.$$

The examined range of the Prandtl number is not given [13].

According to Stein, Eq. (20) can be equally used for other helical impellers with special forms shown in Fig. 7 (b: Paravisc impeller "Ekato," c: Alfa impeller "Stelzer," and d: MUT impeller "Dieder"). All impellers were equipped with bottom blades of different shapes. The experimentally determined constant C_{WR} for each impeller is given in Table 1. Because of uncertainties in the experimental measurements of about 10%, Stein recommends to use a constant value $C_{WR} = 0.48$ for all impellers and for both directions of rotation. The geometrical parameters of the impellers are given in Table 2. More details can be found in [13].

Scraped-surface heat exchanger

According to Weisser, heating or cooling a liquid without phase change in a scraped-surface heat exchanger (Fig. 8) may be calculated from the following equation [14]:

$$\mathrm{Nu} = 1.2Z^{0.26}\mathrm{Re}^{0.5}\mathrm{Pr}^{0.33}. \quad (21)$$

In Eq. (21), the characteristic length in the formation of the Reynolds number is the internal diameter of the inner tube of the heat exchanger (either no clearance or very small clearance exists between the edge of scraper blade and the internal tube surface), or

$$\mathrm{Re} = \frac{nd_B\rho}{\eta}.$$

Validity ranges:

$$150 \le \mathrm{Re} \le 1.8 \times 10^4,$$
$$7 \le \mathrm{Pr} \le 200,$$
$$Z = 2 \text{ or } 4.$$

In case of phase change during cooling, Weisser and Vogelpohl [14] and Weisser [15] suggest the following equation:

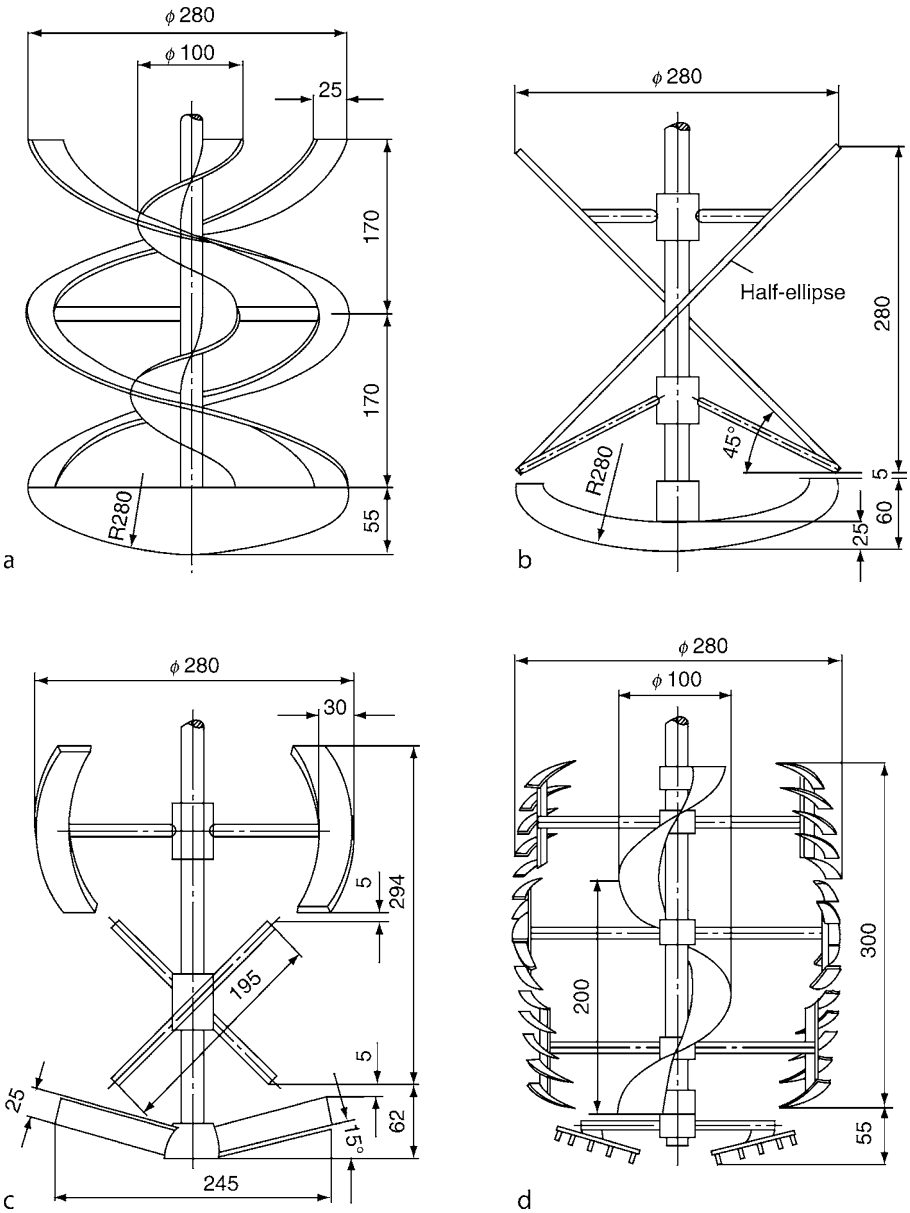
$$\mathrm{Nu} = 1.41Z^{0.5}\mathrm{Re}^{0.5}\mathrm{Pr}^{0.45}. \quad (22)$$

The above equation was derived using sugar solutions with a maximum ice volumetric fraction of 10%. The higher Nusselt number achieved with phase change compared with that without phase change is due to the transport of ice crystals from the cooled surface to the liquid core; this enhances heat transfer [14].

Theoretical approach for predicting the Nusselt number with a rectangular pitched-blade impeller

For approximate heat transfer calculations from the inner surface of a stirred vessel equipped with a rectangular pitched-blade impeller, Stein [16] developed the following equation for the Nusselt number in analogy to heat transfer on a plate using simplified assumptions:

$$\mathrm{Nu} = 0.4K_{ko}\mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_w}\right)^{0.14}. \quad (23)$$



N3. Fig. 7. Different impeller forms for which Eqs. (20) and (119) are valid according to [13].

K_{Ko} is a dimensionless number, which takes into account the constructional and geometrical features of the stirred vessel and the impeller, and is defined by

$$K_{Ko} = \left[10.47 n_R Z \left(\frac{b_R}{d_R}\right)\left(\frac{h}{d_R}\right)\sin^3\gamma\left(\frac{d_R}{d_B}\right)\left(\frac{h_L}{d_B}\right)^{-1}\right]^{1/3}. \quad (24)$$

The following assumptions, which correspond to the geometrical parameters of the baffles mounted in the experimental equipment, were used for the derivation of Eq. (23):

$$n_S = 4,$$
$$\frac{b_S}{d_B} = 0.1,$$
$$\frac{l_S}{h_L} = 0.73,$$
$$\frac{x_S}{d_B} = 0.03.$$

The case $\gamma = 90°$ represents an impeller with vertical rectangular blades. Equation (23) is valid for stirred vessels with baffles and dished bottom in the transition region; according to Stein, the equation can still be used approximately for laminar or turbulent flow.

With the help of a theoretical equation for the power consumption of the impeller (see Sect. 3), Stein derived the following equation, which relates the Nusselt number to the power consumption:

$$\mathrm{Nu} = 0.38\mathrm{Ne}_t^{1/9}\left(\frac{d_R}{d_B}\right)^{5/9}\left(\frac{h_L}{d_B}\right)^{-1/9} Pr^{1/3}\left[\frac{P_t d_B^4 \rho^2}{V_L \eta^3}\right]^{2/9}\left(\frac{\eta}{\eta_w}\right)^{0.14}. \quad (25)$$

In Eq. (25), Ne_t is the Newton number, P_t is the power consumption with turbulent flow, and V_L is the liquid volume. The expression in the square brackets is the dimensionless power consumption per unit liquid volume. Equation (25) shows that for the same power consumption, the same vessel diameter, the same liquid height, and the same physical properties, an impeller with the largest possible diameter with respect to heat transfer is advantageous. The influence of the Newton number – because of the small exponent in Eq. (25) – is negligible.

Example 1:
It is required to calculate the heat transfer coefficient on the heated inner surface of a stirred vessel fitted with four baffles. The vessel is filled with an aqueous solution agitated by a propeller. The physical properties of the aqueous solution may be assumed to be identical with those of pure water. The following geometrical and operational data are available:

Internal vessel diameter $d_B = 1$ m
Propeller diameter $d_R = 0.35$ m
Speed of rotation of propeller $n = 2.4\mathrm{s}^{-1}$
Number of propeller blades $Z = 3$
Propeller pitch $S = 0.35$ m
Mean liquid temperature $\vartheta = 88°C$
Mean wall temperature $\vartheta_w = 95°C$

Physical properties of water:
At mean liquid temperature $\vartheta = 88°C$:
Prandtl number $\mathrm{Pr} = 2.02$
Thermal conductivity $\lambda = 0.672\ \mathrm{W\,m^{-1}\,K^{-1}}$
Density $\rho = 966\ \mathrm{kg\,m^{-3}}$
Dynamic viscosity $\eta = 323 \times 10^{-6}$ Pa s
At mean wall temperature $\vartheta_w = 95°C$:
Dynamic viscosity $\eta_w = 299 \times 10^{-6}$ Pa s
Solution:
Reynolds number $\mathrm{Re} = \frac{nd_R^2\rho}{\eta} = \frac{2.4\times0.35^2\times966}{323\times10^{-6}} = 8.8\times10^5$,

Equation (8): $\psi_p = \exp(0.3\ln Z - 0.0144Z)\left\{\frac{0.278\exp[0.0469\exp(0.923\ln Z)]}{\frac{S}{d_R}} + 1\right\}^{-1}$
$= \exp(0.3\times\ln 3 - 0.0144\times 3)\left\{\frac{0.278\exp[0.0469\exp(0.923\ln 3)]}{\frac{0.35}{0.35}} + 1\right\}^{-1}$
$= 1.01$

The value of ψ_P can also be obtained directly from Fig. 4.

Equation (7): $\mathrm{Nu} = 0.505\psi_p \mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_w}\right)^{0.14}$
$= 0.505\times1.01\times\left(8.8\times10^5\right)^{2/3}(2.02)^{1/3}\left(\frac{323\times10^{-6}}{299\times10^{-6}}\right)^{0.14} = 5985$

The heat transfer coefficient α can be calculated from the Nusselt number, or

$$\alpha = \frac{\mathrm{Nu}\lambda}{d_B} = \frac{5985 \times 0.672}{1} = 4022\ \mathrm{Wm^{-2}K^{-1}}$$

Heat transfer from the outer surface of a coil

Figure 9 shows two different forms of coils, which are used to heat or cool a liquid inside a stirred vessel. In case of a helical coil (Fig. 9a), the baffles can be inserted inside or outside the coil. Mostly, the plates for fixing the coil in the vessel are constructed to function as baffles. A meander coil (Fig. 9b) reduces vortex formation; thus, additional baffles may not be needed. Consequently, such systems are referred to as vertical tube baffles (see also Figs. 10 and 11).

Flat-blade turbine

Mahlfeldt [17] gives the following equation for calculating the Nusselt number in a baffled stirred vessel fitted with a spiral coil (Fig. 9a):

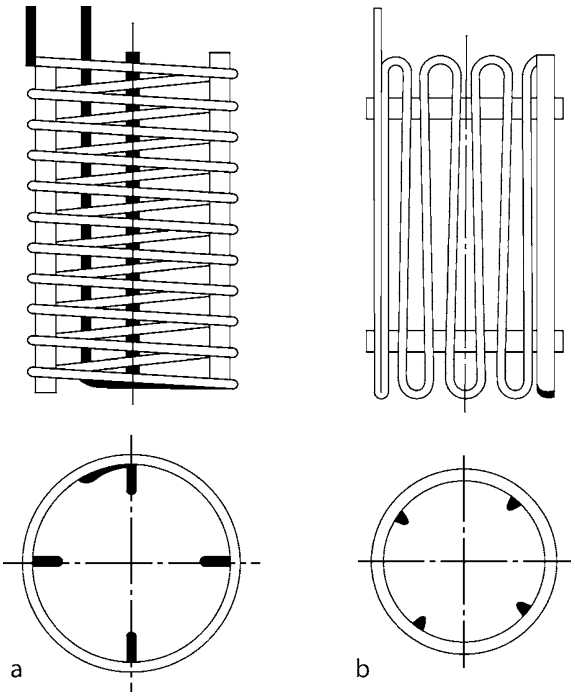
$$\mathrm{Nu_R} = 0.225 \left(\frac{d_R}{d_B}\right)^{0.18} \left(\frac{d}{d_B}\right)^{0.52} \left(\frac{d_S}{d_B}\right)^{-0.27} \left(\frac{h_R}{d_B}\right)^{0.14} \left(\frac{Z}{4}\right)^{0.28} \mathrm{Re}^{2/3}\mathrm{Pr}^{1/3} \left(\frac{\eta}{\eta_w}\right)^{0.14}, \quad (26)$$

with

$$\text{Nusselt number } \mathrm{Nu_R} = \frac{\alpha d}{\lambda}.$$

Validity ranges:

$$1.5 \times 10^3 \le \mathrm{Re} \le 7.7 \times 10^5,$$
$$2 \le \mathrm{Pr} \le 1190,$$
$$0.2 \le \frac{d_R}{d_B} \le 0.4,$$
$$0.023 \le \frac{d}{d_B} \le 0.054,$$
$$0.5 \le \frac{d_S}{d_B} \le 0.7,$$
$$0.27 \le \frac{h_R}{d_B} \le 0.63,$$
$$4 \le Z \le 6,$$



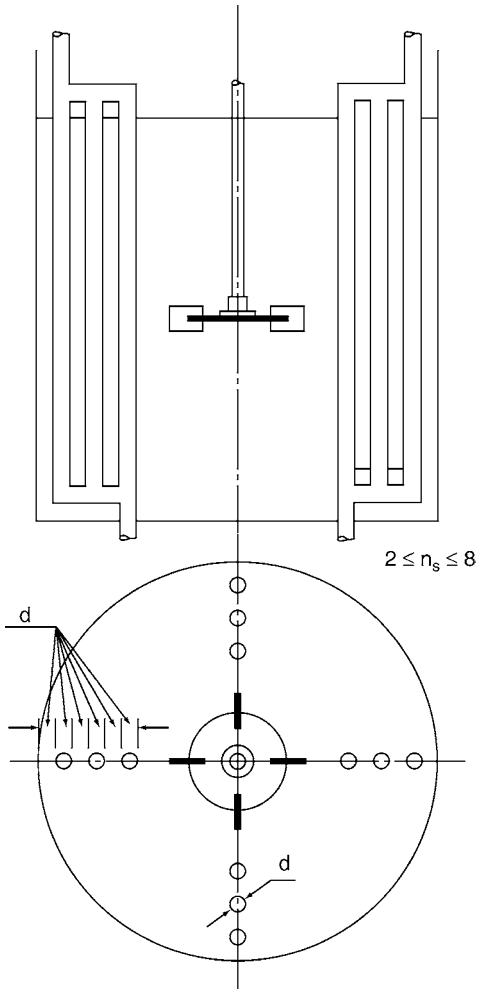
N3. Fig. 9. Coils: (**a**) helical coil, (**b**) meander coil.

According to Dunlap and Rushton [18], the Nusselt number for a stirred vessel equipped with vertical tube baffles (Fig. 10) may be calculated from

$$\mathrm{Nu_R} = 0.09 \left(\frac{d_R}{d_B}\right)^{0.33} \left(\frac{2}{n_S}\right)^{0.2} \mathrm{Re}^{0.65}\mathrm{Pr}^{0.3} \left(\frac{\eta}{\eta_{GS}}\right)^{0.4}. \quad (27)$$

Validity ranges:

$$10^3 \le \mathrm{Re} \le 2 \times 10^6,$$
$$2 \le \mathrm{Pr} \le 10^3,$$
$$\frac{1}{6} \le \frac{d_R}{d_B} \le \frac{1}{2},$$
$$2 \le n_S \le 8,$$



N3. Fig. 10. Stirred vessel with vertical tube baffles, for which Eq. (27) is valid.

$$0.035 \le \frac{d}{d_B} \le 0.040,$$
$$\frac{h_R}{h_L} = 0.5,$$
$$Z = 4,$$
$$n_{RS} = 3.$$

The dynamic viscosity η_{GS} in Eq. (27) is calculated at the mean temperature $(\vartheta + \vartheta_w)/2$ of the thermal boundary layer.

Havas et al. [19, 20] suggest the following equation for a stirred vessel equipped with tube baffles with the construction shown in Fig. 11:

$$Nu_R = 0.291\left(\frac{d_R}{d_B}\right)^{0.89}\left(\frac{d}{d_R}\right)^{0.667} Re^{0.667} Pr^{0.4}\left(\frac{\eta}{\eta_w}\right)^{0.16}. \quad (28)$$

Validity ranges:

$$3 \times 10^3 \le Re \le 5 \times 10^5,$$
$$4 \le Pr \le 240,$$
$$0.3 \le \frac{\eta}{\eta_w} \le 4,$$
$$0.25 \le \frac{d_R}{d_B} \le 0.5,$$
$$0.01 \le \frac{d}{d_B} \le 0.02,$$
$$\frac{h_R}{h_L} = 0.5,$$
$$n_S = 5,$$
$$\beta = +50^\circ \text{ or } -50^\circ,$$
$$Z = 6,$$
$$8 \le n_{RS} \le 18.$$

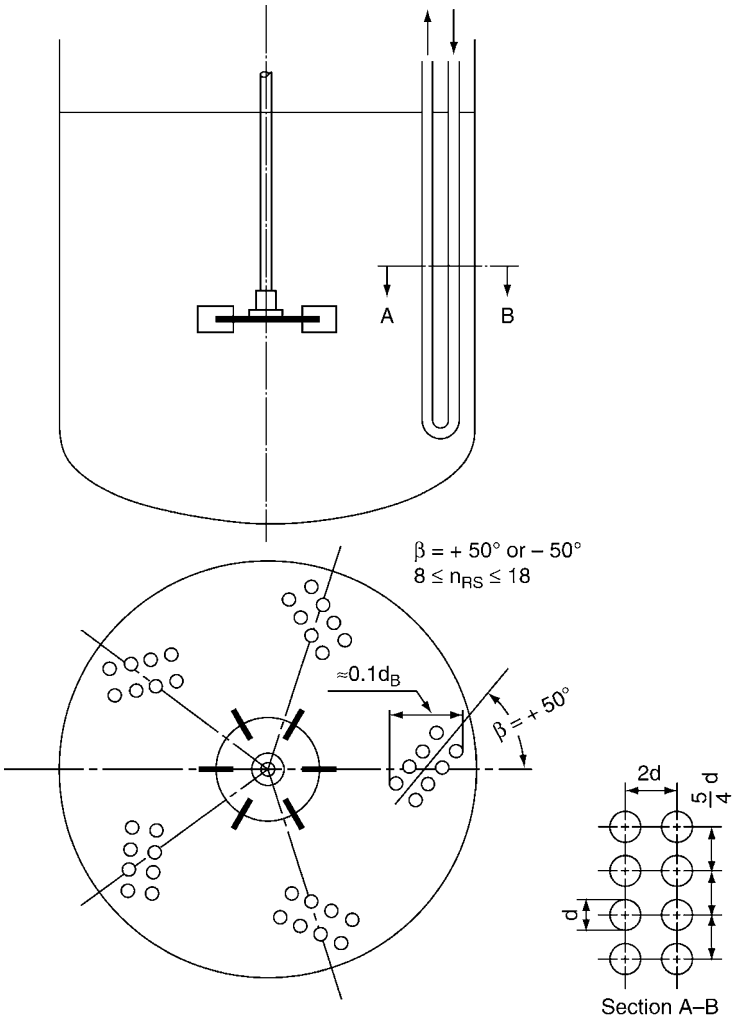
Other geometrical parameters examined by Havas et al. are given in Fig. 11.

Correlations for predicting the heat transfer from vertical plate coils in a stirred vessel equipped with two flat-blade turbines can also be presented [21].

Propeller

Skelland et al. [22] give the following equation for a baffled stirred vessel fitted with a helical coil:

$$Nu_R = 0.0573\left(\frac{h_R}{d_B}\right)^{-0.254}\left(\frac{S}{d_R}\right)^{2.33}\left(\frac{d}{d_B}\right)^{0.572}\left(\frac{s_S}{d}\right)^{-0.018} (n_S)^{-0.077}\left(\frac{b_S}{d_B}\right)^{-0.058} Re^{0.67} Pr^{0.41}\left(\frac{\eta}{\eta_w}\right)^{0.034}. \quad (29)$$



N3. Fig. 11. Stirred vessel with vertical tube baffles, for which Eq. (28) is valid.

Validity ranges:

$$1.3 \times 10^4 \le \mathrm{Re} \le 1.1 \times 10^6,$$
$$3 \le \mathrm{Pr} \le 300,$$
$$0.16 \le \frac{h_R}{d_B} \le 0.82,$$
$$1.0 \le \frac{S}{d_R} \le 1.33,$$
$$0.014 \le \frac{d}{d_B} \le 0.042,$$
$$1.2 \le \frac{s_S}{d} \le 8.0,$$
$$2 \le n_S \le 6,$$
$$0.06 \le \frac{b_S}{d_B} \le 0.17,$$
$$0.16 \le \frac{d_R}{d_B} \le 0.5,$$
$$1.4 \le \frac{d_S}{d_R} \le 4.1,$$
$$0.5 \le \frac{d_S}{d_B} \le 0.7,$$
$$\frac{h_L}{d_B} \approx 1.1.$$

Paddle

According to Chilton et al. [23], the following equation can be used for an unbaffled stirred vessel equipped with a helical coil:

$$\mathrm{Nu_R} = 0.87\left(\frac{d}{d_B}\right)\mathrm{Re}^{0.62}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_w}\right)^{0.14}. \quad (30)$$

Validity ranges:

$$300 \le \mathrm{Re} \le 4 \times 10^5,$$
$$3 \le \mathrm{Pr} \le 2 \times 10^3,$$
$$\frac{d_R}{d_B} = 0.6,$$
$$\frac{h}{d_B} = 0.1,$$
$$\frac{d}{d_B} = 0.042,$$
$$\frac{d_S}{d_B} = 0.8,$$
$$\frac{h_L}{d_B} = 0.83,$$
$$\frac{h_{RK}}{d_B} = 0.15,$$

Anchor impeller

Balsinski et al. [24] examined heat transfer in a stirred vessel equipped with an anchor impeller and a helical coil fixed inside the impeller and recommend the following equation:

$$\mathrm{Nu_R} = 0.084\left(\frac{d_S}{d_B}\right)^{0.74}\mathrm{Re}^{0.55}\mathrm{Pr}^{0.33}\left(\frac{\eta}{\eta_w}\right)^{0.14}. \quad (31)$$

Validity ranges:

$$31 \le \mathrm{Re} \le 2.8 \times 10^4,$$
$$19 \le \mathrm{Pr} \le 8.3 \times 10^3,$$
$$\frac{d_R}{d_B} = 0.95,$$
$$\frac{d}{d_B} = 0.04,$$
$$0.4 \le \frac{d_S}{d_B} \le 0.73.$$

Example 2:

It is required to calculate the heat transfer coefficient α at the outer surface of a helical coil in a stirred vessel. The liquid in the vessel is agitated by means of a flat-blade turbine with six blades and the outer diameter d of the tube of the coil is 0.022 m. The following operating conditions and geometrical parameters are given:

$$n = 1.5\,\mathrm{s}^{-1},$$
$$\frac{d_R}{d_B} = \frac{1}{3},$$
$$\frac{h_R}{d_B} = \frac{1}{3},$$
$$\frac{d_S}{d_B} = 0.7.$$

Furthermore, the data given in Example 1 related to the vessel diameter and physical properties should be used in this example.

Solution:

$$d_R = \frac{d_B}{3} = \frac{1}{3}\ \mathrm{m},$$
$$\mathrm{Re} = \frac{n d_R^2 \rho}{\eta} = \frac{1.5 \times \left(\frac{1}{3}\right)^2 \times 966}{323 \times 10^{-6}} = 4.98 \times 10^5,$$

Equation (26):

$$\mathrm{Nu_R} = 0.225\left(\frac{d_R}{d_B}\right)^{0.18}\left(\frac{d}{d_B}\right)^{0.52}\left(\frac{d_S}{d_B}\right)^{-0.27}\left(\frac{h_R}{d_B}\right)^{0.14}\left(\frac{Z}{4}\right)^{0.28}$$
$$\mathrm{Re}^{2/3}\mathrm{Pr}^{1/3}\left(\frac{\eta}{\eta_w}\right)^{0.14}$$
$$= 0.225\left(\frac{1}{3}\right)^{0.18}\left(\frac{0.022}{1}\right)^{0.52}(0.7)^{-0.27}\left(\frac{1}{3}\right)^{0.14}\left(\frac{6}{4}\right)^{0.28}$$
$$\left(4.98 \times 10^5\right)^{2/3}(2.02)^{1/3}\left(\frac{323}{299}\right)^{0.14}$$
$$= 215.4$$

Hence

$$\alpha = \frac{\mathrm{Nu_R}\lambda}{d} = \frac{215.4 \times 0.672}{0.022} = 6579\ \mathrm{W\,m^{-2}K^{-1}}.$$

Non-Newtonian liquids

Numerous experimental data gained with non-Newtonian liquids were examined by Edwards and Wilkinson [25]. It was demonstrated that heat transfer correlations developed for Newtonian liquids can still be used for non-Newtonian liquids, if the viscosity η of the Newtonian liquids in the Reynolds number, the Prandtl number, and the viscosity ratio is replaced

by the apparent viscosity η_{app} of the non-Newtonian liquids as defined by

$$\eta_{app} = \frac{\tau}{\dot{\gamma}}, \tag{32}$$

with τ the shear stress associated with the shear rate $\dot{\gamma}$. Different to Newtonian liquids, the relation between τ and $\dot{\gamma}$ for non-Newtonian liquids is nonlinear; the flow curve relating τ and $\dot{\gamma}$ can be determined experimentally for the considered non-Newtonian liquid. The apparent viscosity η_{app} decreases with increasing shear rate $\dot{\gamma}$ for pseudoplastics and increases for dilatants. It is assumed [25] that a linear relationship exists between the shear rate $\dot{\gamma}$ in a stirred vessel and the speed of rotation n of the impeller, or

$$\dot{\gamma} = k_S n. \tag{33}$$

The proportionality constant k_S may be approximated as follows:

For pseudoplastics:

Paddles, flat-blade turbines, propellers, and other high-speed impellers [25]:

$$k_S \approx 11. \tag{34}$$

Typical values available in the literature for k_S vary between 9 and 15 [25].

Anchor impellers:

$$k_S \approx 9.5 + \frac{9s^2}{s^2 - 1}. \tag{35}$$

Helical impellers [12]:

$$k_S = 4\pi. \tag{36}$$

For dilatants:

High-speed impellers with standard geometry [25]:

$$k_S \approx \frac{22s^2}{s^2 - 1}. \tag{37}$$

In Eqs. (35) and (37), $s = \frac{d_B}{d_R}$.

Since the Nusselt number is roughly proportional to the viscosity raised to the power $(-1/3)$, the uncertainty in evaluating the apparent viscosity is largely reduced.

Example 3:

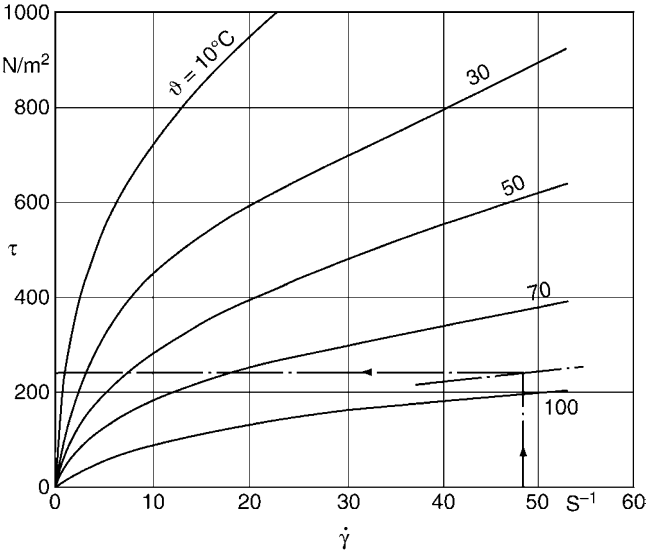
In Example 1, instead of using an aqueous solution, the stirred vessel is filled with a pseudoplastic liquid with flow characteristics given by the flow curve shown in Fig. 12. It is required to calculate the heat transfer coefficient α for the case in which the propeller in the stirred vessel is replaced by an anchor impeller with a diameter $d_R = 0.91$ m and a speed of rotation $n = 0.8\,s^{-1}$. Other physical properties of the pseudoplastic liquid are similar to that of pure water and are given in Example 1.

Solution:

The constant k_s in Eq. (33) for an anchor impeller is given by Eq. (35), or

$$k_S = 9.5 + \frac{9s^2}{s^2 - 1} = 9.5 + \frac{9\left(\frac{1.0}{0.91}\right)^2}{\left(\frac{1.0}{0.91}\right)^2 - 1} = 61.9.$$

Equation (33): $\dot{\gamma} = k_S n = 61.9 \times 0.8 = 49.5\ s^{-1}$.



N3. Fig. 12. Flow curve for a 6% aqueous solution of carboxymethyl cellulose (CMC).

The shear stress τ at $\dot{\gamma} = 49.5\,s^{-1}$ and $\vartheta = 88°$ C can be estimated from Fig. 12, or

$$\tau = 247\,N\,m^{-2}.$$

Equation (32): $\eta_{app} = \frac{\tau}{\dot{\gamma}} = \frac{247}{49.5} = 4.99$ Pa s.

At liquid temperature $\vartheta = 88°$ C:

$$\rho = 966\,kg\,m^{-3}.$$

Thus,

$$Re = \frac{nd_R^2\rho}{\eta_{app}} = \frac{0.8 \times 0.91^2 \times 966}{4.99} = 128.2$$

and

$$Pr = \left(\frac{Pr}{\eta}\right)_{(\text{in Example 1})} \times \eta_{app} = \left(\frac{2.02}{323 \times 10^{-6}}\right) \times 4.99 = 31207.$$

In Eq. (16), $\nu = \eta/\rho$ should be replaced by $\nu_{app} = \eta_{app}/\rho$ and $\nu_w = \eta_w/\rho_w$ should be replaced by $\nu_{w,app} = \eta_{w,app}/\rho_w$, where ν_{app} is the apparent kinematic viscosity corresponding to the apparent dynamic viscosity η_{app} at liquid temperature ϑ, $\nu_{w,app}$ the apparent kinematic viscosity corresponding to the apparent dynamic viscosity $\eta_{w,app}$ at wall temperature ϑ_w and ρ_w the liquid density at wall temperature ϑ_w.

Now

$$\frac{\nu_{app}}{\nu_{w,app}} = \left(\frac{\left(\frac{\eta_{app}}{\rho}\right)}{\left(\frac{\eta_{w,app}}{\rho_w}\right)}\right) = \left(\frac{\eta_{app}}{\eta_{w,app}}\right) \times \left(\frac{\rho_w}{\rho}\right)$$

$$= \cdot\left(\frac{\left(\tau/\dot{\gamma}\right)_\vartheta}{\left(\tau/\dot{\gamma}\right)_{\vartheta_w}}\right) \times \left(\frac{\rho_w}{\rho}\right) = \left(\frac{(\tau)_\vartheta}{(\tau)_{\vartheta_w}}\right) \times \left(\frac{\rho_w}{\rho}\right).$$

At wall temperature $\vartheta_w = 95°$ C:

$$\rho_w = 962\,kg\,m^{-3}$$

and

$\tau = 205\,\mathrm{N\,m^{-2}}$ (estimated from Fig. 12 at $\dot{\gamma} = 49.5\,\mathrm{s^{-1}}$ and $\vartheta_w = 95°\,\mathrm{C}$).

Thus,

$$\frac{\nu_{app}}{\nu_{w,app}} = \left(\frac{247}{205}\right) \times \left(\frac{962}{966}\right) = 1.2.$$

Equation (17):

$$m = 2.2 \times 10^{-3}\left[\frac{d_B}{d_R} - 0.99\right]^{-1} = 2.2 \times 10^{-3}\left[\frac{1.0}{0.91} - 0.99\right]^{-1} = 0.02,$$

Equation (16): $\mathrm{Nu} = 0.358\left(\mathrm{RePr}^{1/2} + 4000\right)^{2/3}\left(\frac{\nu}{\nu_w}\right)^{-m}$

$$= 0.358\left(128.2 \times 31207^{0.5} + 4000\right)^{2/3}(1.2)^{-0.02}$$
$$= 318.$$

Hence

$$\alpha = \frac{\mathrm{Nu}\lambda}{d_B} = \frac{318 \times 0.672}{1} = 214\,\mathrm{W\,m^{-2}K^{-1}}.$$

2.1.2 Multiphase Systems

There are only a few publications available about heat transfer for multiphase systems in stirred vessels. A review is made by Steiff et al. and Kurpiers et al. [26–31].

Gas–Liquid Mixtures

Heat transfer studies on stirred gas–liquid mixtures show that in the case of a homogenous bubble flow, substantial enhancement of the heat transfer with increasing superficial gas velocity u_{GO} $\left(u_{GO} = \dot{V}_G/\left((\pi/4)d_B^2\right)\right)$ occurs only at low impeller speed. At high speed of rotation, the enhancement of heat transfer achieved by increasing the superficial gas velocity is relatively small; the heat transfer may even be impaired if the superficial gas velocity is increased at very high speed of rotation [26]. In the range of heterogeneous bubble flow, that is, above a superficial gas velocity of about 0.05–0.15 m $\mathrm{s^{-1}}$, heat transfer is independent of the speed of rotation or the superficial gas velocity [26]. The gas phase is often introduced in the liquid by means of a gas distributor, for example, a ring underneath the impeller. In case of a flat-blade turbine, the gas is guided through the disc of the impeller into the zone of high shear rate; there it is dispersed in the form of fine bubbles. For this reason, flat-blade turbines are eminently suitable for gas dispersion. On the other hand, impellers generating an axial flow (e. g., propellers) are less suitable for gas dispersion; the buoyancy-induced upward motion of the bubbles near the impeller shaft at high gas flow rates has a negative effect on the downward axial flow induced by the impeller. Another method of gas dispersion is aeration induced by hollow impellers. According to [28, 30, 31], the Nusselt number at the inner surface of a stirred vessel with four baffles, a standard flat-blade turbine, and a ring gas distributor may be calculated from the following equation:

$$\mathrm{Nu} = 0.1\left\{\xi\left(\frac{d_B}{d_R}\right)\left(\frac{d_B^3}{V_L}\right)\mathrm{Ne_B Re}^3 + \mathrm{GaRe_G}\left[1 - 2\left(\frac{d_R}{d_B}\right)\left(\frac{d_R}{h_{LO} - h_{BR}}\right)\mathrm{Ne_B^{0.5}Fr}\right]\right\}^{0.25}\mathrm{Pr}^{0.4}\left(\frac{\eta}{\eta_w}\right)^{0.23}. \quad (38)$$

The constant ξ depends on the ratio $\left(d_B/d_R\right)$ as follows:

$$\xi = 0.2 \text{ for } \left(\frac{d_B}{d_R}\right) = 3,$$

$$\xi = 0.37 \text{ for } \left(\frac{d_B}{d_R}\right) = 1.93.$$

The dimensionless numbers present in Eq. (38), are defined as follows:

$\mathrm{Ne_B} = \dfrac{P_B}{\rho n^3 d_R^5}$. Newton number for gas−liquid mixture,

$\mathrm{Fr} = \dfrac{n^2 d_R}{g}$. Froude number,

$\mathrm{Ga} = \dfrac{d_B^3 g}{\nu^2}$. Galileo number,

$\mathrm{Re_G} = \dfrac{u_{GO} d_B}{\nu}$. Reynolds number (characteristic velocity is the superficial gas velocity);

thus,

$$\mathrm{GaRe_G} = \frac{d_B^4 g u_{GO}}{\nu^3}.$$

V_L in Eq. (38) is the volume of the unaerated liquid, P_B is the power consumption of the impeller for the gas–liquid mixture. Equations for calculating the Newton number Ne_B for gas–liquid mixtures are presented in Sect. 3; other equations can also be found in [32]. Differences in calculating the Newton number from the different equations are – because of the small exponent of the Newton number – largely suppressed

According to [28], Eq. (38) is valid also for the following limiting cases:

Unagitated gas–liquid system (bubble column):

$$\mathrm{Ne_B} = 0,\ \mathrm{Re} = 0.$$

Unaerated agitated liquid:

$$GaRe_G = 0.$$

Validity ranges:

Equation (38) was derived from measurements obtained with different liquids and air in a vessel with the following dimensions and geometrical ratios:

$$d_B = 0.45\,\mathrm{m},$$
$$\frac{d_B}{d_R} = 1.93,\ 3,$$
$$\frac{h_R}{d_R} = 0.5,$$

$$\frac{h_{LO}}{d_B} = 1.35,$$
$$\frac{h_{BR}}{d_B} = 0.083.$$

The dimensionless numbers were changed in the following ranges:

$$4.3 \le \mathrm{Pr} \le 630,$$
$$0.024 \le \frac{\eta}{\eta_w} \le 3.6,$$
$$2.47 \times 10^8 \le \mathrm{Ga} \le 2.16 \times 10^{12},$$
$$0.65 \le \mathrm{Ne_B} \le 4.65,$$
$$1.26 \times 10^3 \le \mathrm{Re} \le 4.15 \times 10^5,$$
$$0.127 \le \mathrm{Fr} \le 2.19,$$
$$5.47 \le \mathrm{Re_G} \le 7.83 \times 10^4.$$

Example 4:

It is required to calculate the heat transfer coefficient α at the inner surface of a heated stirred vessel filled with an aqueous solution. The liquid is agitated by means of a flat-blade turbine having six blades and is aerated by means of a ring underneath the impeller. The gas flow rate $\dot{V}_G$ amounts to 6 $m^3\ h^{-1}$. The physical properties of the aqueous solution may be assumed to be similar to those of pure water. The stirred vessel has four baffles and the following dimensions and operating parameters:

Vessel diameter $d_B = 0.5\,m$
Geometrical ratios: $d_R = \frac{d_B}{3}$,
$h_R = 0.5 d_R$
$h_{LO} = 1.35 d_B$
$h_{BR} = 0.083 d_B$
Speed of rotation of impeller $n = 7\ s^{-1}$
Power consumption of impeller $P_B = 106\,W$
Mean liquid temperature $\vartheta = 20°\,C$
Mean wall temperature $\vartheta_w = 30°\,C$

Physical properties of water:

At mean liquid temperature $\vartheta = 20°\,C$:
Prandtl number Pr = 6.99,
Thermal conductivity $\lambda = 599.6 \times 10^{-3}\,W\,m^{-1}\,K^{-1}$
Density $\rho = 998.3\,kg\,m^{-3}$
Dynamic viscosity $\eta = 1002.6 \times 10^{-6}\,pa\,s$
Kinematic viscosity $\nu = 1.004 \times 10^{-6}\,m\,s^{-2}$

At mean wall temperature $\vartheta_w = 30°\,C$:

Dynamic viscosity $\eta_w = 797.7 \times 10^{-6}\,pa\,s$

Solution:

$$\mathrm{Re} = \frac{n d_R^2 \rho}{\eta} = \frac{7 \times \left(\frac{0.5}{3}\right)^2 \times 998.3}{1002.6 \times 10^{-6}} = 1.94 \times 10^5,$$
$$u_{GO} = \frac{\dot{V}_G}{\left(\frac{\pi d_B^2}{4}\right)} = \frac{\left(\frac{6}{3600}\right)}{\left(\frac{\pi \times 0.5^2}{4}\right)} = 0.00849\,m\,s^{-1},$$
$$\mathrm{Re_G} = \frac{u_{GO} d_B}{\nu} = \frac{0.00849 \times 0.5}{1.004 \times 10^{-6}} = 4228,$$
$$\mathrm{Ga} = \frac{d_B^3 g}{\nu^2} = \frac{0.5^3 \times 9.81}{(1.004 \times 10^{-6})^2} = 1.22 \times 10^{12},$$
$$\mathrm{Fr} = \frac{n^2 d_R}{g} = \frac{7^2 \times \left(\frac{0.5}{3}\right)}{9.81} = 0.832,$$
$$\mathrm{Ne_B} = \frac{P_B}{\rho n^3 d_R^5} = \frac{106}{998.3 \times 7^3 \times \left(\frac{0.5}{3}\right)^5} = 2.41,$$
$$V_L = \left(\frac{\pi d_B^2}{4}\right) h_{LO} = \left(\frac{\pi d_B^2}{4}\right)(1.35 d_B) = 1.06 d_B^3,$$
$$\xi = 0.2 \ (\text{since } (d_B/d_R) = 3).$$

Hence

$$\mathrm{Nu} = 0.1\left\{\xi\left(\frac{d_B}{d_R}\right)\left(\frac{d_B^3}{V_L}\right)\mathrm{Ne_B Re}^3 + \mathrm{GaRe_G}\left[1 - 2\left(\frac{d_R}{d_B}\right)\left(\frac{d_R}{h_{LO} - h_{BR}}\right)\mathrm{Ne_B}^{0.5}\mathrm{Fr}\right]\right\}^{0.25} \mathrm{Pr}^{0.4}\left(\frac{\eta}{\eta_w}\right)^{0.23}$$
$$= 0.1\left\{0.2 \times (3) \times \left(\frac{1}{1.06}\right) \times 2.41 \times \left(1.94 \times 10^5\right)^3 + \left(1.22 \times 10^{12}\right) \times 4228 \times \left[1 - 2 \times \left(\frac{1}{3}\right) \times \left(\frac{\frac{1}{3}}{1.35 - 0.083}\right) \times 2.41^{0.5} \times 0.832\right]\right\}^{0.25} \times 6.99^{0.4} \times \left(\frac{1002.6}{797.7}\right)^{0.23}$$
$$= 2493.$$

The heat transfer coefficient is thus given by

$$\alpha = \frac{\mathrm{Nu}\lambda}{d_B} = \frac{2493 \times (599.6 \times 10^{-3})}{0.5} = 2990\,W\,m^{-2}K.$$

Immiscible Liquids

Heat transfer to a mixture of two immiscible liquids is a complex process. It depends not only on the heat transfer parameters of the single-phase "liquid", but also on additional parameters of the two-phase "liquid–liquid," which include the fractions of each component, the local form and distribution of each phase in the stirred vessel, the interfacial tension, as well as the concentration of impurities. At high impeller speed and correspondingly a uniform distribution of the dispersed phase, it can be assumed that a quasi-homogeneous mixture is present in the stirred vessel. The equations derived for the single-phase liquid can be used for the two-phase mixture, when the physical properties of the single-phase liquid are replaced by the mean physical properties of the quasi-homogeneous two-phase mixture. Mostly, the equation derived by Olney and Carlson [33] for the dynamic viscosity

$$\eta_m = \eta_d^{\varphi} \eta_c^{(1-\varphi)} \tag{39}$$

and the equation derived by Maxwell [26, 34] for the thermal conductivity

$$\lambda_m = \lambda_c \left[\frac{2\lambda_c + \lambda_d - 2\varphi(\lambda_c - \lambda_d)}{2\lambda_c + \lambda_d + \varphi(\lambda_c - \lambda_d)}\right] \tag{40}$$

are used for the two-phase mixture. The density and the specific heat are determined usually from the arithmetic mean

$$\rho_m = \varphi\rho_d + (1 - \varphi)\rho_c, \tag{41}$$
$$c_m = \varphi c_d + (1 - \varphi)c_c. \tag{42}$$

In Eqs. (39–42), the subscripts *m*, *d*, and *c* are for the quasi-homogenous two-phase mixture, the dispersed phase, and the continuous phase respectively; φ is the volumetric fraction of the dispersed phase. The influence of phase separation in the vicinity of the wall on heat transfer in agitated emulsions has

been reported in [26, 34]. Both radial flow and axial flow impellers are used to disperse a liquid. However, preference is given to radial flow impellers, especially flat-blade turbines, for dispersion purposes owing to the high shear rates, high turbulence, and the associated good dispersion characteristics.

Suspensions

If the suspended solids are uniformly distributed (i.e., turbulent flow, high impeller speed, small fraction of solid particles, and small particle diameter), it may be assumed that a quasi-homogenous phase is present inside the stirred vessel. The heat transfer equations for the single-phase liquid can be used for the suspension provided that the physical properties for the single-phase liquid are replaced by the mean physical properties of the suspension. There are different equations present in the literature to determine the mean dynamic viscosity of the suspension. According to Eilers (as reported [31]), the following equation may be used:

$$\eta_m = \eta_c \left[1 + \frac{2.5\varphi}{2\left(1 - \frac{\varphi}{\varphi_{max}}\right)}\right]^2, \tag{43}$$

where φ is volumetric fraction of the dispersed phase, φ_{max} the maximal volumetric fraction in the batch, η_m the mean dynamic viscosity of the quasi-homogenous suspension, and η_c the dynamic viscosity of the continuous phase (liquid phase). For a batch of spherical particles, $\varphi_{max} = 0.74$. Other equations are reported in [26]. The other physical properties of the suspension can be determined as described in the section titled "*Immiscible liquids*." According to Kwasniak [34], the mentioned procedure of calculation should be applied only if the density of the solid particles is substantially higher than that of the liquid ($\rho_d > 2.2\rho_c$). Under such conditions, the boundary layer near the heat transfer surface of the stirred vessel will not be free of solid particles and the mean values of the physical properties of the suspension can be used in all parameters of the heat transfer equations. If the density of the solid particles differs only insignificantly from that of the liquid ($\rho_d \approx \rho_c$), phase separation will occur in the boundary layer. In such cases, the physical properties of the continuous liquid phase should be used in the parameters relevant to heat transfer in the vicinity of the wall (i.e., λ in Nu, a in Pr, and η_w in the viscosity ratio (η/η_w)); the mean physical properties of the suspension should be inserted in the other parameters (i.e., ν in Re and Pr as well as η in the viscosity ratio (η/η_w)). Axial flow impellers (e.g., propellers) are usually used for suspending solid particles in a liquid, because their power consumption is lower than that for radial-flow impellers.

Gas–Suspension Mixtures

Although axial-flow impellers are preferred for suspending solids, they are not suitable for mixing suspensions with gases owing to the adverse effect exerted by the movement of the gas bubbles on the axial-flow induced by the impeller. Flat-blade turbines are predominantly used for this task. Studies on gas–suspension mixtures have revealed that heat transfer in the three-phase system "gas–solid–liquid" can be determined from equations of the two-phase systems "gas–liquid" and "solid–liquid" [31]. Thus, Eq. (38) for gas–liquid mixtures can also be used for gas–suspension mixtures provided that the physical properties of the liquid in Eq. (38) are replaced by the mean physical properties of the solid–liquid mixture as given in the section titled "Suspensions." The validity of Eq. (38) for gas–suspensions was checked by experiments in which the solid particles were glass beads: the diameter of the beads was varied between 15 and 1800 μm and the volumetric fraction between 0.01 and 0.1.

The distribution of the solid particles can be improved in multistage systems by mounting a number of agitators on the same shaft. According to [30, 31], the following equation may be used for gas–suspensions in a stirred vessel equipped with a two-stage system having two flat-blade turbines:

$$Nu = 0.1\left[11.58\left(\frac{d_B}{d_R}\right)\left(\frac{d_B^3}{V_L}\right)Ne_B Re^3 + GaRe_G\right]^{0.238} Pr^{0.362}\left(\frac{\eta}{\eta_w}\right)^{0.23}. \tag{44}$$

The dimensionless numbers in Eq. (44) are formed with the mean physical properties of the solid–liquid suspension according to the equations given in the section titled "Suspensions."
Validity ranges:
Geometrical ratios:

$$\frac{d_B}{d_R} = 3,$$
$$\frac{h_{R1}}{d_R} = 0.5,$$
$$\frac{h_{R2}}{d_R} = 2.58,$$
$$\frac{h_{LO}}{d_B} = 1.35,$$

Operating dimensionless parameters:

$$4.2 \le Pr \le 632,$$
$$0.033 \le \frac{\eta}{\eta_w} \le 3.02,$$
$$2.69 \times 10^8 \le Ga \le 2.16 \times 10^{12},$$
$$1.94 \le Ne_B \le 10.2,$$
$$6.51 \times 10^2 \le Re \le 4.05 \times 10^5,$$
$$0.021 \le Fr \le 2.15,$$
$$0 \le Re_G \le 7.07 \times 10^4.$$

h_{R1} and h_{R2} in Eq. (44) are the height of the lower and the upper agitators from the bottom of the vessel respectively. According to [31], Eq. (44) is also valid for the single-phase system "liquid" and for the two-phase systems "gas–liquid" and "solid–liquid." For the single-phase system "liquid" and for the two-phase-system "gas–liquid," the physical properties of the liquid and for the two-phase system "solid–liquid" the mean physical properties of the suspension have to be used.

2.2 Heat Transfer from a Jacket or from a Coil

2.2.1 Heat Transfer from a Jacket

A limited number of publications are available about heat transfer on the jacket side of a stirred vessel. The relatively

simple flow geometry in the annular space between the outer surface of the stirred vessel and the inner surface of the jacket encouraged workers to develop equations for predicting the jacket-side heat transfer on semitheoretical basis using different analogies. Known methods are due to Lehrer [35] and Stein and Schmidt [36–38]. The last method presented by Stein and Schmidt [38] is a modification and hence a replacement of earlier methods. Heat transfer coefficients on the jacket side calculated by means of these methods differ significantly. For that reason, both the method of Lehrer [35] and the modified method of Stein and Schmidt [38] are described hereafter; a numerical example using both methods and some comments are also presented.

Method of Lehrer

Lehrer [35] used the Prandtl analogy between momentum and heat transfer and derived the following equation:

$$\mathrm{Nu}_{S,L} = \left[\frac{0.03\mathrm{Re}_S^{0.75}\mathrm{Pr}}{1+\frac{1.74(Pr-1)}{\mathrm{Re}_S^{0.125}}}\right]\left(\frac{\eta}{\eta_w}\right)^{0.14} \tag{45}$$

with

Nusselt number $\mathrm{Nu}_{S,L} = \frac{\alpha d_g}{\lambda}$,

Reynolds number $\mathrm{Re}_S = \frac{u_h d_g \rho}{\eta}$.

The physical properties in Eq. (45) (λ, ρ, η, Pr) are evaluated at the mean jacket-side liquid temperature ϑ_J and the dynamic viscosity η_W at the mean jacket wall temperature $\vartheta_{J,w}$. The characteristic length d_g in the Nusselt number and in the Reynolds number and the characteristic velocity u_h in the Reynolds number are given by

$$d_g = \left(\frac{8}{3}\right)^{1/2}\delta, \tag{46}$$

$$u_h = (u_S u_O)^{1/2} + u_A. \tag{47}$$

δ in Eq. (46) is the width of the annular space and u_O in Eq. (47) is the velocity through the inlet tube of the jacket given by

$$u_O = \frac{\dot{V}_J}{\left(\frac{\pi}{4}\right)d_O^2} \tag{48}$$

with $\dot{V}_J$ the volumetric flow rate in the jacket and d_O the inside diameter of the inlet tube. u_S in Eq. (47) is the velocity in the annular space of the jacket; its magnitude depends on the type of flow in the annular space as dictated by the layout of the inlet tube (radial or tangential). $(u_S u_O)^{1/2}$ is the geometric mean velocity in the jacket and u_A is an additional velocity component introduced by Lehrer to take into account the influence of buoyancy.

For radial inlet:

$$u_S = \frac{\dot{V}_J}{\left(\frac{\pi}{4}\right)\left(d_J^2 - d_{BA}^2\right)}, \tag{49}$$

$$u_A = 0.5(2gh_S\beta\Delta\vartheta_J)^{1/2} \tag{50}$$

with d_{BA} the outer vessel diameter, d_J the inner diameter of the jacket ($d_J = d_{BA} + 2\delta$), g the acceleration due to gravity, h_S the jacket height, β the volumetric expansion coefficient, and $\Delta\vartheta_J$ the temperature rise or temperature drop of the jacket-side liquid ($\Delta\vartheta_J = |(\vartheta_{J,i} - \vartheta_{J,o})|$). In Eq. (47), the velocity u_A due to buoyancy is added to the geometric mean velocity $(u_S u_O)^{1/2}$, since an upward jacket-side flow and cooling the contents of the stirred vessel with a temperature rise $\Delta\vartheta_J$ are assumed; in that case u_A and $(u_S u_O)^{1/2}$ have the same direction. This applies also for a downward jacket-side flow and heating the contents of the stirred vessel (temperature drop $\Delta\vartheta_J$). If the velocity component u_A opposes the geometric mean velocity $(u_S u_O)^{1/2}$ (i.e., an upward jacket-side flow and heating the contents of the stirred vessel or a downward jacket-side flow and cooling the contents of the stirred vessel) u_A should be subtracted from $(u_S u_O)^{1/2}$.

For tangential inlet:

$$u_S = \frac{\dot{V}_J}{h_S\delta}, \tag{51}$$

$$u_A = 0. \tag{52}$$

The velocity component u_A due to buoyancy has also a nonzero value with tangential inlet. However, since u_A and $(u_S u_O)^{1/2}$ are perpendicular to each other in this case, vector addition is required; for simplicity Lehrer ignored u_A.

Equation (45) was examined using a jacketed stirred vessel equipped with four baffles and different paddles [35]. The tests were carried out with cooling the contents of the vessel. Other parameters are given below:

$$d_B = 610\,\mathrm{mm}$$
$$\delta = 25.4\,\mathrm{mm}$$
$$\frac{h_L}{d_B} = 1,$$
$$d_O = 19.1\,\mathrm{mm}\ \text{(for radial inlet)}$$
$$d_O = 12.7\ \text{(for tangential inlet)}$$
$$5 < \mathrm{Pr} < 7\ \text{(cooling medium: water)}$$
$$9\times10^3 \le \mathrm{Re}_S \le 4\times10^4\ \text{(for radial inlet)}$$
$$2.2\times10^4 \le \mathrm{Re}_S \le 8\times10^4\ \text{(for tangential inlet)}$$

The ratio of the calculated Nusselt number to the Nusselt number derived experimentally for radial inlet varied between 0.794 and 1.258 with an average of 1.014 and for tangential inlet from 0.759 to 1.293 with an average of 1.037 [35].

Method of Stein and Schmidt

Stein and Schmidt [38] presented different models and carried out own experimental measurements. The measurements were used to compare the different models discussed in the paper including the model of Lehrer. Finally, Stein and Schmidt [38] recommended the following procedure to determine the jacket-side heat transfer coefficient:

A characteristic length l_{ch} is calculated from

$$l_{ch} = \left(\left(\frac{\pi}{2}\right)^2 d_{BA}^2 + h_S^2\right)^{0.5}. \tag{53}$$

A characteristic diameter d_{ch} is calculated from

$$d_{ch} = d_h = 2\delta. \tag{54}$$

A characteristic velocity u_{ch} is calculated as follows:

For radial inlet tubes:

$$u_{ch} = u_{Mit}\left(\frac{\ln\left(\frac{b_{Mit}}{b_{Ein}}\right)}{1-\left(\frac{b_{Ein}}{b_{Mit}}\right)}\right) \tag{55}$$

with

$$b_{\mathrm{Ein}} = \left(\frac{\pi}{8}\right)\left(\frac{d_{\mathrm{O}}^2}{\delta}\right), \tag{56}$$

$$b_{\mathrm{Mit}} = \left(\frac{\pi}{2}\right) d_{\mathrm{BA}} \left(1 + \left(\frac{\pi}{2}\right)^2 \left(\frac{d_{\mathrm{BA}}}{h_{\mathrm{S}}}\right)^2\right)^{0.5}, \tag{57}$$

$$u_{\mathrm{Mit}} = \frac{\dot{V}_{\mathrm{J}}}{2\delta b_{\mathrm{Mit}}}. \tag{58}$$

For tangential inlet tubes and tangential inlet nozzles with diameter d_{O}:

$$u_{\mathrm{ch}} = \left(u_{\mathrm{x}}^2 + u_{\mathrm{z}}^2\right)^{0.5}, \tag{59}$$

$$u_{\mathrm{x}} = u_{\mathrm{O}} \left(\frac{\ln\left[1 + \left(\frac{\xi_{\mathrm{J}} d_{\mathrm{BA}} h_{\mathrm{S}}}{d_{\mathrm{O}}^2}\right)\left(\frac{u_{\mathrm{x}}(0)}{u_{\mathrm{O}}}\right)\right]}{\left(\frac{\xi_{\mathrm{J}} d_{\mathrm{BA}} h_{\mathrm{S}}}{d_{\mathrm{O}}^2}\right)}\right), \tag{60}$$

$$u_{\mathrm{x}}(0) = K_3 + \left(K_3^2 + K_4\right)^{0.5}, \tag{61}$$

$$K_3 = \left(\frac{u_{\mathrm{O}}}{4}\right) - \left(\frac{d_{\mathrm{O}}^2 u_{\mathrm{O}}}{4\xi_{\mathrm{J}} d_{\mathrm{BA}} h_{\mathrm{S}}}\right), \tag{62}$$

$$K_4 = \frac{d_{\mathrm{O}}^2 u_{\mathrm{O}}^2}{2\xi_{\mathrm{J}} d_{\mathrm{BA}} h_{\mathrm{S}}}, \tag{63}$$

$$u_{\mathrm{z}} = \frac{\dot{V}_{\mathrm{J}}}{\pi d_{\mathrm{BA}} \delta}, \tag{64}$$

$$u_{\mathrm{O}} = \frac{\dot{V}_{\mathrm{J}}}{\left(\frac{\pi}{4}\right) d_{\mathrm{O}}^2}. \tag{65}$$

The friction factor ξ_{J} in the above equations is calculated as follows:

For laminar flow through a rectangular gap or an annulus the following equation applies

$$\xi_{\mathrm{J}} = \frac{96}{\mathrm{Re_J}} \tag{66}$$

with the Reynolds number $\mathrm{Re_J}$ given by

$$\mathrm{Re_J} = \frac{u_{\mathrm{ch}} d_{\mathrm{ch}} \rho}{\eta}. \tag{67}$$

For turbulent flow through a noncircular conduit, the friction factor ξ_{J} is equivalent to the friction factor for a circular conduit with the same equivalent diameter. For technically smooth tubes, the friction factor due to Blasius may be used, or

$$\xi_{\mathrm{J}} = \frac{0.3164}{\mathrm{Re_J^{0.25}}} \quad \text{for } 3 \times 10^3 \leq \mathrm{Re_J} \leq 10^5. \tag{68}$$

The characteristic velocity u_{ch} for tangential inlet tubes and tangential nozzles has to be determined iteratively.

Other required dimensionless parameters are:

Grashof number $\mathrm{Gr_J}$ defined by

$$\mathrm{Gr_J} = \frac{g\rho(\rho - \rho_{\mathrm{w}}) d_{\mathrm{ch}}^3}{\eta^2} \text{ (can be either positive or negative, depending on } \rho \text{ and } \rho_{\mathrm{w}}) \tag{69}$$

and the equivalent Reynolds number $\mathrm{Re_{J,eq}}$ defined by

$$\mathrm{Re_{J,eq}} = \left[\mathrm{Re_J^2} \pm \left(\frac{|\mathrm{Gr_J}| \times \left(\frac{h_{\mathrm{S}}}{d_{\mathrm{ch}}}\right)}{50}\right)\right]^{1/2}. \tag{70}$$

The physical properties ρ and η have to be evaluated at the mean jacket-side liquid temperature ϑ_{J} and the density ρ_{w} has to be evaluated at the mean jacket wall temperature $\vartheta_{\mathrm{J,w}}$. The positive sign in Eq. (70) has to be used, when natural convection assists forced convection and vice versa.

The last step embraces the computation of the Nusselt number $\mathrm{Nu_J}$ from the following equation:

$$\mathrm{Nu_J} = \left(\mathrm{Nu_A^3} + \mathrm{Nu_B^3} + \mathrm{Nu_C^3} + \mathrm{Nu_D^3}\right)^{1/3} \left(\frac{\eta}{\eta_{\mathrm{w}}}\right)^{0.14}, \tag{71}$$

where

$$\mathrm{Nu_J} = \frac{\alpha d_{\mathrm{ch}}}{\lambda}, \tag{72}$$

$$\mathrm{Nu_A^3} = 3.66^3, \tag{73}$$

$$\mathrm{Nu_B^3} = 1.62^3 \mathrm{Pr Re_{J,eq}} \left(\frac{d_{\mathrm{ch}}}{l_{\mathrm{ch}}}\right), \tag{74}$$

$$\mathrm{Nu_C^3} = 0.664^3 \mathrm{Pr}\left(\mathrm{Re_{J,eq}}\left(\frac{d_{\mathrm{ch}}}{l_{\mathrm{ch}}}\right)\right)^{1.5}, \tag{75}$$

$$\mathrm{Nu_D^3} = 0 \text{ for } \mathrm{Re_{J,eq}} < 2300, \tag{76}$$

$$\mathrm{Nu_D^3} = 0.0115^3 \mathrm{Pr Re_{J,eq}^{2.7}} \left(1 - \left(\frac{2300}{\mathrm{Re_{J,eq}}}\right)^{2.5}\right)^3 \times \left(1 + \left(\frac{d_{\mathrm{ch}}}{l_{\mathrm{ch}}}\right)^{2/3}\right)^3 \text{ for } \mathrm{Re_{J,eq}} > 2300. \tag{77}$$

The thermal conductivity λ has to be evaluated at the mean jacket-side liquid temperature ϑ_{J} and the dynamic viscosity η_{w} at the mean jacket wall temperature $\vartheta_{\mathrm{J,w}}$. Details about the basis of the different equations are found in [38]. Equation (71) was examined using a jacketed unbaffled stirred vessel with an internal diameter of 544 mm, a flat bottom, and a variable height. The liquid in the vessel was agitated by means of a paddle. The three different inlet arrangements to the jacket (radial inlet tube, tangential inlet tube, and tangential nozzle) were examined. The tests were carried out with an upward flow for the case in which, the contents of the vessel were cooled. Other geometrical and operating parameters are given below:

$$58 \leq \mathrm{Re_{J,eq}} \leq 1.1 \times 10^4,$$

$$3 \leq \mathrm{Pr} \leq 830,$$

$$1.2 \leq \frac{\eta}{\eta_{\mathrm{w}}} \leq 3.5,$$

$$0.035 \leq \frac{d_{\mathrm{ch}}}{l_{\mathrm{ch}}} \leq 0.054.$$

The own measurements show for some experimental points deviations up to about ±50% between predictions and measurements. The mean relative errors for all measurements amount to 28.6% for radial inlet tubes, 26.4% for tangential inlet tubes, and 27.7% for tangential nozzles and are lower than those obtained from the model of Lehrer (43.7%, 44.0%, and 58.9%, respectively) [38].

Example 5:

It is required to calculate the heat transfer coefficient α on the jacket-side of a stirred vessel. The jacket is equipped with a tangential inlet tube placed at the bottom of the jacket. The contents of the stirred vessel are cooled by means of water

flowing through the annular space of the jacket. The data given below are available:

Outside vessel diameter	$d_{BA} = 0.6\,m$
Width of annular space	$\delta = 0.025\,m$
Height of jacket	$h_S = 0.6\,m$
Inlet diameter of tangential inlet tube	$d_O = 0.025\,m$
Jacket-side mass flow rate	$\dot{M}_J = 2.5\,kg\,s^{-1}$
Inlet water temperature	$\vartheta_{J,i} = 20°C$
Outlet water temperature	$\vartheta_{J,o} = 40°C$
Mean jacket wall temperature	$\vartheta_{J,w} = 80°C$

Physical properties:

At mean water temperature in jacket $\vartheta_J = \frac{20+40}{2} = 30°C$:

Prandtl number	$Pr = 5.42$
Thermal conductivity	$\lambda = 0.615\,W\,m^{-1}\,K^{-1}$
Density	$\rho = 995.7\,kg\,m^{-3}$
Dynamic viscosity	$\eta = 798 \times 10^{-6}\,Pa\,s$

At inlet water temperature $\vartheta_{J,i} = 20°C$:

Density	$\rho = 998.3\,kg\,m^{-3}$

At mean jacket wall temperature $\vartheta_{J,w} = 80°C$:

Density	$\rho_w = 971.8\,kg\,m^{-3}$
Dynamic viscosity	$\eta_w = 355 \times 10^{-6}\,Pa\,s$

Solution:

Method of Lehrer:

$$\dot{V}_J = \frac{\dot{M}_J}{\rho_{(at\,\vartheta_J=30°C)}} = \frac{2.5}{995.7} = 2.51 \times 10^{-3}\,m^3\,s^{-1},$$

Equation (51): $u_S = \frac{\dot{V}_J}{h_S \delta} = \frac{2.51\times10^{-3}}{0.6\times0.025} = 0.167\,m\,s^{-1}$,

Equation (48): $u_O = \frac{\dot{V}_J}{\left(\frac{\pi}{4}\right)d_O^2} = \frac{2.51\times10^{-3}}{\left(\frac{\pi}{4}\right)\times0.025^2} = 5.1\,m\,s^{-1}$,

Equation (52): $u_A = 0\ m\,s^{-1}$,

Equation (47): $u_h = (u_S u_O)^{1/2} + u_A = (0.167 \times 5.1)^{1/2} + 0 = 0.923\,m\,s^{-1}$,

Equation (46): $d_g = \left(\frac{8}{3}\right)^{1/2}\delta = \left(\frac{8}{3}\right)^{1/2}\times0.025 = 0.0408\ m$,

$$Re_S = \frac{u_h d_g \rho}{\eta} = \frac{0.923 \times 0.0408 \times 995.7}{798 \times 10^{-6}} = 4.7 \times 10^4,$$

Equation (45):

$$Nu_{S,L} = \left[\frac{0.03 Re_S^{0.75} Pr}{1 + \frac{1.74(Pr-1)}{Re_S^{0.125}}}\right]\left(\frac{\eta}{\eta_w}\right)^{0.14} = \left[\frac{0.03 \times (4.7\times10^4)^{0.75} \times 5.42}{1 + \frac{1.74(5.42-1)}{(4.7\times10^4)^{0.125}}}\right]\left(\frac{798\times10^{-6}}{355\times10^{-6}}\right)^{0.14} = 193.5.$$

The heat transfer coefficient is given by

$$\alpha = \frac{Nu_{S,L}\lambda}{d_g} = \frac{193.5 \times 0.615}{0.0408} = 2917\ W\,m^{-2}K^{-1}.$$

Method of Stein and Schmidt:

Equation (53):

$$l_{ch} = \left(\left(\frac{\pi}{2}\right)^2 d_{BA}^2 + h_S^2\right)^{0.5} = \left(\left(\frac{\pi}{2}\right)^2 \times 0.6^2 + 0.6^2\right)^{0.5} = 1.12\,m,$$

Equation (54): $d_{ch} = 2\delta = 2 \times 0.025 = 0.05\,m$,

The iterative solution of Eqs. (59–63) gives with the help of Eqs. (67) and (68) the following numerical value for the velocity u_{ch}:

$$u_{ch} = 0.855\,m\,s^{-1}.$$

Check:

Equation (67): $Re_J = \frac{u_{ch} d_{ch} \rho}{\eta} = \frac{0.855\times0.05\times995.7}{798\times10^{-6}} = 53341$.

Equation (68): $\xi_J = \frac{0.3164}{Re_J^{0.25}} = \frac{0.3164}{53341^{0.25}} = 0.02081$ (since $3 \times 10^3 \le Re_J \le 10^5$; assumption: smooth tube),

$u_O = 5.1\,m\,s^{-1}$ (s. solution: method of Lehrer),

Equation (62): $K_3 = \left(\frac{u_O}{4}\right) - \left(\frac{d_O^2 u_O}{4\xi_J d_{BA} h_S}\right) = \left(\frac{5.1}{4}\right) - \left(\frac{0.025^2 \times 5.1}{4 \times 0.02081 \times 0.6 \times 0.6}\right) = 1.169\,m\,s^{-1}$,

Equation (63): $K_4 = \frac{d_O^2 u_O^2}{2\xi_J d_{BA} h_S} = \frac{0.025^2 \times 5.1^2}{2 \times 0.02081 \times 0.6 \times 0.6} = 1.085\,m^2\,s^{-2}$,

Equation (61): $u_x(0) = K_3 + \left(K_3^2 + K_4\right)^{0.5} = 1.169 + (1.169^2 + 1.085)^{0.5} = 2.735\,m\,s^{-1}$,

Equation (60):

$$u_x = u_O\left(\frac{\ln\left[1 + \left(\frac{\xi_J d_{BA} h_S}{d_O^2}\right)\left(\frac{u_x(0)}{u_O}\right)\right]}{\left(\frac{\xi_J d_{BA} h_S}{d_O^2}\right)}\right) = 5.1\left(\frac{\ln\left[1 + \left(\frac{0.02081\times0.6\times0.6}{0.025^2}\right)\left(\frac{2.735}{5.1}\right)\right]}{\left(\frac{0.02081\times0.6\times0.6}{0.025^2}\right)}\right) = 0.853\,m\,s^{-1},$$

Equation (64): $u_z = \frac{\dot{V}_J}{\pi d_{BA}\delta} = \frac{2.51\times10^{-3}}{\pi\times0.6\times0.025} = 0.0532\,m\,s^{-1}$,

Equation (59): $u_{ch} = \left(u_x^2 + u_z^2\right)^{0.5} = (0.853^2 + 0.0532^2)^{0.5} = 0.855\,m\,s^{-1}$.

Thus, the numerical value $u_{ch} = 0.855\,m\,s^{-1}$ fulfills Eqs. (59–63).

Equation (69):

$$Gr_J = \frac{g\rho(\rho - \rho_w)d_{ch}^3}{\eta^2} = \frac{9.81 \times 995.7 \times (995.7 - 971.8) \times 0.05^3}{(798\times10^{-6})^2} = 4.58 \times 10^7,$$

Equation (70):

$$Re_{J,eq} = \left[Re_J^2 + \left(\frac{|Gr_J| \times \left(\frac{h_S}{d_{ch}}\right)}{50}\right)\right]^{1/2} = \left[(53341)^2 + \left(\frac{(4.58\times10^7)\times\left(\frac{0.6}{0.05}\right)}{50}\right)\right]^{1/2} = 53444.$$

The positive sign in Eq. (70) is considered, since natural convection assists forced convection. Comparing the numerical values of Re_J and $Re_{J,eq}$ indicates that natural convection in the considered case is insignificant.

Equation (73): $Nu_A^3 = 3.66^3 = 49.03$,

Equation (74): $Nu_B^3 = 1.62^3 PrRe_{J,eq}\left(\frac{d_{ch}}{l_{ch}}\right) = 1.62^3 \times 5.42 \times 53444 \times \left(\frac{0.05}{1.12}\right) = 5.5 \times 10^4$,

Equation (75): $Nu_C^3 = 0.664^3 Pr\left(Re_{J,eq}\left(\frac{d_{ch}}{l_{ch}}\right)\right)^{1.5} = 0.664^3 \times 5.42 \times \left(53444 \times \left(\frac{0.05}{1.12}\right)\right)^{1.5} = 1.85 \times 10^5$,

Equation (77):

$$Nu_D^3 = 0.0115^3 PrRe_{J,eq}^{2.7}\left(1 - \left(\frac{2300}{Re_{J,eq}}\right)^{2.5}\right)^3\left(1 + \left(\frac{d_{ch}}{l_{ch}}\right)^{2/3}\right)^3 = 0.0115^3 \times 5.42 \times 53444^{2.7} \times \left(1 - \left(\frac{2300}{53444}\right)^{2.5}\right)^3\left(1 + \left(\frac{0.05}{1.12}\right)^{2/3}\right)^3 = 6.84 \times 10^7.$$

Equation (71): $$\mathrm{Nu_J} = \left(\mathrm{Nu_A^3} + \mathrm{Nu_B^3} + \mathrm{Nu_C^3} + \mathrm{Nu_D^3}\right)^{1/3} \left(\frac{\eta}{\eta_w}\right)^{0.14}$$
$$= \left(49.03 + \left(5.5 \times 10^4\right) + \left(1.85 \times 10^5\right) + \left(6.84 \times 10^7\right)\right)^{1/3} \left(\frac{798 \times 10^{-6}}{355 \times 10^{-6}}\right)^{0.14}$$
$$= 458.6\,.$$

The heat transfer coefficient α is given by

$$\alpha = \frac{\mathrm{Nu_J}\lambda}{d_{ch}} = \frac{458.6 \times 0.615}{0.05} = 5641\,\mathrm{W\,m^{-2}K^{-1}}.$$

The example shows that high uncertainty exists in evaluating the jacket-side heat transfer coefficient. This might lead in certain cases to underestimating the heat transfer surface required for a particular heat transfer rate during dimensioning a newly designed stirred vessel for a particular process. It is also not clear a priori, which method predicts the more conservative heat transfer coefficient under all possible design conditions. In many cases this can be compensated during operation by changing the flow rate and/or the temperature of the jacket-side liquid. If this facility is not available, it might be advantageous – particularly in cases, in which underestimating the heat transfer rate has an adverse effect on the process – to calculate the heat transfer coefficient from both methods and use in dimensioning the stirred vessel the more conservative value. However, in many cases the heat transfer coefficient on the inner surface of the stirred vessel, especially with high viscous liquids, is much smaller than the jacket-side heat transfer coefficient; in such cases the high uncertainty in evaluating the jacket-side heat transfer coefficient is largely suppressed in calculating the overall heat transfer coefficient.

2.2.2 Heat Transfer from the Inside Surface of a Helical Coil

Helical Coil of Circular Tubes Inside the Stirred Vessel

Secondary effects in the flow through a helical coil of circular tubes are responsible for a better heat transfer than that in straight tubes. Equations for the determination of the heat transfer coefficient in such cases are presented in Chap. G3.

Helical Coil of Semicircular Tubes Welded at the Outside Surface of the Stirred Vessel

According to Stein and Schmidt [37], the equations given in Chap. G3 for heat transfer from a helical coil of circular tubes can be used also for a helical coil of semicircular tubes welded at the outer surface of a stirred vessel. The inside tube diameter in the Reynolds number and in the Nusselt number in the equations in Chap. G3 should be replaced now by the thermal diameter $d_{th,H}$ of the semicircular tubes given by $d_{th,H} = (\pi/2)d_i$ with d_i the internal diameter of the semicircular tubes. The critical Reynolds number for a helical coil of semicircular tubes can be calculated from the equation in Chap. G3 for a helical coil of circular tubes by replacing the curvature ratio in that equation by the ratio $(d_i/(2d_{BA}))$.

2.3 Methods of Heating or Cooling of a Stirred Vessel

In batch operation, the temperature of the contents of the stirred vessel, at least during the early period of the process, is time dependent. The change of temperature of the vessel contents with time depends on the method used to heat (or cool) the contents of the stirred vessel. Usually, one of the following methods is used:

1. Heat added at a constant heat flow rate $\dot{Q}$ (e.g., electrical heating); heat removal at a constant heat flow rate is difficult to achieve technically.
2. Heat added or removed at a spatially constant and time-independent temperature ϑ_J of the heating or cooling medium (e.g., condensation of a saturated vapor or boiling of a saturated liquid in the jacket).
3. Heat added or removed by means of a thermal fluid (mostly liquid) flowing in the jacket or through the coil. The temperature of the thermal fluid changes from the constant inlet temperature $\vartheta_{J,i}$ to the time-dependent outlet temperature $\vartheta_{J,o}(t)$.

Equations (78)–(80), given hereafter to calculate the change of temperature of the vessel contents with time are valid under the following assumptions:

- Heat capacity of the stirred vessel is small compared with heat capacity of the vessel contents.
- Heat losses to or heat gains from the surroundings are negligible.
- Heat added or removed by means of a continuous gas flow during aerating the contents of the stirred vessel in a two-phase system "gas–liquid" or a multiphase system "gas–liquid–solid" is negligible.
- Physical properties (specific heats) of the jacket-side fluid and the vessel contents are independent of temperature.
- Overall heat transfer coefficient is independent of temperature.
- Mechanical power required by an impeller (dissipated in the vessel contents as heat) is negligible.
- Heat added to the vessel contents due to a chemical reaction is negligible.

For constant heat flow rate $\dot{Q}$:

$$\vartheta(t) = \vartheta_0 + \frac{\dot{Q}}{Mc}t. \tag{78}$$

For spatially constant time-independent temperature ϑ_J of the thermal fluid:

$$\frac{\vartheta_J - \vartheta(t)}{\vartheta_J - \vartheta_0} = \exp\left(-\frac{UA}{Mc}t\right). \tag{79}$$

For constant inlet temperature $\vartheta_{J,i}$ and time-dependent exit temperature $\vartheta_{J,o(t)}$ of the thermal fluid:

$$\frac{\vartheta_{J,i} - \vartheta(t)}{\vartheta_{J,i} - \vartheta_0} = \exp\left[-\frac{\dot{M}_J c_J}{Mc}\left\{1 - \exp\left(-\frac{UA}{\dot{M}_J c_J}\right)\right\}t\right]. \tag{80}$$

Wolf [39] included the mechanical power P_{Ad} required by the impeller and any additional periphery equipment (e.g., pumps

and compressors, which consume mechanical power and lead to heat dissipation in the contents of the vessel) and obtained the following equations:
For constant heat flow rate $\dot{Q}$:

$$\vartheta(t) = \vartheta_0 + \frac{\dot{Q} + P_{Ad}}{Mc}\, t. \tag{81}$$

For spatially constant time-independent temperature ϑ_J of the thermal fluid:

$$\frac{\vartheta_J + \left(\frac{P_{Ad}}{UA}\right) - \vartheta(t)}{\vartheta_J + \left(\frac{P_{Ad}}{UA}\right) - \vartheta_0} = \exp\left(-\frac{UA}{Mc}t\right). \tag{82}$$

For constant inlet temperature $\vartheta_{J,i}$ and time-dependent exit temperature $\vartheta_{J,o}(t)$ of the thermal fluid:

$$\frac{\vartheta_{J,i} + \left(\frac{K_1}{K_2}\right) - \vartheta(t)}{\vartheta_{J,i} + \left(\frac{K_1}{K_2}\right) - \vartheta_0} = \exp\left[-\frac{\dot{M}_J c_J}{Mc}\left\{1 - \exp\left(-\frac{UA}{\dot{M}_J c_J}\right)\right\}t\right], \tag{83}$$

where

$$K_1 = \frac{P_{Ad}}{Mc}, \tag{84}$$

$$K_2 = \frac{\dot{M}_J c_J}{Mc}\left\{1 - \exp\left(-\frac{UA}{\dot{M}_J c_J}\right)\right\}. \tag{85}$$

Equations (78)–(83) give the temperature $\vartheta(t)$ of the vessel contents as a function of the elapsed time t. Rearranging the equations gives the required time t to reach a certain temperature $\vartheta(t)$.

The specific heat capacity c in Eqs. (78–85) for the contents of the stirred vessel (single-phase liquid or quasi-homogeneous-phase in two-phase or multiphase systems) and the specific heat capacity c_J for the jacket (or coil) fluid are to be evaluated at the mean temperatures; bearing in mind that the temperatures are time- and space-dependent. The thermal resistance of the vessel wall and any possible fouling have to be considered in evaluating the overall heat transfer coefficient. In case of enameled stirred vessels, the thermal resistance of the enamel may be larger than that of the thermal boundary layers of the fluids on both sides of the vessel wall, as well as that of the vessel wall itself. If the overall heat transfer coefficient U changes with time due to change in the physical properties, the time-dependent overall heat transfer coefficient $U(t)$ has to be replaced by a mean value U. Another procedure, which might be more appropriate (but time-consuming) in case of a significant change in $U(t)$ with time (due to a possible significant change in the viscosity of the vessel contents with time) is to apply the given equations for small time intervals (or small temperature intervals) with a mean overall heat transfer coefficient in each interval.

2.4 Remarks on Maximal Heat Removal

Increasing the speed of rotation of the impeller during cooling the contents of a stirred vessel leads to an increase in the vessel-side heat transfer coefficient and hence to an increase in the heat removed by the cooling medium in a jacket or in a coil; at the same time, the power consumption of the impeller increases with the increase in the impeller speed. During exothermal reactions, not only the heat of reaction, but also the mechanical energy dissipated as heat should be removed from the vessel contents. Since the power consumption of the impeller increases much faster with the impeller speed than the overall heat transfer coefficient, the net heat removal – i.e., heat of reaction less heat dissipated by the impeller – from the vessel contents with increasing impeller speed under otherwise same operating conditions passes through a maximum. Increasing the impeller speed beyond the optimal speed based on maximal net heat removal during dimensioning a newly designed stirred vessel leads to an increase in both investment and operating costs. Thus, the optimal impeller speed based on economical considerations is either less than or equal to the optimal impeller speed based on maximal net heat removal. Methods as well as examples for the determination of the optimal impeller speed for maximal net heat removal can be presented [40, 41].

3 Power Consumption

In this section, diagrams and equations are presented for the determination of the power consumption of different impellers in single-phase and multiphase systems; they are valid for stirred vessels without internal coils. The remarks made in Sect. 2 about the validity ranges of the empirical correlations apply also in this section. The predicted power consumption of the impellers does not include the additional power required to cover the demand of other components of the stirred vessel (e.g., gearbox and shaft bearings); the power consumption of these components has to be added to the power consumption of the impeller in determining the total power consumption of the system.

3.1 Single-Phase Systems

3.1.1 Newtonian Liquids

The power consumption of an impeller to agitate a single-phase Newtonian liquid in a vessel can be determined from dimensionless equations of the following form [42]:

$$\mathrm{Ne} = f(\mathrm{Re}, \mathrm{Fr}, \pi_1, \pi_2, \ldots), \tag{86}$$

with

$$\text{Newton number Ne} = \frac{P}{\rho n^3 d_R^5},$$

$$\text{Reynolds number Re} = \frac{d_R^2 n \rho}{\eta},$$

$$\text{Froude number Fr} = \frac{n^2 d_R}{g}.$$

π_1, π_2,...are geometrical parameters. The Froude number takes into account the fluid dynamic effects at the free surface of the liquid such as vortex formation. If vortex formation is suppressed (e.g., through the use of baffles), the Froude number

in Eq. (86) can be ignored. Thus, in the case of suppressing vortex formation the Newton number for systems having same geometrical ratios but different sizes may be determined from the simpler equation

$$\mathrm{Ne} = f(\mathrm{Re}). \tag{87}$$

According to measurements made by a number of investigators, the Newton number in the laminar range can be expressed by

$$\mathrm{Ne} = \frac{C_{\mathrm{N,lam}}}{\mathrm{Re}} \tag{88}$$

and in the turbulent range by

$$\mathrm{Ne} = \frac{C_{\mathrm{N,turb}}}{\mathrm{Re}^{m}} \; (m << 1). \tag{89}$$

$C_{\mathrm{N,lam}}$ and $C_{\mathrm{N,turb}}$ are constants. If the stirred vessel is equipped with baffles, the Newton number in the turbulent range is nearly constant at high Reynolds numbers. The range of the Reynolds number, in which Eqs. (88) and (89) are valid, depends on the type of the impeller. In a number of publications, the dependence of the Newton number on the Reynolds number in a wide range covering laminar, transition, and turbulent ranges is presented graphically. A comprehensive review can be found in [43, 44].

Flat-blade turbine or pitched-blade impeller

Figure 13 gives the dependence of the Newton number on the Reynolds number and the Froude number for a flat-blade turbine (see Fig. 2a) from measurements made by Rushton et al. [45, 46] on stirred baffled and unbaffled vessels with a flat bottom and an inner vessel diameter of 457 mm. The equipment used has the following standard geometrical parameters:

$$\frac{d_{\mathrm{R}}}{d_{\mathrm{B}}} = \frac{1}{3},$$
$$\frac{h_{\mathrm{R}}}{d_{\mathrm{B}}} = \frac{1}{3},$$
$$\frac{h_{\mathrm{L}}}{d_{\mathrm{B}}} = 1,$$
$$Z = 6$$
$$\frac{h}{d_{\mathrm{R}}} = \frac{1}{5},$$
$$\frac{b_{\mathrm{R}}}{d_{\mathrm{R}}} = \frac{1}{4},$$
$$n_{\mathrm{S}} = 4 \text{ (for baffled vessel)}.$$

The exponent r of the Froude number in Fig. 13 is also given [45, 46]:
For unbaffled vessels:

$$r = 0 \quad \text{for Re} \leq 300, \tag{90}$$
$$r = \frac{a - \log \mathrm{Re}}{b} \quad \text{for Re} > 300. \tag{91}$$

For baffled vessels:

$$r = 0 \text{ (Newton number independent of the Froude number)}. \tag{92}$$

According to Rushton et al. [45, 46], the constants a and b in Eq. (91) have the following values in the examined ranges:

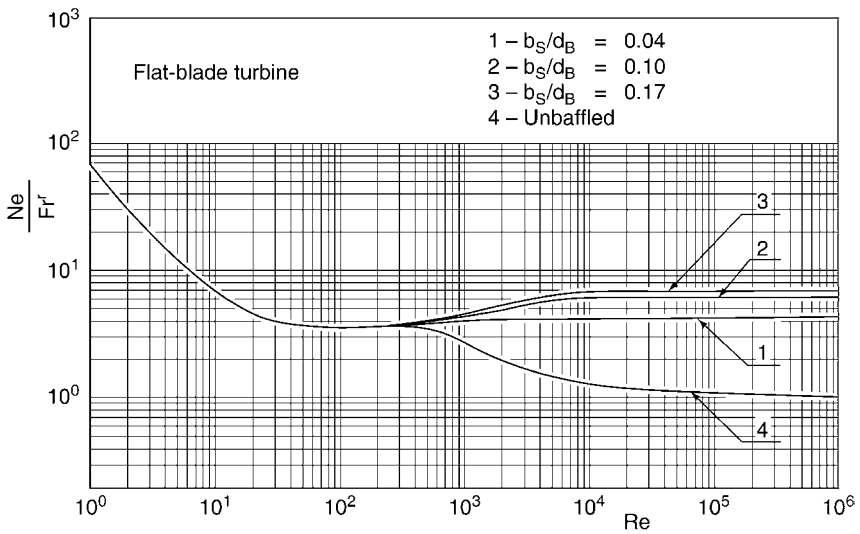
$$a = 1.0, \tag{93}$$
$$b = 40.0. \tag{94}$$

The baffle width b_s was changed in three steps as follows:

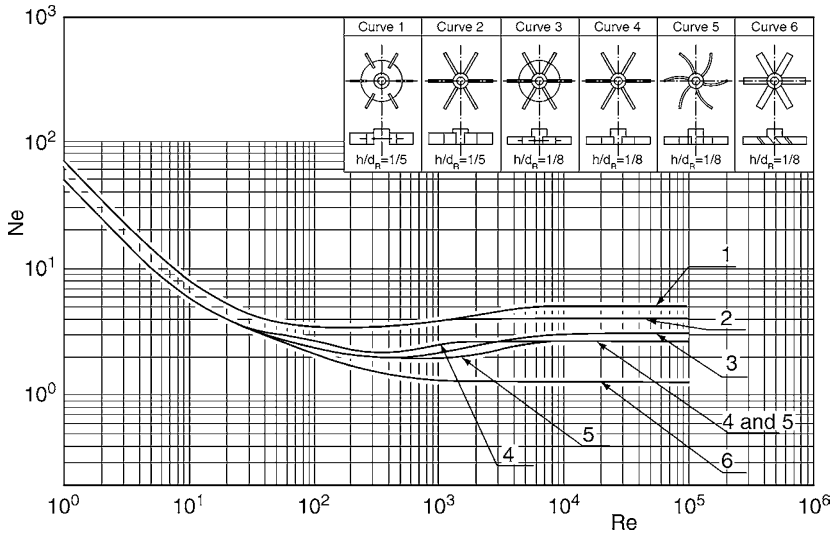
$$\frac{b_{\mathrm{S}}}{d_{\mathrm{B}}} = 0.04, 0.10, 0.17.$$

Figure 13 shows that the baffles have no influence on the Newton number in the laminar range (Re $\leq$ 10), but they lead to a higher Newton number in the transient and turbulent ranges; the increase in the Newton number is larger when the width of the baffles is increased. The Newton number for baffled vessels has a minimum at a Reynolds number of about 200 and is independent of the Reynolds number at very high Reynolds numbers (Re $\geq 10^4$).

Figure 14 shows the dependence of the Newton number on the Reynolds number from experimental measurements made



N3. Fig. 13. Dependence of the Newton number on the Reynolds number and the Froude number for a flat-blade turbine according to Rushton et al. [45, 46]. (With permission of the American Institute of Chemical Engineers.)



N3. Fig. 14. Dependence of the Newton number on the Reynolds number for different impellers according to Bates et al. [47]. (With permission of the Ind Chem Process Des Dev – American Chemical Society.)

by Bates et al. [47] for six different impellers. The examined stirred vessels shown in Fig. 14 had internal vessel diameters between 152 and 610 mm and were equipped with four baffles with a ratio $(b_S/d_B) = 1/12$; the other geometrical parameters (d_R/d_B), (h_R/d_B), and (h_L/d_B) were similar to the standard parameters in the investigation of Rushton et al. [45, 46]. Curves 1 and 3 are for two different flat-blade turbines, curves 2 and 4 for two different flat-blade impellers with the blades having full length originating at the hub, curve 5 for an impeller with curved blades, and curve 6 for a pitched-blade impeller. The impellers shown in curves 1 and 3 or 2 and 4 differ from one another in the ratio (h/d_R). According to Bates et al. [47], the experimentally determined Newton number in their investigation for the standard flat-blade turbine (curve 1) was in the turbulent range less than that determined by Rushton et al. [45, 46] under similar operating conditions. At a Reynolds number $Re = 10^5$, Bates et al. measured with two stirred vessels equipped with baffles having slightly different baffle width ratios ($b_S/d_B = 1/12$ and $1/10$) Newton numbers of 4.8 and 5.0, respectively; Rushton et al. measured for the same Reynolds number and a baffle width ratio $b_S/d_B = 1/10$ a Newton number of 6.3.

Hirschberg [43] recommends the following equations to predict approximately the Newton number for standard impellers:

For an unbaffled stirred vessel:

Flat-blade turbine or pitched-blade impeller:

$$Ne = \frac{50}{Re} \text{ for } 1 < Re < 3.1, \tag{95}$$

$$Ne = \frac{4}{(\log Re)^2} \text{ for } 3.1 < Re < 553, \tag{96}$$

$$Ne = \frac{1}{Re^{0.1}} \text{ for } 553 < Re < 10^5. \tag{97}$$

For a baffled stirred vessel:

Flat-blade turbine:

$$Ne = \frac{80}{Re} \text{ for } 1 < Re < 16, \tag{98}$$

$$Ne = 5 \text{ for } 16 < Re < 10^5. \tag{99}$$

Pitched-blade impeller:

$$Ne = \frac{80}{Re} \text{ for } 1 < Re < 40, \tag{100}$$

$$Ne = 2 \text{ for } 40 < Re < 10^5. \tag{101}$$

The higher power consumption of a flat-blade turbine at low Reynolds numbers in the laminar range $(1 \le Re \le 3.1)$ as a result of using baffles (compare Eqs. (95) and (98)) was not noticed by Rushton et al. [45, 46] (see Fig. 13).

Propeller

The power consumption for a propeller (see Fig. 2c) may be predicted according to Rushton et al. [45, 46] for different geometrical parameters from Fig. 15. The measurements were made with stirred vessels (flat bottom) having different vessel diameters varying from 330 to 1372 mm. Curves 1–5 in Fig. 15 are for unbaffled stirred vessels and curve 6 is for a baffled vessel with four baffles and a geometrical ratio $b_S/d_B = 0.1$. The geometrical parameters of the examined propellers are given in Fig. 15.

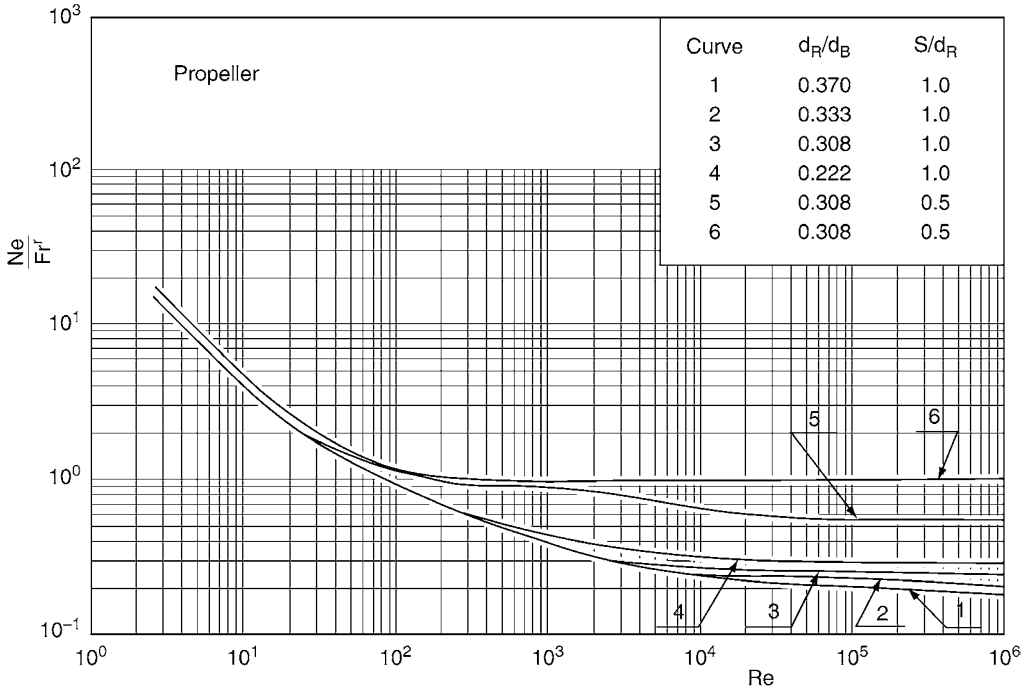
Equations (90)–(92) giving the exponent r of the Froude number are also valid for a propeller. The constants a and b in Eq. (91), which depend on the geometrical ratio d_R/d_B, are given in Table 3.

Hirschberg [43] recommends the following equations for an approximate evaluation of the Newton number for propellers with standard geometries:

For an unbaffled stirred vessel:

$$Ne = \frac{50}{Re} \text{ for } 1 < Re < 3.1, \tag{102}$$

$$Ne = \frac{4}{(\log Re)^2} \text{ for } 3.1 < Re < 2 \times 10^4. \tag{103}$$



N3. Fig. 15. Dependence of the Newton number on the Reynolds number and the Froude number for a Propeller according to Rushton et al. [45, 46]. (With permission of the American Institute of Chemical Engineers.)

N3. Table 3. Values of the constants a and b in Eq. (91) for propellers with different ratios d_R/d_B

d_R/d_B	a	b
0.471	2.6	18.0
0.370	2.3	18.0
0.333	2.1	18.0
0.308	1.7	18.0
0.222	0	18.0

For a baffled stirred vessel:

$$\mathrm{Ne} = \frac{50}{\mathrm{Re}} \text{ for } 1 < \mathrm{Re} < 3.1, \tag{104}$$

$$\mathrm{Ne} = \frac{4}{(\log \mathrm{Re})^2} \text{ for } 3.1 < \mathrm{Re} < 635. \tag{105}$$

$$\mathrm{Ne} = 0.8\mathrm{Re}^{-0.07} \text{ for } 635 < \mathrm{Re} < 2 \times 10^5. \tag{106}$$

Pfaudler *impeller*

According to Post [8], the Newton number for a Pfaudler impeller (see Fig. 5) is given by:
For an unbaffled stirred vessel:

$$\mathrm{Ne} \approx 0.32 \text{ for } 6 \times 10^3 < \mathrm{Re} < 5 \times 10^4. \tag{107}$$

For a baffled stirred vessel with four standard baffles:

$$\mathrm{Ne} \approx 1.2 \text{ for } 2 \times 10^4 < \mathrm{Re} < 5 \times 10^4. \tag{108}$$

Validity ranges:

$$\frac{d_R}{d_B} = 0.513,$$
$$\frac{h_L}{d_B} = 1.0.$$

Paddle

Figure 16 shows the dependence of the Newton number on the Reynolds number for a paddle (see Fig. 2d) according to measurements carried out by Zlokarnik [48] in an unbaffled stirred vessel with a flat bottom and internal diameters of 200, 400, and 600 mm.
Validity ranges:

$$\frac{d_R}{d_B} = 0.5,$$
$$\frac{h_L}{d_B} = 1,$$
$$\frac{h}{d_R} = 1,$$
$$\frac{h_{RK}}{d_R} = 0.4.$$

Hirschberg [43] recommends for an approximate evaluation of the Newton number for a paddle ($h/d_R < 0.25$) the following equations:
For an unbaffled stirred vessel:

$$\mathrm{Ne} = \frac{50}{\mathrm{Re}} \text{ for } 1 < \mathrm{Re} < 3.1, \tag{109}$$

$$\mathrm{Ne} = \frac{4}{(\log \mathrm{Re})^2} \text{ for } 3.1 < \mathrm{Re} < 553, \tag{110}$$

$$\mathrm{Ne} = \frac{1}{\mathrm{Re}^{0.1}} \quad \text{for } 553 < \mathrm{Re} < 10^5. \tag{111}$$

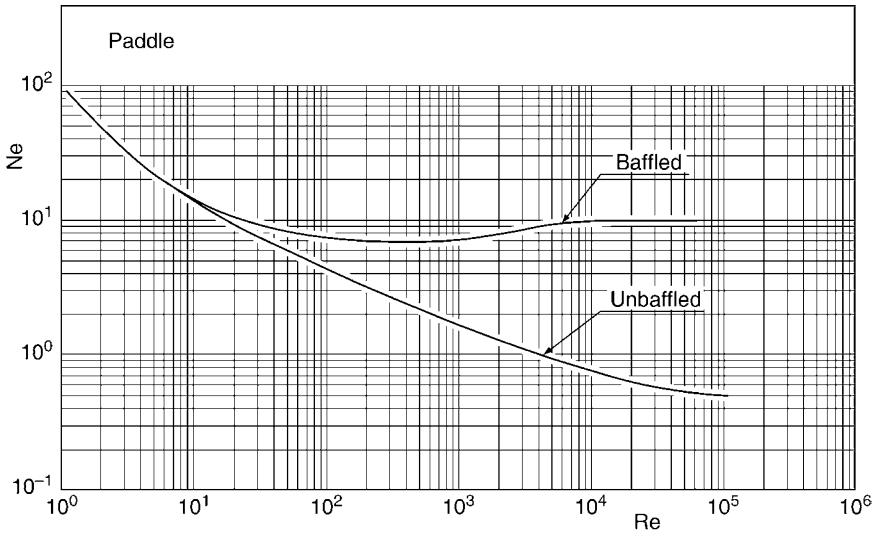
For a baffled stirred vessel:

$$\mathrm{Ne} = \frac{80}{\mathrm{Re}} \quad \text{for } 1 < \mathrm{Re} < 24, \tag{112}$$

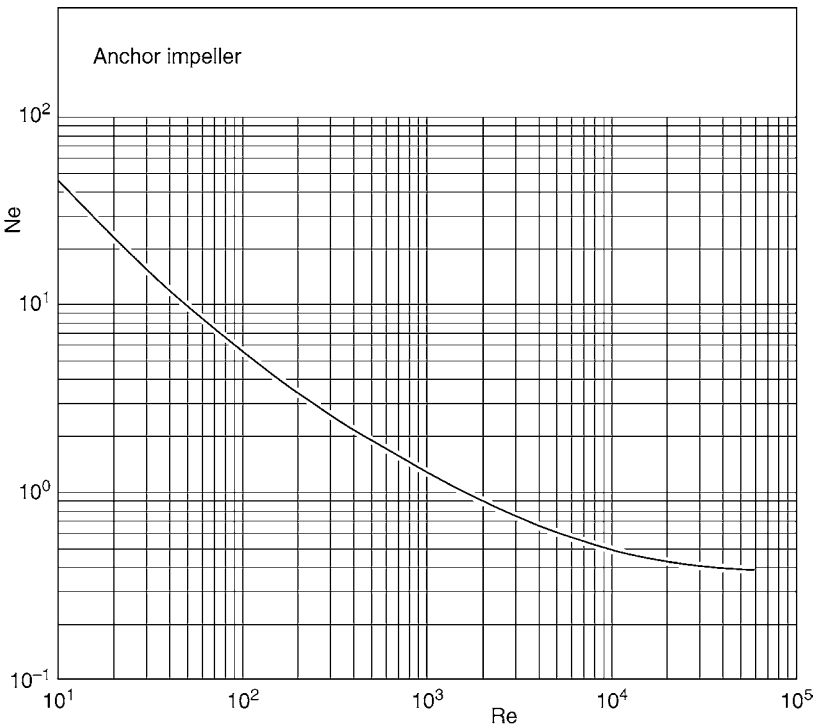
$$\mathrm{Ne} = \frac{10}{3} \quad \text{for } 24 < \mathrm{Re} < 10^5 \text{ and } \frac{d_R}{d_B} = \frac{1}{3}. \tag{113}$$

Anchor Impeller

The dependence of the Newton number on the Reynolds number for an anchor impeller (see Fig. 2e) according to measurements made by Zlokarnik [48] is shown in Fig. 17; the examined stirred vessels with flat bottom had internal diameters of 190 and 290 mm.



N3. Fig. 16. Dependence of the Newton number on the Reynolds number for a paddle according to Zlokarnik [48] (With permission of "VCH-Verlag.")



N3. Fig. 17. Dependence of the Newton number on the Reynolds number for an anchor impeller according to Zlokarnik [48]. (With permission of "VCH-Verlag.")

Validity ranges:

$$\frac{h}{d_B} = 1.0,$$
$$\frac{b_{SR}}{d_R} = 0.1,$$
$$\frac{d_B}{d_R} = 1.02,$$
$$\frac{h_{RK}}{d_R} = 0.01,$$
$$\frac{h_L}{d_B} = 1.0.$$

The examined anchor impellers had two or four arms; the measurements show that the Newton number is independent of the number of arms.

Uhl and Voznik [49] examined the influence of the clearance between the anchor impeller and the inside surface of the vessel on the power consumption of an anchor impeller. The experimental measurements were presented graphically. According to their measurements, the power consumption of the impeller increases with decreasing clearance. However, the influence of the clearance on the Newton number diminishes at high Reynolds numbers ($Re > 10^3$); this is attributed to the decreasing influence of viscosity with increasing Reynolds number.

For an approximate determination of the Newton number for anchor impellers, Hirshberg [43] recommends the following equations:

For an unbaffled stirred vessel:

$$Ne = \frac{180}{Re} \quad \text{for } 1 < Re < 167, \tag{114}$$

$$Ne = \frac{3}{Re^{0.2}} \quad \text{for } 167 < Re < 5 \times 10^4. \tag{115}$$

For a baffled stirred vessel:

$$Ne = \frac{180}{Re} \quad \text{for } 1 < Re < 30, \tag{116}$$

$$Ne = 6 \text{ for } 30 < Re < 10^5. \tag{117}$$

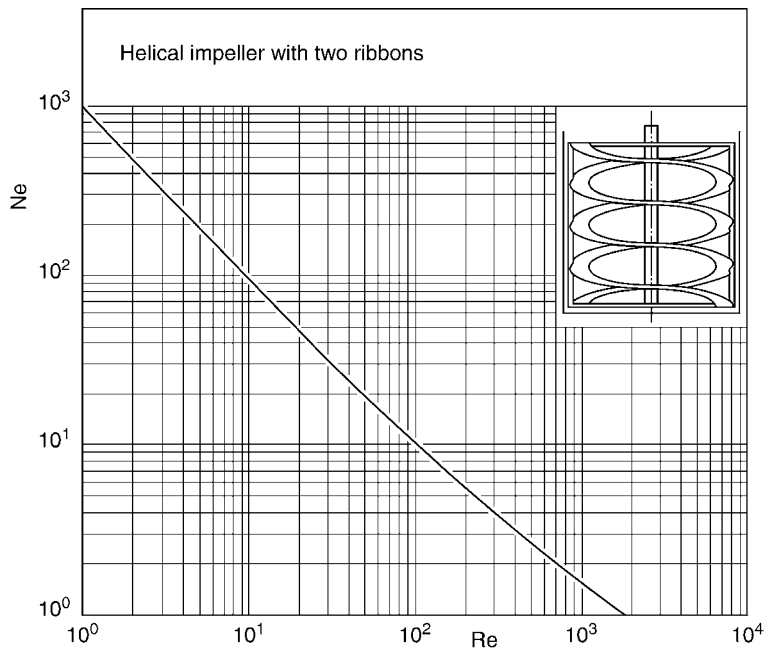
Helical impeller

Figure 18 shows the dependence of the Newton number on the Reynolds number based on measurements carried out by Zlokanik [48] with helical impellers having two ribbons and a pitch ratio $(S/d_R) = 0.5$. Other geometrical parameters are

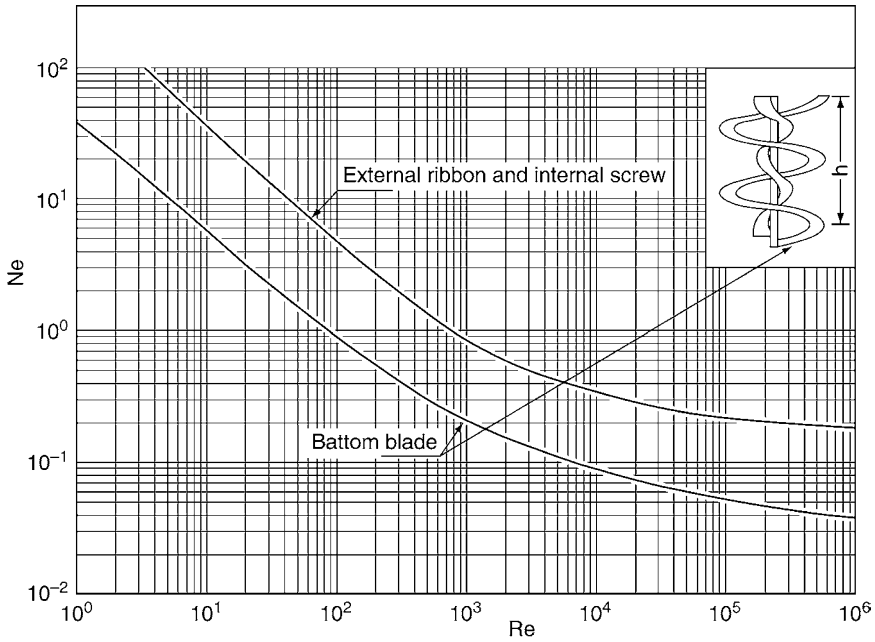
$$\frac{h_L}{d_B} = 1.0,$$
$$\frac{h}{d_B} = 1.0$$
$$\frac{d_B}{d_R} = 1.02,$$
$$\frac{h_{RK}}{d_R} = 0.01,$$
$$\frac{b_{WR}}{d_R} = 0.1.$$

Additional measurements presented in [48] with geometrically different helical impellers having one or two ribbons and pitch ratios $(S/d_R) = 0.5$ or 1.0 show that the influence of the number of the ribbons and the pitch ratio can be accounted for by means of the geometrical ratio (F_W/d_R^2) with F_W the area of the helical ribbons. Accordingly, the Newton number for the examined helical impellers (different number of ribbons and different pitch ratios) can be predicted from

$$Ne = 10^3 Re^{-1} \left(\frac{Fw}{d_R^2}\right)^{0.187}. \tag{118}$$



N3. Fig. 18. Dependence of the Newton number on the Reynolds number for a helical impeller with two ribbons and a pitch ratio $(S/d_R) = 0.5$ according to Zlokarnik [48] (With permission of "VCH-Verlag.")



N3. Fig. 19. Dependence of the Newton number on the Reynolds number for a helical impeller equipped with an external helical ribbon and an internal screw as well as a bottom blade according to Oldshue [50]. (With permission of "McGraw-Hill Publications Co.")

Oldshue [50] presents Fig. 19 for the evaluation of the Newton number for a stirred vessel equipped with a helical impeller especially designed for very viscous materials. The impeller is constructed with an outer helical ribbon and an inner screw fixed to the shaft of the impeller. The inner screw pumps the viscous material downwards and the outer helical ribbon pumps it upwards. Figure 19 shows also the additional power consumption, when the stirred vessel is provided with a bottom blade.

Validity ranges:

$$\frac{d_{R,S}}{d_{R,W}} = \frac{1}{3},$$

$$\frac{h}{d_{R,W}} = 1.0$$

$$\frac{s_B}{d_{R,W}} = 0.0375,$$

$$\frac{b_{WR}}{d_{R,W}} = \frac{1}{6}.$$

A smaller ratio $(s_B/d_{R,W})$ or a higher ratio $(h/d_{R,W})$ leads to higher energy consumption [50]. According to Oldshue, this impeller type has been installed with diameters in the range of 0.5–3 m with rotational speed in the range of 5.5–45 min^{-1}.

Stein [13] examined also a helical impeller constructed from an outer helical ribbon, an inner screw, and a bottom blade (see Fig. 7) and recommends the following equation:

$$Ne = \left[\left(\frac{C_{S,lam}}{Re}\right)^2 + \left(\frac{C_{S,turb}}{(10+Re)^{1/4}}\right)^2\right]^{1/2}. \quad (119)$$

Equation (119) is also valid for the other impellers with special forms shown in Fig. 7 (b: Paravisc impeller "Ekato," c: Alfa impeller "Stelzer," and d: MUT impeller "Dieder;" all impellers are equipped with bottom blades). The numerical values for the constants $C_{S,lam}$ and $C_{S,turb}$ are given in Table 4.

N3. Table 4. Values of the constants $C_{S,lam}$ and $C_{S,turb}$ in Eq. (119) for the different impellers

	Helical impeller with an outer helical ribbon and an inner screw	Paravisc-impeller "Exato"	Alfa-impeller "Stelzer"	MUT impeller "Dieder"
$C_{s,lam}$	315	290	190	430
$C_{s,turb}$	4.3	4.3	4.3	4.3

The constant $C_{S,lam}$ can be calculated in dependence on the geometrical parameters from an empirical correlation given by Shamlou and Edwards [51] (As quoted in [13]), or

$$C_{S,lam} = 150\left(\frac{h_{WR}}{d_R}\right) n_{WR}^{0.5} \left(\frac{b_{WR}}{d_R}\right)^{0.335} \left[0.5\left\{\left(\frac{d_B}{d_R}\right) - 1\right\}\right]^{-0.335} \left(\frac{S}{d_R}\right)^{-0.5}. \quad (120)$$

Scraped-surface heat exchanger

Skelland and Leung [52] recommend for a scraped-surface heat exchanger (see Fig. 8) the following equation:

$$Ne = 77500 Re^{-1.27} Z^{0.59}. \quad (121)$$

Validity ranges:

$$90 \le Re \le 242,$$

$$\frac{d_R}{d_B} = 1.0,$$

$$2 \le Z \le 5,$$
$$\frac{h}{d_R} = 6.0.$$

Other correlations for predicting the power consumption of a scraped-surface heat exchanger can be found in [14, 53].

Theoretical approach for predicting the Newton number with a rectangular pitched-blade impeller

For approximate power consumption calculations in a stirred vessel equipped with a rectangular pitched-blade impeller, Stein [16] developed the following equation for the Newton number using simplified assumptions:

$$\mathrm{Ne} = 10.47 n_R Z \left(\frac{b_R}{d_R}\right)\left(\frac{h}{d_R}\right)\sin^3\gamma. \qquad (122)$$

The case $\gamma = 90°$ represents an impeller with vertical rectangular blades. Equation (122) is valid for a baffled stirred vessel with four baffles in the turbulent range.

Example 6:

Calculate the power consumption of a flat-blade turbine with standard dimensions in a stirred vessel with four baffles; the vessel is filled with an aqueous solution with physical properties similar to those of pure water. The following geometrical and operating parameters are valid:

Vessel diameter $d_B = 0.5\,\mathrm{m}$

Geometrical ratios $\frac{d_R}{d_B} = \frac{1}{3}$,

$$\frac{h_R}{d_B} = \frac{1}{3},$$
$$\frac{h_L}{d_B} = 1.0,$$
$$\frac{b_S}{d_B} = \frac{1}{10},$$

Speed of rotation $n = 3\,\mathrm{s}^{-1}$

Mean liquid temperature $\vartheta = 20°\mathrm{C}$

Physical properties of water at mean temperature $\vartheta = 20°\mathrm{C}$

Density $\rho = 998.3\,\mathrm{kg\,m}^{-3}$

Dynamic viscosity $\eta = 1002.6 \times 10^{-6}\,\mathrm{pa\,s}$

Solution:

Reynolds number $\mathrm{Re} = \frac{n d_R^2 \rho}{\eta} = \frac{3 \times \left(\frac{0.5}{3}\right)^2 \times 998.3}{1002.6 \times 10^{-6}} = 8.3 \times 10^4$,

Equation (99): Ne = 5.

Hence,

$$P = \mathrm{Ne}\rho n^3 d_R^5 = 5 \times 998.3 \times 3^3 \times \left(\frac{0.5}{3}\right)^5 = 17.3\,\mathrm{W}.$$

3.1.2 Non-Newtonian Liquids

Correlations derived to predict the Newton number from the Reynolds number during the agitation of a Newtonian liquid can also be used to predict the Newton number for a non-Newtonian liquid, if the Newtonian dynamic viscosity η in the Reynolds number is replaced by the apparent dynamic viscosity η_{app} of the non-Newtonian liquid. Equations for calculating the apparent viscosity of a non-Newtonian liquid are presented in Sect. 2.1.1.

3.2 Multiphase Systems

3.2.1 Gas-Liquid Mixtures

The power required in the turbulent range to agitate a gas–liquid mixture in a stirred vessel is lower than that required for a single-phase liquid. Zlokarnik [54] recommends for predicting the Newton number during aerating a liquid in a baffled stirred vessel by means of a standard flat-blade turbine the following equation:

$$\mathrm{Ne}_B = \frac{\left[1.5 + \left(0.5A^{0.075} + 1600A^{2.6}\right)^{-1}\right]}{F}, \qquad (123)$$

where

$$\mathrm{Ne}_B = \frac{P_B}{\rho n^3 d_R^5} \qquad (124)$$

with P_B the power consumption of the impeller for agitating a gas–liquid mixture,

$$A = Q\left[1 + 38\left(\frac{d_B}{d_R}\right)^{-5}\right], \qquad (125)$$

$$Q = \frac{\dot{V}_G}{n d_R^3}, \qquad (126)$$

$$F = 1 + \left[\left(3.9\mathrm{Re}^{0.12} + 6 \times 10^{-12}\mathrm{Re}^{3.45}\right)\left(0.22Q^{0.1} + 6.25Q^3\right)\right]^{-1}$$
$$\text{for } 10^3 < \mathrm{Re} < 10^4, \qquad (127)$$

$$F = 1 \quad \text{for Re} > 10^4. \qquad (128)$$

Three dished stirred vessels with internal diameters 200, 300, and 450 mm were used for the derivation of Eq. (123). The gas used was air; it was fed under the flat-blade turbine through an aerating tube.

Validity ranges:

$$0.2 \le \frac{d_R}{d_B} \le 0.45,$$
$$\frac{h_L}{d_B} = 1.0,$$
$$\frac{h_R}{d_R} = 1.0,$$
$$\frac{h_{OBR}}{d_R} = \frac{1}{9},$$
$$\frac{b_S}{d_B} = 0.1,$$
$$n_S = 4.$$

Further restrictions for the use of Eq. (123) are given below:

- The Froude number should exceed a certain level given by $\mathrm{Fr} \ge 0.65$.
- The gas flow rate should not exceed the limit that can be dispersed by the impeller; otherwise the stirred vessel will be flooded.

According to Zlokarnik and Judat [55], the gas flow rate that will lead to flooding the stirred vessel is given for a flat-blade turbine by the following equation:

$$Q_{\text{flooding}} = 0.194\text{Fr}^{0.75} \text{ for } 0.1 < \text{Fr} < 2. \quad (129)$$

Equation (129) was derived empirically for the following geometrical ratios:

$$\frac{d_R}{d_B} = 0.3,$$
$$\frac{d_R}{h_L} = 0.43,$$
$$\frac{h_R}{d_R} = 1.0.$$

Equation (123) shows an increasing Newton number with decreasing gas flow rate. At a gas flow rate $\dot{V}_G = 0$ (i.e., $Q = 0$ and $A = 0$) and a Reynolds number $\text{Re} > 10^4$, Eq. (123) leads to $\text{Ne}_B = \infty$. Since the Newton number Ne_B with decreasing gas flow rate approaches the Newton number *Ne* for an unaerated single-phase liquid, Eq. (123) should only be used in the range $\text{Ne}_B \leq \text{Ne}$. For a low gas flow rate, for which Eq. (123) leads to $\text{Ne}_B > \text{Ne}$, the Newton number Ne_B for the gas–liquid mixture should be replaced by the Newton number Ne for the single-phase liquid. Equation (123) shows also that the Froude number has no influence on the Newton number in the range $\text{Fr} \geq 0.65$. It has, however, some influence in the range $\text{Fr} < 0.65$; according to Zlokarnik [54], this is insignificant.

For a multistage impeller with n_R flat-blade turbines mounted on the same shaft, Henzler [56] recommends the following equation to calculate the Newton number Ne_B:

$$\text{Ne}_B = n_R \left[\frac{\text{Ne} + 187Q\text{Fr}^{-0.32}\left(\frac{d_R}{d_B}\right)^{1.53} - 4.6Q^{1.25}}{1 + 136Q\left(\frac{d_R}{d_B}\right)^{1.14}} \right] \quad (130)$$

with

$$\text{Ne} \approx 4.9.$$

Validity ranges:

$$\text{Fr} \leq 0.07\left(\frac{d_B}{d_R}\right)^3,$$
$$0.2 \leq \frac{d_R}{d_B} \leq 0.42,$$
$$\frac{\Delta h_R}{d_B} > 0.75,$$
$$\text{Re} \geq 10^4.$$

In the range $800 < \text{Re} < 10^4$ and $Q < 0.05$, the Newton number may be approximately calculated [56]

$$\text{Ne}_B = \frac{(\text{Ne}_B)_{\text{at } Re = 10^4}}{F}. \quad (131)$$

The function F in Eq. (131) is given by Eq. (127).

According to Henzler [56], the n_R flat-blade turbines operate independently if the distance Δh_R between adjacent impellers fulfills the condition $\Delta h_R > 0.75 d_B$.

Example 7:

Calculate the power consumption of the flat-blade turbine in Example 6 for the case in which the liquid is aerated by means of a tube placed under the impeller and the speed of rotation of the impeller is increased to 7 s^{-1}. The gas flow rate amounts to 6 $m^3\,h^{-1}$. Otherwise, the data given in Example 6 are valid.

Solution:

$$\text{Re} = \frac{nd_R^2\rho}{\eta} = \frac{7 \times \left(\frac{0.5}{3}\right)^2 \times 998.3}{1002.6 \times 10^{-6}} = 1.94 \times 10^5,$$

Equation (126): $Q = \frac{\dot{V}_G}{nd_R^3} = \frac{\left(\frac{6}{3600}\right)}{7 \times \left(\frac{0.5}{3}\right)^3} = 0.0514,$

Equation (128): $F = 1$ (since $\text{Re} > 10^4$),

Equation (125):

$$A = Q\left[1 + 38\left(\frac{d_B}{d_R}\right)^{-5}\right] = 0.0514\left[1 + 38 \times (3)^{-5}\right] = 0.0595,$$

Equation (123):

$$\text{Ne}_B = \frac{\left[1.5 + \left(0.5A^{0.075} + 1600A^{2.6}\right)^{-1}\right]}{F} = \frac{\left[1.5 + \left(0.5 \times 0.0595^{0.075} + 1600 \times 0.0595^{2.6}\right)^{-1}\right]}{1} = 2.19.$$

Hence,

$$P_B = \text{Ne}_B \rho n^3 d_R^5 = 2.19 \times 998.3 \times 7^3 \times \left(\frac{0.5}{3}\right)^5 = 96.4\,\text{W}.$$

3.2.2 Immiscible Liquids

At a high impeller speed and correspondingly a uniform distribution of the dispersed phase in a stirred vessel, it is reasonable to assume that a quasi-homogeneous liquid is present in the stirred vessel. The empirical equations and the diagrams developed for predicting the Newton number for the single-phase system can be used for the two-phase system provided that the physical properties of the single-phase liquid are replaced by the mean physical properties of the quasi-homogenous liquid of the two-phase system. Equations for calculating the physical properties ρ_m and η_m in a two-phase system are given in Sect. 2.1.2.

3.2.3 Suspensions

If the suspended solids are uniformly distributed (i.e., turbulent flow, high impeller speed, small fraction of solid particles, and small particle diameter), it may be assumed that a quasi-homogenous phase is present inside the stirred vessel. The empirical equations and the diagrams developed for predicting the Newton number for the single-phase liquid can be used for the suspension provided that the physical properties of the single-phase liquid are replaced by the mean physical properties of the suspension. Equations to calculate the mean physical properties of a suspension (ρ_m, η_m) are given in Sect. 2.1.2.

3.2.4 Gas–Suspension Mixtures

In analogy to the presentation made in Sect. 2.1.2 about heat transfer in gas–suspension mixtures, Eq. (123) can be used also for predicting the Newton number in gas–suspension mixtures provided that the mean physical properties of the suspension (ρ_m, η_m) according to the equations given in Sect. 2.1.2 are used instead of the physical properties of the single-phase liquid.

The use of a multistage impeller with a number of flat-blade turbines mounted on the same shaft improves the distribution of the solid particles in comparison with a single flat-blade turbine. Equations (130) and (131) can thus be used for gas–suspension mixtures with the appropriate physical properties ρ_m and η_m.

4 Vortex Depth in Stirred Vessels Without Baffles

The depth of the vortex h_V for a single-phase liquid in an unbaffled stirred vessel increases with increasing impeller speed. The maximum power consumption is reached, when the lowest point of the vortex reaches the upper edge of the impeller. A further increase in the impeller speed leads to sucking gas from the surroundings and dispersing the gas in the single-phase liquid. The depth of the vortex $h_{V,crit}$ ($h_{V,crit} = h_{LC}$, see Fig. 20) and the corresponding Reynolds number Re_{crit}, when the lowest point of the vortex just reaches the upper edge of the impeller, are usually referred to as the critical vortex depth and the critical Reynolds number. If the Reynolds number is increased beyond the critical value, a decrease in the power consumption of the impeller occurs. Operating the impeller in the range $Re \geq Re_{crit}$ is not advisable; since it leads to mechanical vibrations.

Zlokarnik [57] recommends the following equations to calculate the vortex depth:
For a flat-blade turbine:

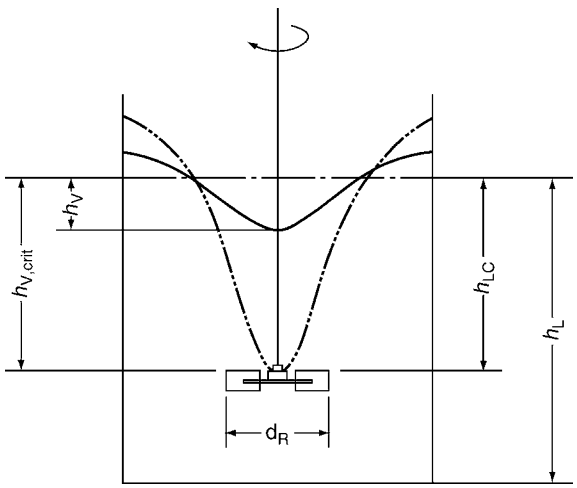
$$\frac{h_V}{d_R} = 62.0\,Fr\left(0.1 - Ga_R^{-0.18}\right)\left(\frac{h_{LC}}{d_R}\right)^{-0.16}. \quad (132)$$

For a propeller:

$$\frac{h_V}{d_R} = 13.8\,Fr\left(0.25 - Ga_R^{-0.10}\right)\left(\frac{h_{LC}}{d_R}\right)^{-0.33}. \quad (133)$$

For a grid impeller:

$$\frac{h_V}{d_R} = 20.0\,Fr\left(0.25 - Ga_R^{-0.19}\right). \quad (134)$$



N3. Fig. 20. Critical vortex depth.

(A grid impeller is an impeller in the form of a frame with two horizontal and two vertical bars; mostly [examined case] an additional horizontal bar of equal length to the upper and lower bars midway between is present. This type of impeller is considered a representative for other low-speed impellers, which create essentially a tangential flow.)

The Froude number Fr and the Galileo number Ga_R in Eqs. (132–134) are defined by

$$Fr = \frac{n^2 d_R}{g},$$

$$Ga_R = \frac{Re^2}{Fr} = \frac{d_R^3 \rho^2 g}{\eta^2}.$$

Validity ranges:
For a flat-blade turbine:

$$2.7 \times 10^6 \leq Ga_R \leq 1.7 \times 10^{10},$$
$$5 \times 10^{-2} \leq Fr \leq 1,$$
$$1.0 \leq \frac{h_L}{d_B} \leq 1.75.$$

For a propeller:

$$1.1 \times 10^8 \leq Ga_R \leq 1.7 \times 10^{10},$$
$$2 \times 10^{-1} \leq Fr \leq 3,$$
$$1.0 \leq \frac{h_L}{d_B} \leq 1.75.$$

For a grid impeller:

$$2.9 \times 10^5 \leq Ga_R \leq 2.7 \times 10^{11},$$
$$1.1 \times 10^{-2} \leq Fr \leq 4 \times 10^{-1},$$
$$0.5 \leq \frac{h_L}{d_B} \leq 1.75.$$

The investigation was carried out with three stirred vessels having flat bottoms and internal diameters 300, 400, and 600 mm. The important geometrical parameters are given in Table 5.

Substituting in Eq. (132), Eq. (133) or Eq. (134) $h_V = h_{V,crit} = h_{LC}$ gives the critical Froude number Fr_{crit} from

N3. Table 5. Examined geometrical parameters in the investigation in [58]

	Flat-blade turbine	Propeller	Grid impeller
$\frac{d_R}{d_B}$	$\frac{1}{3}$	$\frac{1}{3}$	$\frac{1}{2}$
$\frac{h_R}{d_R}$	1	1	–
$\frac{h_{RK}}{d_R}$	–	–	$\frac{1}{5}$
$\frac{h}{d_R}$	$\frac{1}{5}$	–	$\frac{3}{2}$
$\frac{b_R}{d_R}$	$\frac{1}{4}$	–	–
$\frac{b_{SR}}{d_R}$	–	–	$\frac{1}{10}$

which the critical impeller speed n_{crit} and hence the critical Reynolds number Re_{crit} can be calculated. The Galileo number Ga_R does not depend on the speed of rotation. Further equations for predicting the vortex depth are also given [58].

h_L	liquid height in a stirred vessel (m)
h_{LC}	height of liquid above upper edge of an impeller (m)
h_{LO}	liquid height of unaerated liquid or unaerated suspension in a three-phase system "gas–liquid–solid" (m)
h_{OBR}	distance between the opening of the aerating tube and the impeller (m)
h_R	height of impeller above vessel bottom (see Fig. 1) (m)
h_{R1}	height of lower impeller above vessel bottom (case of a two-stage impeller) (m)
h_{R2}	height of higher impeller above vessel bottom (case of a two-stage impeller) (m)
$h_{R,i}$	height of impeller i on a shaft equipped with n_R impellers above vessel bottom (m)
h_{RK}	distance between the lower edge of an impeller and the bottom of a stirred vessel (see Fig. 1) (m)
Δh_R	spacing between impellers mounted on a common shaft (m)
h_s	height of jacket (m (mm))
h_V	vortex depth (m)
$h_{V,crit}$	critical vortex depth (m)
h_{WR}	height of a helical impeller (m)
K_1	quantity in Eq. (83) defined by Eq. (84) ($K\ s^{-1}$)
K_2	quantity in Eq. (83) defined by Eq. (85) (s^{-1})
K_3	quantity with the dimension of velocity (see Eq. (62)) ($m\ s^{-1}$)
K_4	quantity with the dimension of square of velocity (see Eq. (63)) ($m^2\ s^{-2}$)
K_{Ko}	dimensionless number given by Eq. (24) (1)
k_S	constant in Eq. (33) (1)
l_{ch}	characteristic length given by Eq. (53) (m)
l_s	immersed height of baffles (m)
M	mass of liquid or quasi-homogenous mixture in a stirred vessel (kg)

$\dot{M}_J$ mass flow rate of fluid in the jacket or through the inside of a coil (kg s^{-1})
m exponent of the kinematic viscosity ratio in Eqs. (15) and (16) (1)
m exponent of Reynolds number in Eq. (89) (1)
Ne Newton number ($Ne = P/(\rho n^3 d_R^5)$) (1)
Ne_B Newton number for a gas–liquid mixture ($Ne = P_B/(\rho n^3 d_R^5)$) (1)
Ne_t Newton number in a single-phase turbulent flow ($Ne_t = P_t/(\rho n^3 d_R^5)$) (1)
Nu Nusselt number for heat transfer from the inside surface of a stirred vessel ($Nu = \alpha d_B/\lambda$)) (1)
Nu_A Nusselt number given by Eq. (73) (1)
Nu_B Nusselt number given by Eq. (74) (1)
Nu_C Nusselt number given by Eq. (75) (1)
Nu_D Nusselt number given by Eqs. (76) and (77) (1)
Nu_J jacket-side Nusselt number given by Eq. (71) (($Nu_J = \alpha d_{ch}/\lambda$) (1)
Nu_R Nusselt number for heat transfer from the outside surface of an immersed coil ($Nu_R = \alpha d/\lambda$) (1)
$Nu_{S,L}$ jacket-side Nusselt number given by Eq. (45) ($Nu_{S,L} = \alpha d_g/\lambda$) (1)
n speed of rotation of an Impeller (s^{-1})
n_{crit} critical speed of rotation of an Impeller (s^{-1})
n_R number of impellers mounted on a shaft (1)
n_{RS} number of tubes in a vertical tube baffle (1)
n_s baffle number (1)
n_{WR} number of ribbons of a helical impeller (1)
P power consumption of an impeller (W)
P_{Ad} total power dissipated in the contents of a stirred vessel as heat due to power consumption of the impeller and any additional periphery equipment (W)
P_B power consumption of an impeller for a gas–liquid mixture (W)
P_t power consumption in a single-phase turbulent flow (W)
Pr Prandtl number at mean liquid temperature ϑ or ϑ_J($Pr = \upsilon/a$) (1)
p exponent in Eq. (2) (1)
Q parameter in Eq. (125) given by Eq. (126) (1)
$Q_{flooding}$ critical value of the parameter Q, which if exceeded the stirred vessel will be flooded (see Eq. (129)) (1)
$\dot{Q}$ heat flow rate (W)
R radius of curvature of an impeller blade (see Fig. 5a) (m)
Re Reynolds number in Eq. (1) ($Re = nd_R^2\rho/\eta$), in case of a scraped-surface heat exchanger ($Re = nd_B^2\rho/\eta$) (1)
Re_{crit} critical Reynolds number ($Re_{crit} = n_{crit}d_R^2\rho/\eta$) (1)
Re_G Reynolds number ($Re_G = u_{GO}d_B/\upsilon$) (1)
Re_J jacket-side Reynolds number ($Re_J = u_{ch}d_{ch}\rho/\eta$) (1)
$Re_{J,eq}$ jacket-side equivalent Reynolds number given by Eq. (70) (1)
Re_S jacket-side Reynolds number ($Re_S = u_h d_g \rho/\eta$) (1)
r exponent of the Froude number in Figs. 13 and 15 (1)
S pitch of a propeller or a helical impeller ($S = \pi d_R \tan\gamma$) (m (mm))
s ratio (d_B/d_R) (1)
S_B clearance between vessel and helical impeller ($s_B = (d_B - d_R)/2$) or between vessel and outer helical ribbon in Fig. 19($s_B = (d_B - d_{R,W})/2$) (m)
S_S space between tubes in a coil (see Fig. 1) (m)
t time (s)
U overall heat transfer coefficient (constant or mean value) (W m^{-2} K^{-1})
$U(t)$ overall heat transfer coefficient (time dependent) (W m^{-2} K^{-1})
u_A velocity due to buoyancy given by Eqs. (50) and (52) (m s^{-1})
u_{ch} velocity given by Eq. (55) (m s^{-1})
u_{GO} superficial gas velocity ($u_{GO} = \dot{V}_G/((\pi/4)d_B^2)$)) (m s^{-1})
u_h characteristic velocity in annular space of a jacket given by Eq. (47) (m s^{-1})
u_{Mit} velocity given by Eq. (58) (m s^{-1})
u_O velocity in inlet tube of a jacket given by Eq. (48) (m s^{-1})
u_S velocity in annular space of a jacket given by Eqs. (49) and (51) (m s^{-1})
u_x velocity given by Eq. (60) (m s^{-1})
$u_x(0)$ velocity given by Eq. (61) (m s^{-1})
u_z velocity given by Eq. (64) (m s^{-1})
V_L volume of unaerated liquid or unaerated suspension (m^3)
$\dot{V}_G$ volumetric gas flow rate (m^3 s^{-1} (m^3 h^{-1}))
$\dot{V}_J$ jacket-side volumetric flow rate (m^3 s^{-1} (m^3 h^{-1}))
x_s gap between a baffle and the inside surface of a stirred vessel (m)
Z number of blades of an impeller or number of scraper blades in a scraped-surface heat exchanger (1)

Greek Letters

α heat transfer coefficient (W m^{-2} K^{-1})
β angle of an impeller blade (see Fig. 5a) (°)
β angle between vertical tube baffle and radius (see Fig. 11) (°)
β volumetric coefficient of expansion (K^{-1})
γ blade angle of a propeller or ribbon angle for a helical impeller (°)
$\dot{\gamma}$ shear rate (s^{-1})
δ thickness of annular space of a jacket (($\delta = (d_J - d_{BA})/2$) (m (mm))
η dynamic viscosity of liquid at mean liquid temperature ϑ or ϑ_J (Pa s)
η_{app} apparent dynamic viscosity of non-Newtonian liquid at mean temperature ϑ (Pa s)
η_{GS} dynamic viscosity of liquid at mean temperature $(\vartheta + \vartheta_w)/2$ of the thermal boundary layer in a stirred vessel (Pa s)
η_w dynamic viscosity of liquid at mean wall temperature ϑ_w or $\vartheta_{J,w}$ (Pa s)

$\eta_{w,app}$ apparent dynamic viscosity of a non-Newtonian liquid at mean wall temperature ϑ_w (Pa s)
ϑ mean temperature of liquid or homogeneous mixture in a stirred vessel (°C)
$\vartheta_{(t)}$ temperature of liquid or homogeneous mixture in a stirred vessel (at time t during transient operation) (°C)
ϑ_0 initial temperature of liquid or homogeneous mixture in a stirred vessel (at time $t = 0$ during transient operation) (°C)
ϑ_J mean liquid temperature in a jacket or spatially constant and time independent fluid temperature in a jacket (see Eq. (79)) (°C)
$\vartheta_{J,i}$ inlet liquid temperature in a jacket (°C)
$\vartheta_{J,o}$ outlet liquid temperature in a jacket (°C)
$\vartheta_{J,o(t)}$ outlet liquid temperature in a jacket (time dependent) (°C)
$\vartheta_{J,w}$ mean jacket wall temperature (°C)
$\Delta\vartheta_J$ temperature rise or temperature drop of jacket-side liquid (K)
ϑ_w mean wall temperature in a stirred vessel (°C)
λ thermal conductivity of liquid at mean liquid temperature ϑ or ϑ_j (W m^{-1} K^{-1})
ν kinematic viscosity of liquid at mean liquid temperature ϑ or ϑ_j (m^2 s^{-1})
ν_{app} apparent kinematic viscosity of non-Newtonian liquid at mean liquid temperature ϑ (m^2 s^{-1})
ν_w kinematic viscosity of liquid at mean wall temperature ϑ_w (m^2 s^{-1})
$\nu_{w,app}$ apparent kinematic viscosity of non-Newtonian liquid at mean wall temperature ϑ_w (m^2 s^{-1})
ξ constant in Eq. (38) (1)
ξ_j jacket-side friction factor given by Eqs. (66) and (68) (1)
π_1 geometric ratio in Eqs. (2) and (86) (1)
π_2 geometric ratio in Eqs. (2) and (86) (1)
ρ liquid density at mean liquid temperature ϑ or ϑ_j (kg m^{-3})
ρ_w liquid density at mean wall temperature ϑ_w or mean jacket wall temperature $\vartheta_{J,w}$ (kg m^{-3})
τ shear stress (Pa)
ϕ volumetric fraction of the dispersed phase (1)
ϕ_{max} maximal volumetric fraction of solid material in a batch (1)
ψ_p parameter in Eq. (7), defined by Eq. (8) (1)

Subscripts

c physical property for the continuous phase in a mixture (-)
d physical property for the dispersed phase in a mixture (-)
m mean physical property for a mixture (-)

Note: The units between brackets (mm, m^3h^{-1}) are not consistent with the MKS units system; they are used in some places in the text and in the examples for convenience.

N4 Cooling Towers

Paul J. Erens
Private Consulting Engineer, Stellenbosch, Republic of South Africa

1 Introduction

The words cooling and tower come from early model evaporative cooling towers which were used for cooling water by evaporation and were substantial in height to gain a natural draught effect. However, the means of achieving airflow was in some cases replaced by forced or induced draught fan systems, without the need for tall towers but the name cooling tower has stuck. The term in general includes wet as well as dry cooling systems, but as the subject of dry heat exchangers is adequately covered in other sections of this publication this section is dedicated to wet systems using evaporative cooling where the water being cooled is in direct contact with the air flowing through the cooling tower.

Evaporative cooling towers are devices which are used to remove heat from various types of machinery or industrial process equipment either directly or through intermediate heat exchangers by making use of evaporative cooling. By implication, when using this principle, some water, usually 1–2% of the water flow rate, is sacrificed in order to get rid of the heat.

In any closed thermodynamic cycles there is always a heat source and heat sink e.g., in a steam cycle the steam has to be condensed by transferring heat to the surroundings or in a refrigeration cycle heat is absorbed in the evaporator and released in the condenser also giving off heat to the surroundings. This process of transferring heat to the surroundings takes place through various types of heat exchanger which are either air cooled or water cooled. Simple thermodynamics tells us that to obtain maximum efficiency in the cycle it is desirable to give off heat at the lowest possible temperature.

An evaporative cooling tower is a device which can theoretically cool water near to the wet-bulb temperature which is usually considerably lower than the dry-bulb temperature. This is one reason that a cooling tower or other evaporative cooling device is often favored over a dry cooling system when getting rid of heat at temperatures slightly above the atmospheric temperature. A further reason for using evaporative cooling is the increased ability of the air to absorb heat when taking up moisture. For example, air at a dry-bulb temperature of 25°C and a wet-bulb temperature of 20°C when heated up to 35°C by dry heating is able to absorb only 10.3 kJ/kg, whereas with heating combined with evaporation i.e., saturation of the air, this is increased to 71.9 kJ/kg of dry air representing a sevenfold increase. This leads to greatly reduced airflow rates and fan power consumption when compared to dry cooling.

When heat in a fluid is being disposed of at temperatures considerably higher than that of the surroundings the advantage

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_64,

of evaporative cooling is somewhat diminished and dry heat exchangers are often regarded as suitable equipment. However, when cooling solids such as steel billets, direct cooling with water is often preferred and a cooling tower can be efficiently used to re-cool the water.

The need for cooling at around atmospheric temperatures is not restricted to thermodynamic cycles but also to numerous manufacturing processes such as the cooling of food products after cooking in cans or in the operation of machinery such as air compressors, rolling mills, and hydraulic and electrical equipment. In fact, there are far more evaporative cooling towers used in manufacturing and industrial processes than in thermodynamic cycles. In general, cooling towers are used to cool water between 85°C and wet-bulb temperature, but most cooling towers operate with a water temperature below 55°C and down to about 20°C.

In some systems where closed circuit cooling is required, *closed circuit evaporative coolers* are employed where any fluid or condensable gas is passed through a closed circuit tube bundle placed inside a cooling tower with water recirculating over the outside.

2 Types of Cooling Towers and Evaporative Coolers/Condensers

Evaporative cooling towers can be grouped into various categories as follows:

	Mechanical draught cooling tower (MDCTs)	Natural draught cooling tower (NDCTs)
Open circuit	Forced draught	Counterflow
	Induced draught	Crossflow
	Counterflow	
	Crossflow	
Closed circuit	Evaporative coolers	
	Evaporative condensers	

Some examples of cooling towers are shown in Figs. 1–4.

In a few cases mechanically assisted natural draught cooling towers may be encountered. Many different variations are also shown in Singham [1], Stoecker and Jones [2] and Burger [3], and Kröger[4].

3 Cooling Tower Construction and Materials

3.1 Basic Elements

All cooling towers, no matter what the configuration is, have certain basic elements viz:

(1) A casing or shell;
(2) Fill or packing material;
(3) A water distribution system;
(4) An air-moving system, fan or natural draught;
(5) A drift elimination system;
(6) Makeup supply;
(7) Blowdown system;
(8) Basin;
(9) Inlet louvres, wind louvers, and wind barriers.

3.1.1 Structure

The main structure of the cooling towers is usually made of one or more of the following materials:

(1) Wood
(2) FRP (fiber reinforced plastic) or molded plastics
(3) Steel or other metals
(4) Reinforced concrete

3.1.2 Fill Materials, Packing, or Wet-deck

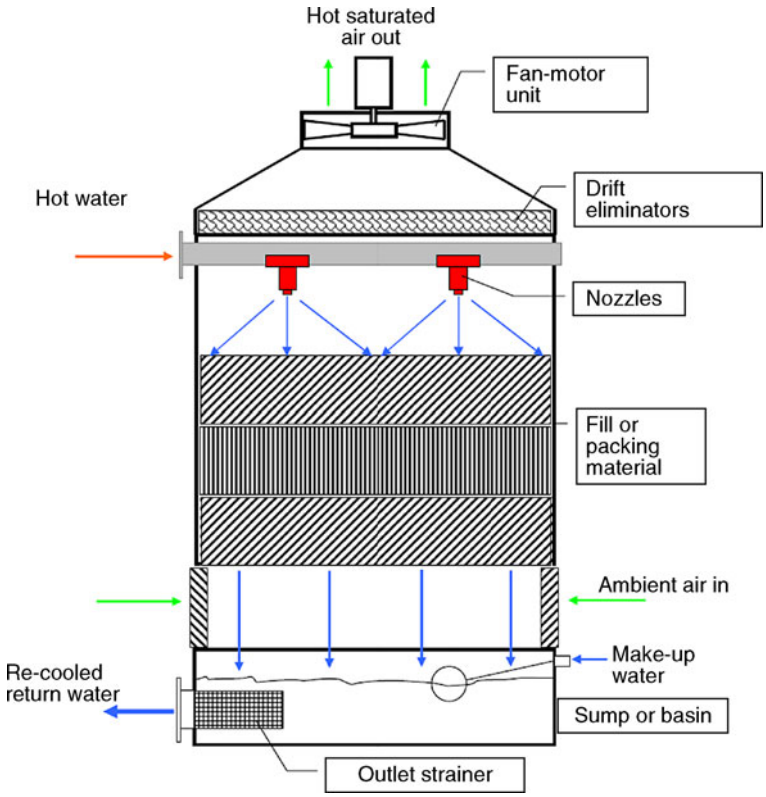
Most fill materials are made from plastics, metals, or wood, with the greater majority in molded or vacuum formed plastics. The preferred plastics are PVC, polyethylene, polypropylene, and ABS. Many fills today are also made of steel particularly where high temperature water is being cooled. Although wood is still sometimes used, this is usually only for particular applications such as in phosphoric acid towers or when wood is in free supply.

Fill materials are discussed in detail in Sect. 5.

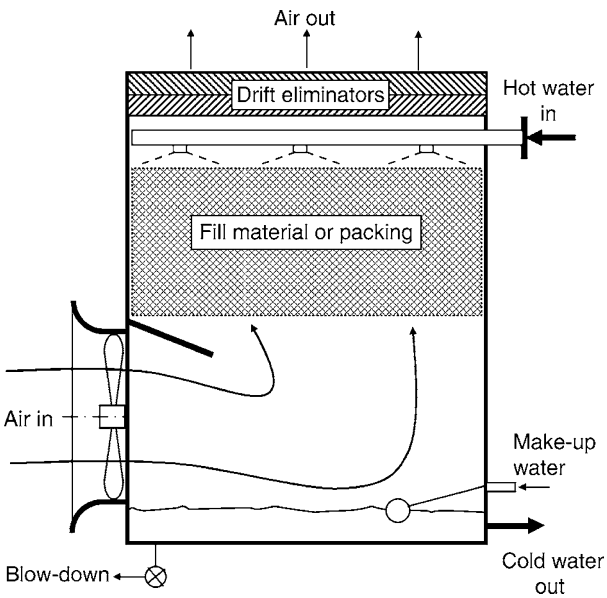
3.1.3 Nozzles and Water Distribution

Even distribution of water in cooling towers is very important to achieve maximum cooling effect and efficient cooling tower operation. The water distribution system is required to spread the water evenly over the fill material and can consist of closed water ducts with a number of nozzles in plastic or metal, open overflow ducts or open ducts with low pressure nozzles.

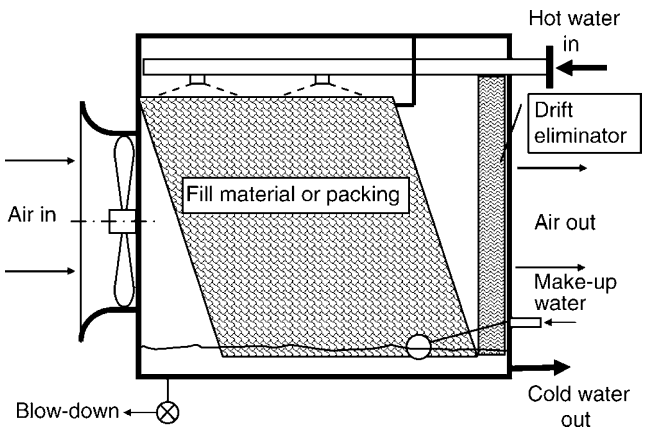
In small towers it is important to use well-designed square-pattern sprayers or multiple small nozzles to achieve the desired distribution usually operating in the pressure range of 2–5 m of water, see Fig. 5a. In very large towers, low pressure nozzles (0.5–1.5 m water) with less ideal distribution characteristics may be used provided there is sufficient overlap between the adjacent nozzles. Some examples are shown in Fig. 5b with two upward spraying nozzles shown in Fig. 5c. It has been proved that nozzles which give a radial distribution with maximum water loading at the center decreasing linearly with radius produce excellent distribution when their spray patterns are overlapped. Some small towers also use rotating spreaders, similar to a lawn sprinkler, but these can only be used in circular towers. The size and number of nozzles and distribution ducts depend on the required flow density required for a particular application.



N4. Fig. 1. Induced draught counterflow cooling tower.



N4. Fig. 2. Forced draught, axial fan, and counterflow cooling tower.



N4. Fig. 3. Forced draught, axial fan, and crossflow cooling tower.

High pressure sprayers are seldom, if ever, used in view of the severe pumping power requirements and their tendency to produce small droplets leading to high drift loss.

Water distribution piping can be in plastics or metals, depending on temperature and corrosion considerations. In general they are low pressure systems and only require thin-walled piping. Low pressure nozzles are often fixed beneath open distribution duct systems fed from a main header channel or pipe.

3.1.4 Drift Eliminators

Monjoie and Lauraine [5] have discussed a method of measuring drift as well as three classes of drift eliminators with classification according to separation efficiency. The separation efficiency defined as a percentage of water flow rate in the tower is strongly related to drop-size distribution as well as air velocity through the tower. Foster et al. [6] have discussed two types of drift eliminators and their separation efficiency having measure droplet distributions upstream and downstream of them, while Chan and Golay [7] have compared three different wave forms for drift elimination. Golay et al. [8] have discussed a number of methods to measure drift.

N4. Fig. 4. A site-built counterflow induced draught cooling tower (Picture supplied by Industrial Water Cooling, South Africa).

Drift eliminators are required to retain spray droplets which move upward with the air within the cooling tower. They generally consist of devices which are designed to induce a number of sudden directional changes of the air in order to deflect the entrained droplets onto solid surfaces so that the water runs back into the tower. There are various patents using PVC-film, composites or S-shaped louvres in plastic or metal. In general, a separation efficiency of roughly 0.01–0.0005% of cooling tower water flow rate is attainable without special arrangements such as double rows of drift eliminator to reduce this further.

In practice, separation efficiency of 0.0002% can be achieved but at much greater cost and care should be taken not to unnecessarily overspecify this requirement. The 0.01% figure is usually adequate for most industrial applications although in recent times there has been a demand for high efficiency drift eliminators of the 0.0002% class due to environmental considerations.

The % figures quoted above usually apply to a maximum velocity of 3 m/s using medium or low pressure sprayers and these will not be achieved should the velocity go above this figure or where the sprayers form fine water droplets.

Some examples of drift eliminators are shown in Fig. 6.

3.1.5 Air-moving System

The air-moving system in MDCTs is usually chosen to give air velocities of 2.5–3.5 m/s in the tower. This velocity is limited to <3.5 m/s to avoid upward transfer of water through the fill and also the drift eliminators. Probably, the most common air-moving system is the axial fan in either forced- or induced-draught towers, with some forced draught towers using centrifugal fans.

Both types of fan can be direct-driven (up to about 2 m diameter in axial fans) and above this through belts or gearboxes with drive shafts. It is becoming more and more common to find variable frequency fan-speed controls (VFDs) as a means of controlling the temperature of the cooled water.

Fan pressures are generally low in the order of 150–300 Pa so that single-stage axial fans can be used although some towers use two-stage low-speed axial fans to achieve low noise output.

In natural draught cooling towers the difference in air densities inside and outside the tower is the driving force and generally much lower fill air velocities below about 1.5 m/s are experienced.

3.1.6 Makeup and Blowdown Equipment

Obviously, when water is continually being evaporated and bled off it is necessary to add water to the system to make up the evaporation and blowdown loss. This amount is usually in the order of 1–2% of the flow rate through the cooling tower. Makeup is usually controlled by means of a level control in the pond, but can also be controlled from elsewhere in the system. It is usually controlled by monitoring the level in the pond.

3.1.7 The Basin

The basin of a cooling tower is used to catch the re-cooled water and often also to act as a reservoir for the system although

N4. Fig. 5. (**a**) A Selection of medium-pressure square-pattern nozzles (nozzles shown inverted). (**b**) A selection of low-pressure down-spraying nozzles. (**c**) Two up-spraying nozzles.

separate reservoirs are often used. The size and volume of the basin are usually determined from practical considerations regarding the particular application.

In small molded FRP and sheet metal cooling towers, the basin is often an integral part, whereas in large towers these can be built of FRP, steel, or concrete.

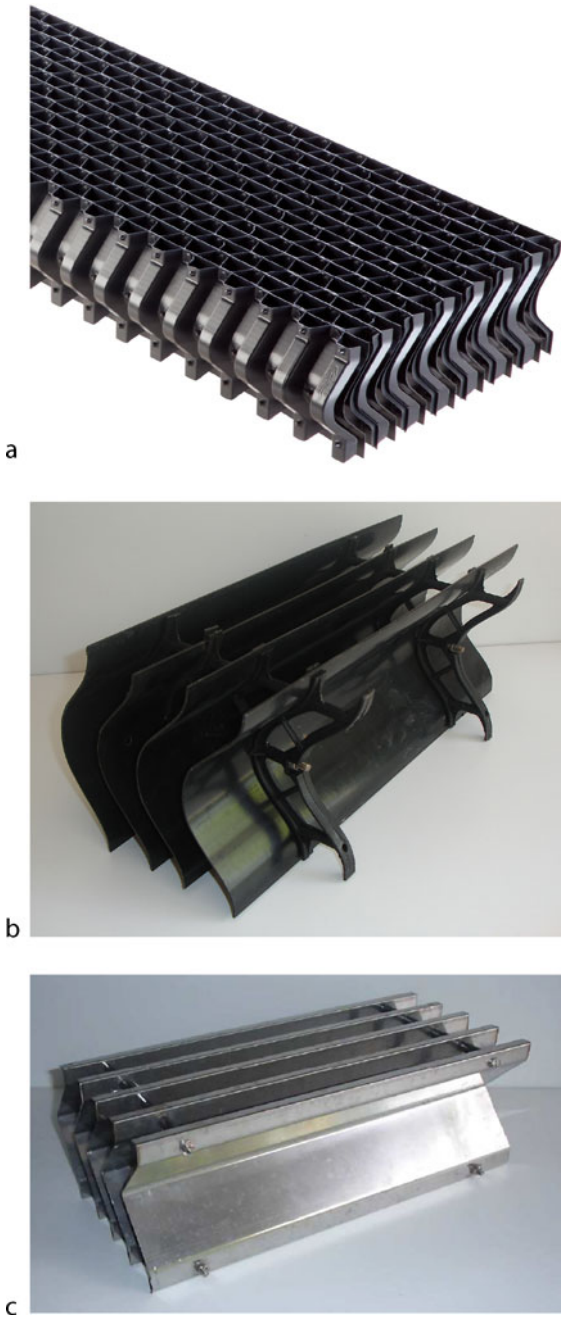
It is not unusual to find even medium-sized molded FRP towers mounted on concrete basins with the water falling directly into the basin.

Basins often also incorporate deflectors, protruding inlets, and inward-sloping catchment ledges to prevent water from leaving the tower via the air inlets.

Some cooling towers are produced without basins using inclined water collection ducts between which the air flows upward into the tower. The advantage of such systems is the virtual elimination of light from the tower which helps to reduce algae formation.

3.1.8 Inlet Louvres, Wind Louvres, and Wind Barriers

Loss of water from a cooling tower through splashing or wind transport needs to be avoided as it represents an



N4. Fig. 6. (**a**) Vacuum-formed drift eliminator (Picture supplied by Brentwood Industries Inc., USA). (**b**) PVC-wave drift eliminator (Picture supplied by Industrial Water Cooling, South Africa). (**c**) Stainless steel drift eliminator (Picture supplied by Industrial Water Cooling, South Africa).

environmental problem as well as a potential source of chemical loss from the tower. This type of loss is prevented by judicious design of tower inlets as well as inlet louvres, wind barriers, and wind louvres.

Inlet louvres are sometimes but not always used to catch water droplets splashed from beneath the tower. They are sloped inward so that any water impinging on them runs back toward the basin. Louvres are manufactured from plastics, FRPs, fiber cement, and galvanized or stainless steel. They are often quite

widely spaced and their effectiveness in preventing water from being blown out of the tower is often limited.

Wind louvres are usually vertically mounted and they are generally much more closely spaced. While their main purpose is to prevent water from being blown out of the tower, they also serve as splashguards.

An additional and often the only means of preventing wind loss is to place dividing walls beneath the fill in the center of the tower, often in both directions. These are fairly effective in preventing wind flow through the tower at right angles to it but they do not prevent the wind almost parallel or at an acute angle to the tower air inlets from entering at one end and leaving at the other, carrying substantial amounts of water with it.

4 Basic Evaporative Cooling Theory

4.1 Properties of Moist Air (Psychrometric Theory)

The properties of moist air are determined by considering the air and water vapor as perfect gasses, the basics of which are summarized next according to Bosnjakovic [9] and numerous first-course texts on thermodynamics.

The mass ratio of water to air in terms of partial pressures is given by

$$X = \frac{M_W}{M_A} = \frac{R_A \cdot p_W}{R_W \cdot p_A} = 0.622 \frac{p_W}{p_{\text{atm}} - p_W} \tag{1}$$

The relative humidity which is the ratio of the partial pressure of water vapor in an air mixture to the saturated value at the same temperature is given as

$$\phi = \frac{p_W}{p''_W(\vartheta)} = \frac{X}{0.622 + X} \cdot \frac{p_{\text{atm}}}{p''_W(\vartheta)} \tag{2}$$

The maximum concentration of water on a mass basis is therefore given as the value of X at the saturated condition in terms of the partial pressure of water vapor at atmospheric temperature $[\vartheta_{\text{atm}}]$:

$$X = X''(\vartheta_{\text{atm}}) = 0.622 \frac{p''_W(\vartheta_{\text{atm}})}{p_{\text{atm}} - p''_W(\vartheta_{\text{atm}})} \tag{3}$$

Practical measurement of the moisture content of water is achieved using measurements of wet-bulb and dry-bulb temperatures, using a sling psychrometer or similar device in conjunction with the following Eq.:

$$p_W = p''_W(\vartheta_{AF}) - \frac{0.5}{755} \cdot p \cdot (\vartheta_{db} - \vartheta_{wb}) \tag{4}$$

where, the saturation pressure of water vapor $[p''_w]$ as a function of temperature is approximated between 0°C and 70°C using

$$\ln p''_W = -5143.12 \left[\frac{1}{273.15 + \vartheta} - \frac{1}{373.16} - 5.471 \ln \left(\frac{373.16}{273.15 + \vartheta} \right) + 0.01656[373.16 - (273.15 + \vartheta)] \right] \tag{5}$$

It follows from partial pressure law that the density of moist air at atmospheric pressure is given by

$$\rho_A = \frac{M_A + M_W}{V} = \frac{1 + X}{R_A + X \cdot R_W} \cdot \frac{p_{\text{atm}}}{T} = \frac{1 + X}{(1 + X/0.622)} \cdot \frac{p_{\text{atm}}}{R_L T} \tag{6}$$

The enthalpy of a moisture–air mixture can be calculated by summing the enthalpies of the air and moisture components to give

$$h_A = (c_{pA} + c_{pv} X) \cdot \vartheta_A + X \cdot \Delta h_{V0} \tag{7}$$

where Δh_{V0} is the enthalpy of evaporation of water at 0°C.

The enthalpy of saturated air is in turn given by

$$h''_A(\vartheta) = (c_{pA} + c_{pv} \cdot X'')\vartheta_A + X'' \cdot \Delta h_{V0} \tag{8}$$

since $h_v = \Delta h_{V0} + c_{pv}\vartheta_v$ and the enthalpy of liquid water can be calculated from

$$h_W = c_{pw} \cdot \vartheta_W \tag{9}$$

The following average values for specific heat of air, water vapor, and water can be used:

$$c_{pA} = 1.006\,\text{kJ/kg K}, \qquad c_{pv} = 1.861\,\text{kJ/kg K}$$
$$c_{pW} = 4.18\,\text{kJ/kg K}$$

While the enthalpy of evaporation at 0°C is $\Delta h_{v0} = 2500$ kJ/kg K.

4.2 Counterflow Theory

The derivation of counterflow cooling tower theory is given in numerous texts including Fujita and Tazuka [10], Kröger [4], Poppe and Rögener [11], Singham [1], Stoecker and Jones [2], Sutherland [12], Baker and Shryock [13], and is summarized next.

A film of water running down the surface of a duct with upward flowing air as shown in Fig. 7a is considered. The following basic assumptions are made:

(1) The system is adiabatic with no heat transfer through the sides of the duct.
(2) The temperature throughout the water film is constant and there is no diffusion resistance between the air and water surfaces so that the temperature of the air at the surface is equal to the water temperature. In other words, $\vartheta_A = \vartheta_w$ at the surface.
(3) The areas for both heat and mass transfer are equal.
(4) The air leaves in a saturated condition.

The energy balance (Fig. 7b) is given by

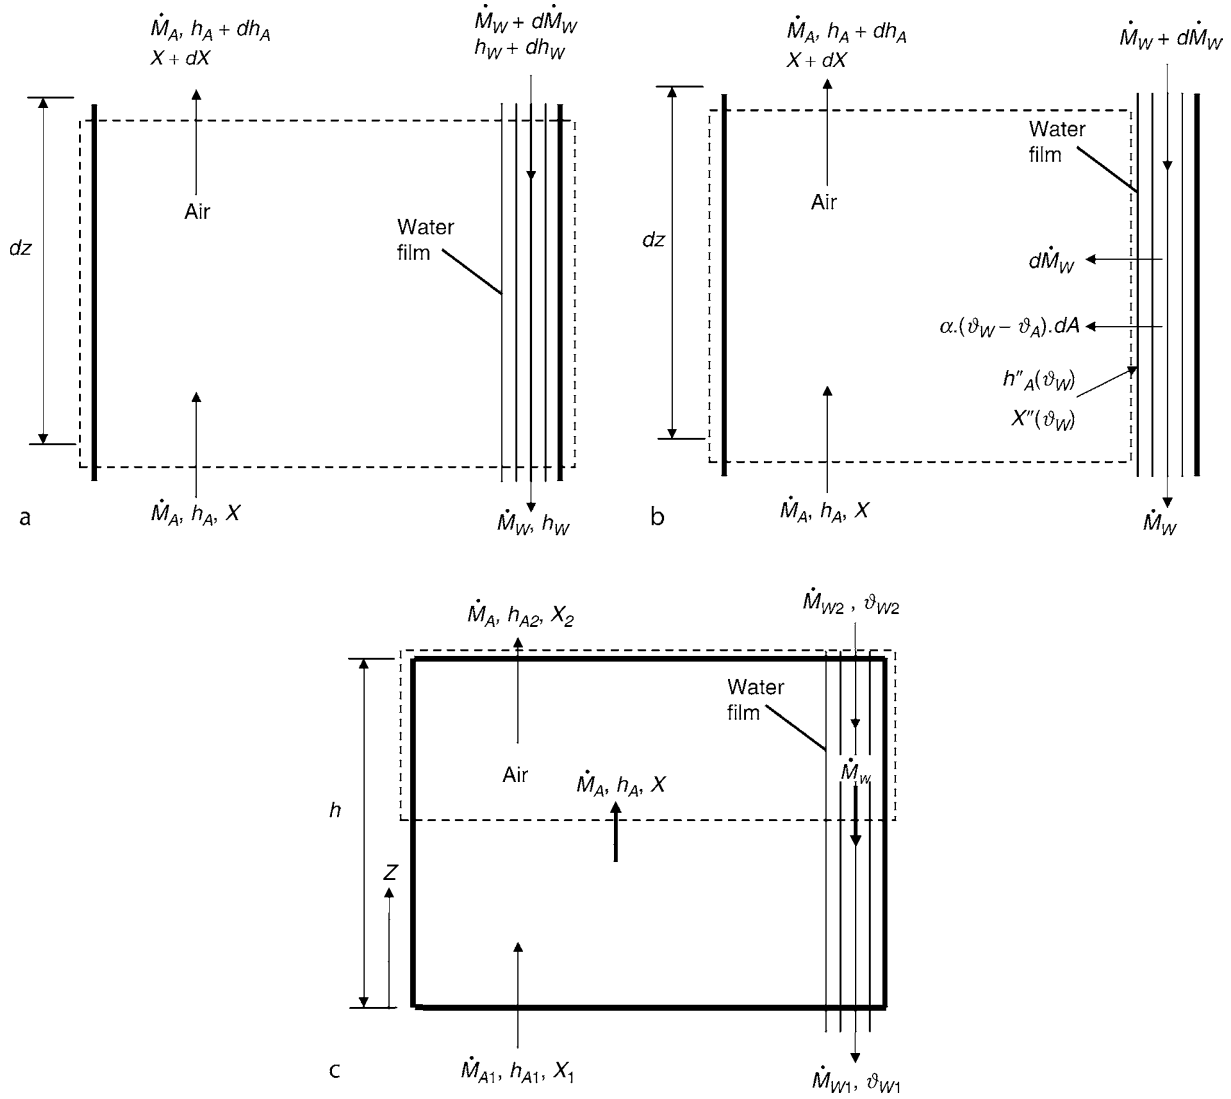
$$\dot{M}_A \cdot dh_A - \dot{M}_W \cdot dh_W - h_W \cdot \dot{M}_W = 0 \tag{10}$$

and the mass balance (Fig. 7c) by

$$\dot{M}_A \cdot dX + d\dot{M}_W = 0 \tag{11}$$

The energy transfer at the water–air interface is also given as the sum of heat transfer and mass transfer:

$$\dot{M}_A \cdot dh_A = h_v \cdot d\dot{M}_W + \alpha \cdot (\vartheta_W - \vartheta_A) \cdot dA \tag{12}$$



N4. Fig. 7. (**a**) Counterflow element model. (**b**) Counterflow energy balance (heat and mass transfer). (**c**) Energy and mass balance for a counterflow system.

The mass transfer rate expressed in terms of concentration difference is given by

$$d\dot{M}_A = \beta_x \cdot \left[X'' \cdot (\vartheta_W) - X\right] \cdot dA \tag{13}$$

Combining the aforementioned equations with the specific heat of the mixture given as

$$c_{pm} = c_{pA} + c_{pv} \cdot X$$

The following equation is obtained:

$$\begin{aligned}\dot{M}_W \cdot dh_W = \beta_x \cdot dA \cdot \Bigg\{ & h''_A(\vartheta_w) - h_A + \left(\frac{\alpha}{\beta_X . c_{pm}} - 1\right) \\ & \times \left[h''_A \cdot (\vartheta_W) - h_A - (X'' \cdot (\vartheta_W) - X) \right. \\ & \left. \cdot \left(\Delta h_{V0} + c_{pv} \cdot \vartheta_W\right)\right] \\ & - \left(X'' \cdot (\vartheta_W) - X\right) \cdot c_{pW} \cdot \vartheta_W \Bigg\}\end{aligned} \tag{14}$$

Merkel [14] simplified the aforementioned equations by applying the following approximations:

(1) Lewis number $\dfrac{\alpha}{\beta_X \cdot c_{pm}} \approx 1$

(2) $\left(X'' - X\right) \cdot c_{pW} \cdot \vartheta_W << h''_A - h''$

Also assuming the evaporation rate relative to the flow is negligible, Merkel's energy transfer equation in terms of enthalpy potential is

$$\dot{M}_W \cdot c_{pW} \cdot d\vartheta_W = \beta_X \cdot dA \cdot (h''_A - h_A) \tag{15}$$

with h''_A = Enthalpy of saturated air at the water surface temperature and h_A = Enthalpy of the air–water mixture flowing past the water and by integrating the Merkel number is obtained as

$$Me = \int \frac{\beta_h \cdot dA}{\dot{M}_w} = \int \frac{c_{pW} \cdot d\vartheta_W}{h''_A - h_A} \tag{16}$$

The energy balance between air and water is

$$\dot{M}_A \cdot (h_{A2} - h_{A1}) = \dot{M}_W \cdot c_{pW} \cdot (\vartheta_{W2} - \vartheta_{W1}) \tag{17}$$

Equations (16) and (17) connect the cooling of the water to the mass transfer rate of the water, considerably simplifying the

calculations. Merkel's assumptions (1 and 2 earlier) have very little influence on results obtained for mechanical draught towers, but they do not result in a correct prediction of air outlet conditions which is problematic in natural draught calculations.

The complete energy balance then becomes

$$\dot{M}_A\left[h_{A2} - h_{A1} - c_{pW}\cdot\vartheta_{W1}\cdot(X_2 - X_1)\right] = \dot{M}_{W2}\cdot c_{pW}\cdot(\vartheta_{W2} - \vartheta_{W1}) \tag{18}$$

4.3 Numerical Calculation Methods

4.3.1 Poppe Method

From Eqs. (10), (13), and (14) it can be shown that

$$\dot{M}_A\cdot dh_A = \beta_x\cdot dA\cdot\left\{h_A'' - h_A + \left(\frac{\alpha}{\beta_X\cdot c_{pm}} - 1\right)\cdot\left[h_A'' - h_A - (X'' - X)\cdot(\Delta h_{V0} + c_{pv}\cdot\vartheta_W)\right]\right\} \tag{19}$$

Using Eqs. (13), (14), and (19) the water temperature can be expressed as independent variable giving

$$\frac{dX}{d\vartheta_W} = c_{pW}\cdot\frac{\dot{M}_W}{\dot{M}_A}\cdot\left\{\frac{X'' - X}{h_A'' - h_A + (\alpha/\beta_X\cdot c_{pm} - 1)\cdot[h_A'' - h_A - (X'' - X)\cdot(\Delta h_{V0} + c_{pv}\cdot\vartheta_W)] - (X'' - X)\cdot c_{pW}\cdot\vartheta_W}\right\} \tag{20}$$

and

$$\frac{dh_A}{d\vartheta_W} = c_{pW}\cdot\frac{\dot{M}_W}{\dot{M}_A}\cdot\left\{1 + \frac{(X'' - X)\cdot c_{pW}\cdot\vartheta_W}{h_A'' - h_A + (\alpha/\beta_X\cdot c_{pm} - 1)\cdot[h_A'' - h_A - (X'' - X)\cdot(\Delta h_{V0} + c_{pv}\cdot\vartheta_W)] - (X'' - X)\cdot c_{pW}\cdot\vartheta_W}\right\} \tag{21}$$

Applying Eqs. (11) and (13) the number of transfer units are given as

$$\mathrm{NTU} = \int\frac{\beta_X\cdot dA}{\dot{M}_W} = \int\frac{dX/d\vartheta_W}{X'' - X}\cdot d\vartheta_W \tag{22}$$

From which it can be seen that

$$\mathrm{NTU} = \frac{\dot{M}_W}{\dot{M}_A}\cdot Me \tag{23}$$

Considering Fig. 7c a simple mass balance gives

$$\dot{M}_{W2} = \dot{M}_W + \dot{M}_A\cdot(X_2 - X)$$

so that

$$\frac{\dot{M}_A}{\dot{M}_W} = \frac{\dot{M}_A}{\dot{M}_{W2}}\cdot\left[1 - \frac{\dot{M}_A}{\dot{M}_{W2}}\cdot(X_2 - X)\right]^{-1} \tag{24}$$

Bosnjakovic [9] derived the following equation giving Lewis number in terms of the air–water content, avoiding the need to approximate it:

$$\frac{\alpha}{\beta_X\cdot c_{pm}} = 0.865^{2/3}\cdot\frac{\frac{0.622 + X''}{0.622 + X} - 1}{\ln\left(\frac{0.622 + X''}{0.622 + X}\right)} \tag{25}$$

Equations (20) and (21) together with Eqs. (22), (24), and (25) can be numerically integrated between the inlet and outlet conditions for given water and airflow ratio, water inlet and outlet temperatures, air inlet wet- and dry-bulb temperatures, and atmospheric pressure, using Runge–Kutta procedure. Since the outlet moisture concentration X_2 is unknown an iterative solution is required. The NTU for the given duty is then calculated by integrating Eq. (22) numerically using Simpson's rule. When the NTU is known for a particular transfer medium from measurements this procedure can be used iteratively to calculate the water outlet temperature for given air and water inlet conditions and flow rates.

In addition, the outlet air state as well as the rate of evaporation can be determined. Kloppers and Kröger [15–17] have shown how the method can be expanded to include supersaturated conditions.

4.3.2 Merkel's Method

Excellent results are obtained using Merkel's Eq. (16) and either a stepwise numerical integration procedure or four-step Chebychev integral to calculate the Merkel number. An example of such a calculation is given by Kröger [4, p. 263].

Yadigaroglu and Pastor [19] and Kloppers and Kröger [15–17, 20] have discussed differences between the more rigorous Poppe method and Merkel's approximate method of calculation. Kloppers and Kröger [21] have also investigated the influence of the Lewis factor assumption on performance predictions. While the Poppe method gives excellent results allowing the determination of the precise air exit conditions as well as accurate predictions of evaporation rates, the Merkel method is most frequently used because of its simplicity. However, according to Kloppers and Kröger [15, 16], as the Merkel method assumes saturated conditions at the exit the value of X is not exact and the evaporation rate calculation is less accurate although the prediction of outlet water temperature is excellent in spite of the deviation of Lewis number from unity. They also found that the Merkel method is considerably improved when the change of water flow rate is taken into account in the numerical integration procedure.

Various methods of integrating Merkel's equation theoretically have been developed in the past by approximating the saturation curve with a parabolic or exponential equation but this is no longer necessary in view of the availability of computer solutions.

4.3.3 NTU Method

Jaber and Webb [22] have shown how the NTU method as applied to heat exchangers can be used for cooling tower calculations, making the same assumptions that Merkel did and approximating the saturated air enthalpy as a linear function of temperature over the range of cooling. (See also Webb [23], Webb and Villacres [24, 25], and Webb and Jaber [26].) A numerical example of such a calculation is also given in Kröger [4, p. 274], who also states that the accuracy of this method is much improved by dividing the calculation into a number of steps.

4.4 Crossflow Theory

Differential equations for a crossflow situation can be derived considering the element in Fig. 8 where the vertical water flow is at right angles to the horizontal airflow. This leads to a set of partial differential equations in the vertical and horizontal directions.

The change of moisture concentration in the horizontal direction is given by

$$\frac{\partial X}{\partial x} = \frac{\beta_X \cdot a \cdot V}{\dot{M}_A} \cdot (X''(\vartheta_W) - X) \tag{26}$$

and the accompanying change of air enthalpy by

$$\frac{\partial h_A}{\partial x} = \frac{\beta_X \cdot a \cdot V}{\dot{M}_A} \cdot \left\{ h_A''(\vartheta_W) - h_A + \left(\frac{\alpha}{\beta_x \cdot c_{pm}} - 1\right) \cdot [h_A''(\vartheta_W) - h_A - (X''(\vartheta_W) - X) \cdot (\Delta h_{V0} + c_{pv} \cdot \vartheta_{W0}] \right\} \tag{27}$$

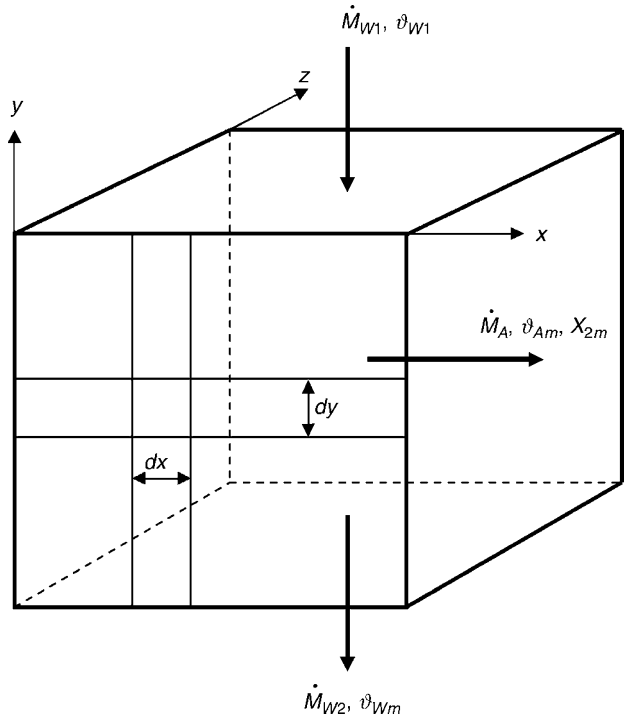
While the temperature change of the water is

$$\frac{\partial \vartheta_W}{\partial y} = \frac{\dot{M}_A}{\dot{M}_W} \cdot \left[\vartheta_W \cdot \frac{\partial X}{\partial x} - \frac{1}{c_{pW}} \cdot \frac{\partial h_A}{\partial x} \right] \tag{28}$$

The Merkel approximation of these equations can be shown to be

$$\frac{\partial h_A}{\partial x} = \frac{\beta_X \cdot a \cdot V}{\dot{M}_A} \cdot (h_A''(\vartheta_W) - h_A) \tag{29}$$

$$\frac{\partial \vartheta_W}{\partial y} = -\frac{\dot{M}_A}{c_{pW} \cdot \dot{M}_W} \cdot \frac{\partial h_A}{\partial x} \tag{30}$$



N4. Fig. 8. Crossflow element model.

The above partial differential equations can be integrated numerically and they have to satisfy the overall energy balance given by

$$\dot{M}_A \cdot [h_{A2} - h_{A1} - c_{pW} \cdot \vartheta_{W2m} \cdot (X_{2m} - X_1)] = \dot{M}_{W1} \cdot c_{pW} \cdot (\vartheta_{W1} - \vartheta_{W2m}) \tag{31}$$

where ϑ_{W2m} and X_{2m} refer to mixing temperature and water content of the outlet water and air streams, respectively. Kloppers and Kröger [27] present a critical analysis of crossflow calculation methods.

5 Fill Materials, Transfer Coefficients, and Pressure Drops

5.1 Fill Transfer and Pressure Drop Coefficients

Theoretical derivations have been done to obtain values for the transfer coefficient β_X but this can only be done for fairly simple geometries e.g., in the work by Poppe and Rogener [11]. Dreyer [28] developed a program to predict the transfer coefficients of splash packs using a complex computer simulation involving dripping, splashing, and film formation and the associated heat and mass transfer with a view to optimizing film design. However, the transfer coefficients used for cooling tower design are invariably determined from experimental test rigs and used in programs employing either Poppe's or Merkel's method of integration. These measurements are usually expressed in equations containing the air and water mass flow rates per unit area or their ratio.

The most common one giving the dimensionless Merkel number as

$$\frac{K \cdot a \cdot V}{\dot{M}_W} = K \cdot \left(\frac{\dot{M}_W}{\dot{M}_A}\right)^{-n} \tag{32}$$

where K (kg/m^2–s/m^3) is a mass transfer coefficient per unit volume. This is usually published as a value per m of h/m^2 of area so that

$$\frac{K \cdot a}{\dot{M}_W} = K_1 \cdot \left(\frac{\dot{M}_W}{\dot{M}_A}\right)^{-n} \Big/ \mathrm{m} \tag{33}$$

Other forms of correlating equations are given below and it is emphasized that these are all dimensional equations so the units used for $\dot{M}_A^a$ and $\dot{M}_w^b$ are of major importance.

$$\frac{\mathrm{NTU}}{h[m]} = K_1 \cdot \dot{M}_A^a \cdot \dot{M}_w^b \tag{34}$$

$$\frac{\mathrm{NTU}}{h[m]} = K_2 \cdot \dot{M}_A^a \cdot \dot{M}_w^b \cdot \vartheta_{Wi}^c \cdot \mathrm{ATD}^d \tag{35}$$

Equally important in the design of cooling towers is the pressure drop (often also referred to as the pressure loss coefficient) as in mechanical draught towers the airflow has to be matched to a chosen fan or in natural draught towers with the difference in densities inside and outside the tower.

The pressure drop coefficient is defined as

$$K_p = \frac{\Delta P}{\rho_m \cdot V^2/2} \tag{36}$$

Next are some commonly encountered correlating equations for pressure drop coefficients as given by Kloppers and Kroger [29]:

$$K_p = K_3 \cdot \dot{M}_A^e \cdot \dot{M}_w^f + K_4 \tag{37}$$

$$K_p = K_5 \cdot \dot{M}_A^g \cdot \dot{M}_W^h \cdot ATD^j \tag{38}$$

It should be noted that these coefficients are usually a weak function of airflow rate and quite strongly dependent on water flow rate.

Typical transfer and pressure drop correlations are shown in Fig. 9a and b.

G_w = Water loading kg/m^2/s; G_A = Airflow rate kg/m^2/s. (L_{fi} = 1.0 m), the form of the second type of equation is proposed by Kloppers and Kröger [29].

5.2 Types of Fill Material

Cooling towers used in the industry contain numerous different kinds of fill material depending on operating conditions. To achieve a high thermal efficiency a high surface transfer area is required and packings with up to 400 m^2/m^3 have been produced. However, high surface densities go hand in hand with high pressure drops and they clog more easily so a compromise is often made.

In high surface density packings, the water is usually spread out over vertical closely packed sheets of plastic material, mostly PVC, and are referred to as film-packs. At the other extreme splashing rather than a water film is used to produce multiple free-falling droplets with high surface area. This is done by using splash bars, wood lattice, or grids of steel or plastic spaced at intervals ranging from 100 to 750 mm. The surface densities thus achieved are considerably lower than that achieved with film-pack, but so are the pressure drops. However, using splashpack a far deeper pack than with film-pack is required to achieve the same amount of cooling leading to greater required pumping heads.

As a compromise trickle-packs are used giving water surface areas somewhere in between film-packs and splash-packs. These packs use a combination of film surface and droplet surface areas and are usually constructed of steel or plastic meshes in various configurations spaced more densely than the splash-packs. They are particularly suitable when nonclogging or easily cleanable fill materials are required for small- and medium-sized cooling towers.

The choice of material from which a pack is made usually depends on the cost, durability, operating temperature, and corrosion resistance. Therefore, stainless steel mesh packs are often used where temperature and durability are strong considerations. Where severe corrosion is a concern, plastics and wood are often used as even stainless steel is sometimes subject to corrosion problems.

Various types of packings are described and their transfer and pressure drop characteristics are given by Cale [30], Kröger [4], and Singham [1].

Some examples of film-, trickle-, and splash-fill are shown in Fig. 10 a–c.

6 Design of Cooling Towers

6.1 Design Conditions for Cooling Towers

To correctly design a cooling tower a number of parameters need to be known including altitude, wet- and dry-bulb temperatures, required water inlet and outlet temperatures, cooling rate, and water flow rate.

In addition to this information on operating conditions including water conditions or dust concentrations in the air, type of operation e.g., continuous or intermittent, as well as supply voltage and frequency is required.

In NDCTs variations of temperature and pressure with altitude as well as temperature inversions can also affect the results.

In selecting design conditions it is important to take the particular application into account. For instance, in air conditioning and chiller applications it is common practice to use a wet bulb which does not extend for more than ten days of the year. It is then accepted that for short periods the system may not cope adequately. Care should also be taken when using published weather data which gives average mean daily values for various periods over numbers of years, as these can often lead to under-design in abnormally long wet-bulb periods. When performance is absolutely critical the maximum expected wet- and dry-bulb conditions should be used.

When designing a cooling tower the total Me transfer units have to be determined and pressure drops have to be accounted for and balanced against either fan pressure in a mechanical draught tower or draught pressure in a natural draught tower.

6.2 Total Transfer Coefficient

The total transfer units include

(1) Fill transfer coefficient;
(2) Spray zone transfer coefficient;
(3) Rain zone coefficient.

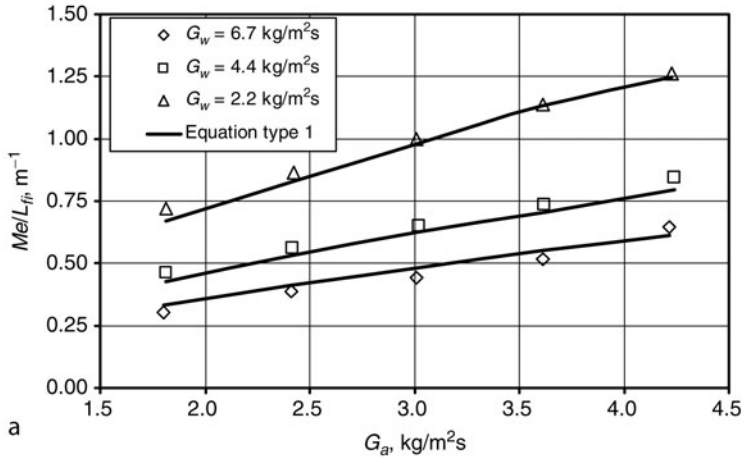
The above values must be calculated for the given height of each section and added so that

$$\frac{K \cdot a \cdot V}{\dot{M}_W} = \frac{K \cdot a \cdot ATD_{\text{fill}}}{\dot{M}_W} + \frac{K \cdot a \cdot ATD_{\text{spray}}}{\dot{M}_W} + \frac{K \cdot a \cdot ATD_{\text{rain}}}{\dot{M}_W} \tag{39}$$

In MDCTs using high density film-fills the spray and rain zone transfer coefficients are usually insignificant compared to the fill transfer coefficient. However, in large MDCTs and NDCTs using trickle- or splash-fills the rain zone especially can make a significant contribution to the overall cooling and pressure drops and need to be taken into account.

The rain zone transfer can be determined using correlations derived by De Villiers and Kröger [31] in terms of tower

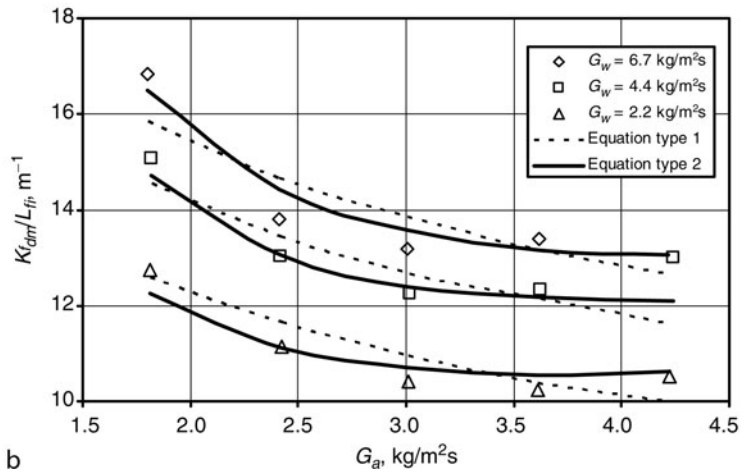
Analysis	Empirical relation	Correlation coefficient
Merkel	$Me_M/L_{fi} = 4.299\ G_w^{-0.657}\ G_a^{0.711}\ T_{wi}^{-0.476}$	0.986



Empirical relations for the loss coefficient (L_{fi} = 1.0 m).

Approach	Eq. type	Empirical relation	Correlation coefficient
Merkel	1	$K_{fdm}/L_{fi} = 12.498\ G_w^{0.209}\ G_a^{-0.267}$	0.874
	2	$K_{fdm}/L_{fi} = 8.829\ G_w^{0.416}\ G_a^{-1.390} + 5.104\ G_w^{0.134}\ G_a^{0.320}$	0.939

Equation types 1 and 2 for the loss coefficient are plotted below.



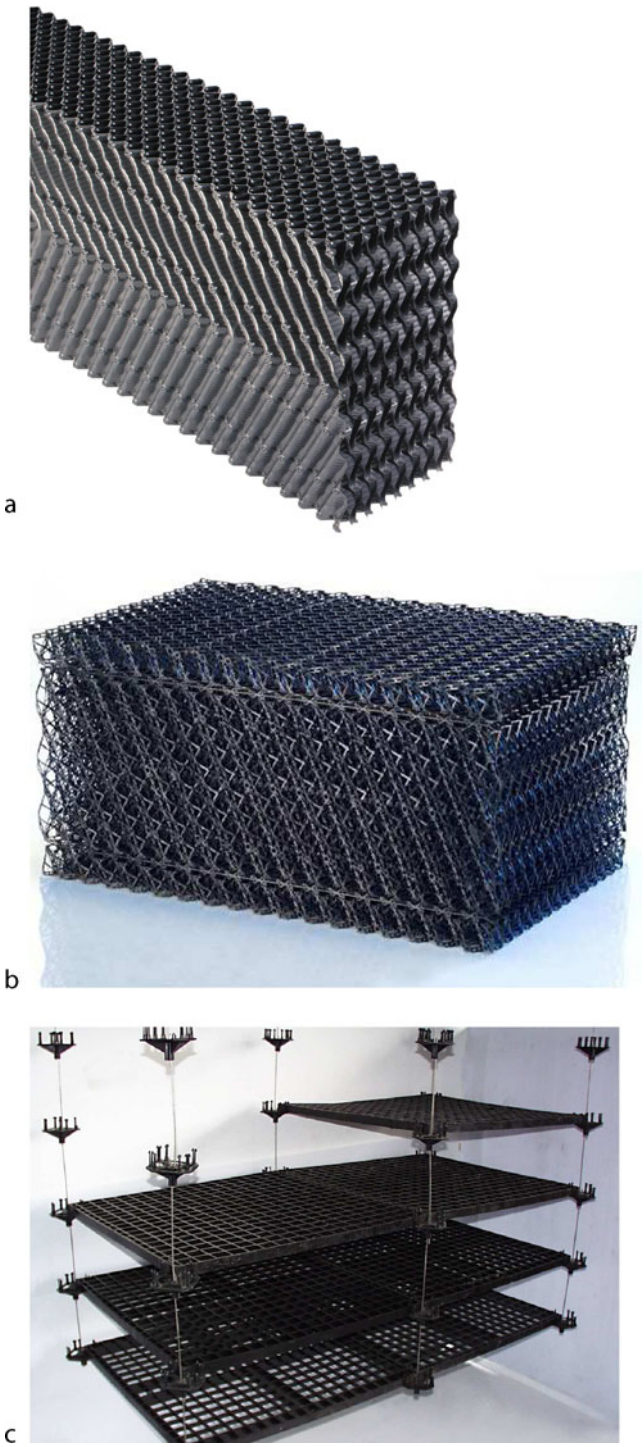
N4. Fig. 9. (**a**) Example of empirical relation for the Merkel number according to the Merkel analyses. (L_{fi} = 1.0 m). (**b**) Example of empirical relations for the fill pressure loss coefficient.

geometry, rain zone height, and droplet size. However, this requires a representative drop diameter. Pearce [32], using the FLUENT CFD program to model rain zones, has shown that the Sauter mean diameter is the representative drop diameter. Terblanche et al. [33] measured drop size distributions beneath film-fills, trickle-fills, and two types of splash-fill. Spray zone transfer can be calculated in a similar way but the Sauter mean needs to be determined for the type of nozzle used.

6.3 Total Pressure Drop

The total pressure drop consists of the following:

(1) Inlet to tower including inlet louvres and support columns;
(2) Rain zone pressure drop;
(3) Fill support system;
(4) Fill;



N4. Fig. 10. (**a**) Film-fill (Picture supplied by Brentwood Industries Inc.). (**b**) Trickle-fill (Picture supplied by GEA Aircooled Systems, South Africa). (**c**) Splash-fill (Picture supplied by GEA Aircooled Systems, South Africa).

(5) Water distribution system and supports;
(6) Drift eliminator support system;
(7) Drift eliminators;
(8) Outlet duct system;
(9) Dynamic pressure of exhaust air.

Each loss coefficient is usually expressed in terms of the mean velocity of the air in the fill so that they can be added together. In the case of the inlet air, the coefficient based on inlet air velocity has to be converted to one based on velocity through the fill so that

$$K_{P1} = K_{p\text{Inlet}} \cdot \frac{V_{\text{Inlet}}^2}{V_{\text{Fill}}^2}$$

And the total pressure loss coefficient is given by

$$K_{\text{Total}} = K_{P1} + K_{P2} + K_{P3} + K_{P4} + K_{P5} + K_{P6} + K_{P7} + K_{P8} + K_{P9} \quad (40)$$

6.4 MDCTs

In a MDCT the fan static pressure is balanced by the pressure drops.

$$\text{Fan static pressure} = K_{\text{Total}} \cdot \rho_{\text{Fill}} \cdot V_{\text{Fill}}^2/2 \quad (41)$$

The static pressure losses together with fan diameter and volume flow rate are used to select a suitable fan.

Whatever type of mechanical draught tower is used computer programs for fan selection are usually employed to select a suitable fan. These could be directly driven fans up to about 1.8 m diameter or fans driven through a gear box or belt transmission system. With large towers the motors are nearly always mounted external to the tower with the fan driven through a transmission system and drive shaft.

Forced draught towers very often use belt-driven centrifugal or axial fans mounted on the side of the tower although certain makes have single or double-impeller axial fans either directly or indirectly driven. As centrifugal fans tend to run more quietly than axial fans of the same capacity, there is often a preference for these in air-conditioning applications. However, in industrial and process applications axial fans tend to dominate.

6.5 NDCTs

In a NDCT, the thermal calculation procedure is identical to that for MDCTs. However, the velocity of the air through the fill has to be assumed and then checked using a draught equation which balances all the flow resistances with the buoyancy of the hot moist air inside the tower against the exterior cold air. This requires multiple iterative procedures which can only be followed using computer routines as hand calculations are an order of magnitude more time consuming than for mechanical draught towers. The relevant draught equations for NDCTs are given in very concise form by Kröger [4] and Singham [1]. In practice even in very tall NDCTs, the air velocities through the fill are much lower than mechanical draught towers, in the order of 0.5–1.5 m/s.

The hyperbolic shape of NDCTs has little to do with the fluid dynamics of the towers and is mainly there for structural reasons. However, the increased exit velocity does help to prevent recirculation of hot outlet air back into the cooling tower.

On the other hand, the higher exit velocity represents a higher flow resistance due to the resulting increase in dynamic loss at the exit.

In a natural draught cooling tower flow of air is achieved due to a difference in the densities of the air inside and outside the tower. A balance is reached when the pressure losses as calculated in Sect. 4.3 are balanced by the pressure difference inside and outside the tower. As the fill height can be quite considerable in large natural draught towers an average height rather than fill exit is used. Referring to Fig. 11.

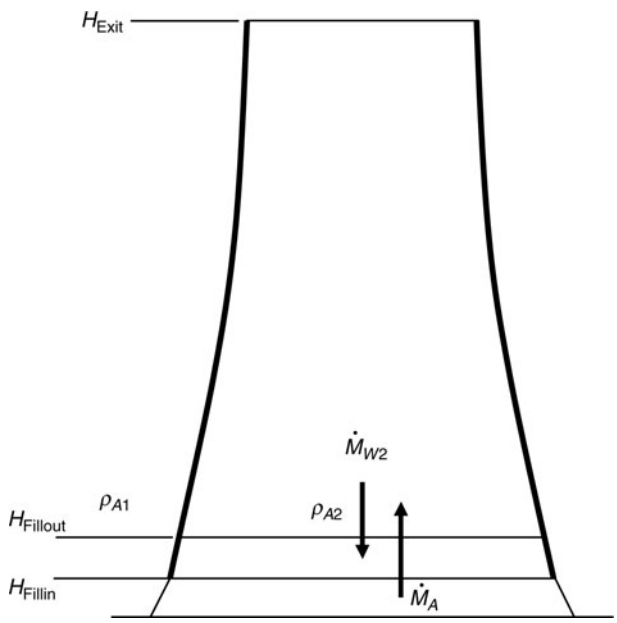
$$-g \cdot [H_{\text{Exit}} - (H_{\text{Fillin}} + H_{\text{Fillout}})/2] \cdot (\rho_{A2} - \rho_{A1}) = K_{\text{Total}} \cdot \frac{\rho_{Ai} \cdot V_{A1}^2}{2} \tag{42}$$

where, the total loss coefficient is calculated as in Eq. (40).

Equation (42) together with the transfer equations has to be solved iteratively to find the steady-state operating condition of the tower. This is usually done in the following steps:

(1) assume a fill velocity (usually between 0.5 and 1.5 m/s);
(2) calculate the cooling rate and outlet condition of the air from the fill;
(3) calculate the total pressure drop;
(4) compare calculated pressure drop to pressure difference due to temperature difference;
(5) adjust velocity until Eq. (42) is balanced.

As natural draught cooling towers are often very high (up to 200 m) this can have a significant influence on the calculated results. Kröger [4] has shown how both pressure and temperature gradients in the atmosphere can be taken into account. As natural draught cooling towers are also very large, the aforementioned one-dimensional approach is essentially an approximation and more accurate results are achieved using axisymmetric two-dimensional computational fluid dynamic procedures as such as those proposed by Majumdar et al. [34, 35]. If wind effects need to be included this would require a three-dimensional numerical approach due to the absence of symmetry.



N4. Fig. 11. Natural draught model.

The air mass flow through the fill is given by

$$\dot{M}_A = A_f \cdot \rho_{A1} \cdot V_{A1} \tag{43}$$

and the inlet air density by

$$\rho_{A1} = \frac{p_A}{R_A \cdot T_A} = \frac{p_{\text{atm}} - p_w}{R_A \cdot T_A} \tag{44}$$

Combining Eqs. (42–44) it can be shown that the mass flow through the tower is given by

$$\dot{M}_A = A_f \cdot \sqrt{\frac{2 \cdot \rho_{A1}^2}{K_{\text{Total}} \cdot \rho_{A1}} \cdot g \cdot [H_{\text{Exit}} - (H_{\text{Fillin}} + H_{\text{Fillout}})/2] \cdot (\rho_{A1} - \rho_{A2})} \tag{45}$$

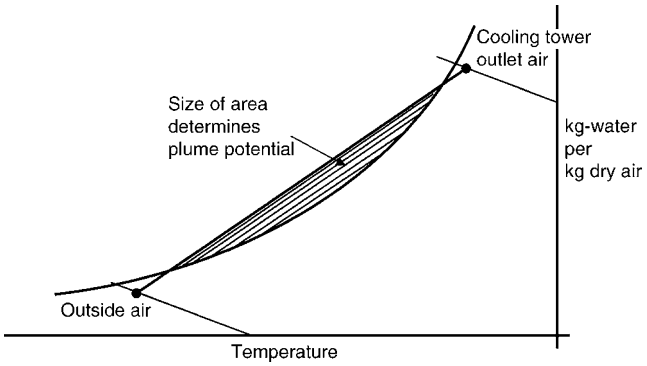
7 Plume Formation

In built-up areas and near highways where low winter temperatures occur, a problem created by the use of evaporative cooling is that of plume formation which people consider unsightly, often leading to mist or drizzle as well as poor visibility on highways. In recent years this subject has enjoyed a considerable amount of attention leading to the use of hybrid systems where dry heat exchangers or stack gases are used to re-evaporate the droplets, thus eliminating visible plumes. When air at saturated or near-saturated conditions is mixed with outside air at low temperatures a supersaturated condition outside the saturation curve is created leading to plume formation as shown in Fig. 12. It has been shown that the degree of plume formation is a function of the area enclosed between the mixing line and the saturation line which should be as small as possible, preferably zero. Kröger [4] gives the theory describing plume formation and discusses several ways of dealing with it by using combinations of wet and dry cooling.

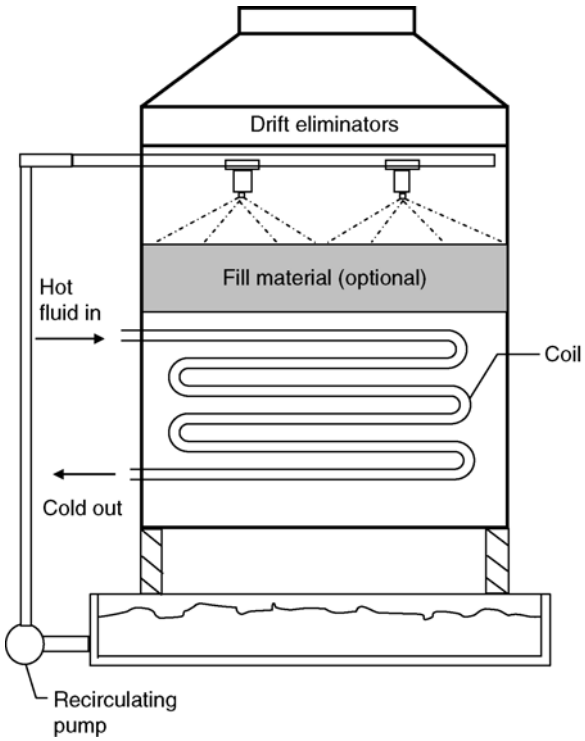
8 Closed Circuit Evaporative Coolers and Condensers

In many instances, it is required that the machine being cooled should not be exposed to open circuit cooling tower water to avoid maintenance problems in the machinery being cooled. This is often the case in compressor cooling in very dusty environments, e.g., cement factories, or where machinery has very small channels through which the water is pumped. Often the fluid being cooled may be another substance such as alcohol, paint, oil or a condensing refrigerant or product in which case a closed circuit is essential. The closed circuit evaporative cooler is nothing more than a heat exchanger inside a cooling tower and is equivalent to a cooling tower with water pumped through an external heat exchanger. Figure 13 shows the arrangement for a closed circuit evaporative cooler/condenser.

In both these devices a multi-tube coil in the tower serves as fill as well as heat exchanger, and sometimes the cooling



N4. Fig. 12. Psychrometric chart illustrating potential for plume formation.



N4. Fig. 13. Closed circuit evaporative cooler or condenser.

capability can be enhanced by the addition of normal cooling tower fill material above or below the coil which increases the evaporative cooling surface area.

These closed circuit evaporative coolers are often referred to as deluged coolers meaning the coil is entirely covered with water at a high flow rate where the evaporation rate is similar to that of a normal cooling tower. Spray cooled heat exchangers which are essentially dry coolers are sometimes sprayed to enhance cooling during high temperature periods where all or most of the water evaporates are also encountered but are beyond the scope of this article.

Probably, the most commonly found closed circuit evaporative cooling device is the evaporative condenser used for condensing refrigerants such as ammonia and HFCLs where, due to the high pressure requirements, they are very competitive against shell-and-tube condensers combined with cooling towers. However, where high pressure is not a consideration a normal plate heat exchanger external to the cooling tower is often price-wise more competitive and the system is easier to maintain.

Evaporative coolers and condensers are very much the same in external appearance to cooling towers and they can usually be identified by the separate closed circuit inlet and outlet headers.

The theory of evaporative coolers/condensers is more complicated than direct evaporative cooling as it incorporates three sets of differential equations for the air, water, and internal fluid which have to be solved simultaneously and a numerical solution of the problem is essential. This theory is covered by Erens [36–39], Finlay and Grant [40], Kröger [4], Leidenfrost and Korenic [41], Mizushina [18] and Webb [42, 43], Parker and Treybal [44]. The combination of coil with fill material has been discussed by Erens [37].

The governing equations for a counterflow closed circuit evaporative cooler are derived next. Similar equations can be derived for evaporative condensers as well as crossflow evaporative coolers and condensers. It is assumed that the airflow is upward and the water flows vertically downward. The fluid inside the tubes moves at right angles to the air and water and can flow in a serpentined arrangement from top to bottom or bottom to top. Obviously, in condensers the tubes are usually slightly inclined and because of condensate flow the general direction is downward i.e., top to bottom.

Considering the element in Fig. 14 and applying Merkel's approximations on the air side:

$$\dot{m}_A \cdot dh_A = \beta_X \cdot dA \cdot (h''_A - h_A) \tag{46}$$

The energy balance between air, water, and process fluid inside the tubes gives

$$\dot{m}_W \cdot c_{pW} \cdot d\vartheta_W = \dot{m}_A \cdot dh_A + \dot{m}_p \cdot c_{pp} \cdot d\vartheta_p \tag{47}$$

and for the heat transfer inside the tubes:

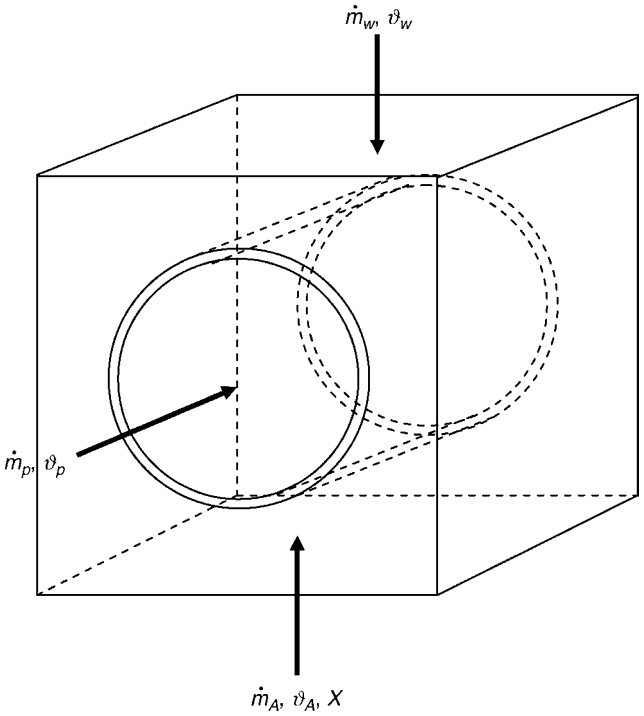
$$\dot{m}_p \cdot c_{pp} \cdot d\vartheta_p = -U_t \cdot (\vartheta_p - \vartheta_W) \cdot dA \tag{48}$$

where U_t is the total heat transfer coefficient between the process fluid and the deluge water so that

$$U_t = \left[\frac{1}{\alpha_W} + \frac{A_e}{A_i \cdot \alpha_p} + \sum \frac{A_e}{A_n} \cdot R_n\right]^{-1} \tag{49}$$

where α_w is the heat transfer coefficient between the water film and tube wall, α_p is the process fluid heat transfer coefficient and the Rn includes all other resistances such as fouling both internal and external as well as the tube wall resistance.

Equations (46–48) have to be integrated numerically over the height, width, and length of the cooler to obtain a solution. By making the simple assumption that the recirculating water has a constant average temperature, Parker and Treybal [44] and Webb [43] have obtained fairly accurate solutions mathematically. The value of β_x has to be determined experimentally in a similar way to that for a conventional fill material.



N4. Fig. 14. Closed circuit evaporative cooler element model.

9 Acceptance Testing

It would be most unusual for a cooling tower to be installed and that the situation arises where the design load occurs at the same time as the design ambient conditions. For this reason, acceptance testing codes have been established, whereby the tower can be tested at a certain condition and the performance predicted for the specified design conditions. The various codes require accurate measurements of water flow rate, inlet and outlet water temperatures, ambient air wet- and dry-bulb temperature and pressure, fan shaft power, wind velocity, and direction.

The cost of an independent cooling tower acceptance test is usually quite high and acceptance testing is therefore not justified in the case of small- and medium-sized towers where the acceptance test cost is a considerable portion of the total cost. Tests are therefore usually carried out only on very large towers. In the USA, the CTI has a system of certifying small tower performance based on standard tests, thus avoiding the expense of testing individual small towers.

Generally, drift-loss measurements are not included in an acceptance test, as this can often prove more difficult and costly than the thermal acceptance test.

The various acceptance test codes are given in British Standard 4485 [45, 46], Cooling Tower Institute [47–50] and Deutsche Normen 1947 [51]. The CTI [52] also publishes a code for testing of closed circuit cooling towers.

10 Water Conditioning

Proper treatment of cooling tower water is essential not only to keep the fill from clogging but also to control corrosion, deposition of solids (scaling) in equipment and to prevent the growth of dangerous bacteria such as *Legionella*.

Burger [3] and Nestor and Cappeline [53] discuss the various factors determining blowdown as well as algae and bacterial control in cooling towers.

When cooling tower water is evaporated the concentrations of chemical substances usually referred to as total dissolved solids (TDS) and total suspended solids (TSS) increase in value. Incoming water from a municipal source usually has a TDS of 50 to 100 ppm, and concentration due to evaporation should not exceed 800 to 900 ppm. This is to prevent precipitation of salts in the fill material. The number of cycles is therefore given by

$$\text{Cycles\_of\_concentration } (C) = \frac{\text{Maximum\_TDS}}{\text{Feedwater\_TDS}} \qquad (50)$$

Blowdown is usually controlled by monitoring the TDS level in the water.

The blowdown can be calculated as

$$\text{Blowdown} = \text{Evaporation\_Rate}/(C-1) - \text{Drift\_loss} \qquad (51)$$

In some cases, the level of the TSS, where feedwater has high levels of silica or high calcium sulfate concentration, can determine the cycles of concentration and also the blowdown rate. In such cases scaling, not just in the fill but in expensive heat exchanger equipment, is the main concern and usually requires more sophisticated monitoring methods for control of blowdown.

Suspended solids entering with the feedwater or ingested at the air intakes can be removed using sidestream filtering depending on the size of the particles involved. A flow rate of 5–10% of cooling tower rate is usually employed. This type of cleaning also assists in removing biological contamination as biological formations often cling to small particles in the water.

In small towers blowdown is often done manually, while in larger units a blowdown solenoid valve is controlled from a TDS sensor. Wirth and Westbrook [54] discuss a method of controlling salinity. The various factors influencing blowdown control are discussed more in detail by Burger [3].

Algae and biological growth are both problematic in cooling tower water, whereas algae requires sunlight to develop and many other biological growths can occur without light forming slimes under any conditions. The latter formations create problems in that they form coatings on the fill and in equipment to which solid particles are attached, clogging the fill and insulating the heat transfer surfaces. These substances have to be prevented from forming by use of biocides, ozone, and chlorine dosing or UV irradiation. All of these methods have their own advantages and disadvantages as corrosion and their influence on precipitation also have to be considered.

Most large installations make use of combinations of filtering and dosing using sophisticated monitoring methods to control water condition, thus maintaining a high cooling efficiency.

11 Symbols

a	area per unit volume (m^2/m^3)
c_p	specific heat at constant pressure (J/kg °C)

p	pressure (Pa)
h	enthalpy (J/kg °C)

N5 Heat Pipes

Peter Stephan
Technische Universität Darmstadt, Darmstadt, Germany

1 Introduction

Heat transfer devices with a very high heat flux density at low temperature differences are typically based on closed two-phase (liquid–vapor) systems. The latent heat of vaporization of the fluid is transferred from the location of the evaporator near the heat source to the location of the condenser near the heat sink. Heat pipes are such heat transfer devices with the particularity that the liquid transport is caused by capillary forces.

Figure 1 shows the principle design of a heat pipe. A closed fluid container, typically a closed pipe or a hollow plate, is internally lined with a capillary structure which is saturated with the liquid phase of the heat transfer fluid. Upon heating one end of the container the liquid evaporates at this location and partially retracts into the capillary structure. The generated vapor flows toward the cold end of the container where it condenses and fills the capillary structure. The difference in the liquid filling height in the structure causes a capillary force that sucks the condensed liquid back to the evaporator. The two-phase loop is thereby closed and the latent heat transferred from the heat source to the heat sink. In between the evaporator and condenser zones an adiabatic transport zone can be located.
Specific features of a heat pipe are

- High heat transport capability at low temperature differences between heat source and sink; e.g., the effective thermal conductivity can be more than two orders of magnitude higher than the thermal conductivity of pure copper.
- Fluid transport without any mechanically moving parts. Therefore, a heat pipe typically shows no wear-out and needs no maintenance.
- The condensate can be transported in a nongravitational environment (e.g., in satellites) or even against gravity.
- Local temperature differences in space or time tend to equalize fast and automatically without control.
- A compact and low-mass architecture of the heat exchanger is possible.
- Complex structural shapes of the heat exchanger can be realized.

Due to these features heat pipes are applied in particular in the following areas:

- Thermal control in space applications, e.g., in satellites.
- Cooling of electronic components, e.g., CPUs.
- Heat recovery in industrial processes and in buildings.

The spectrum of applications hereby spreads over a huge range of operation temperatures from about 5 to 2,200 K.

2 Selection of Fluid, Wall Material, and Capillary Structure

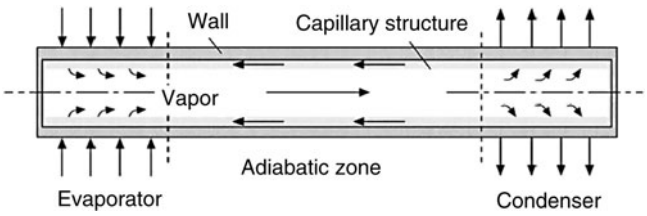
The fluid should have the following properties: high latent heat of vaporization, high thermal conductivity, low viscosity, high surface tension, low wetting contact angle, and neither extremely low nor extremely high vapor pressure at the given operating temperature. Some of these properties are expressed in the so-called merit number M [1],

$$M = \frac{\sigma \Delta h_v}{v_l}, \tag{1}$$

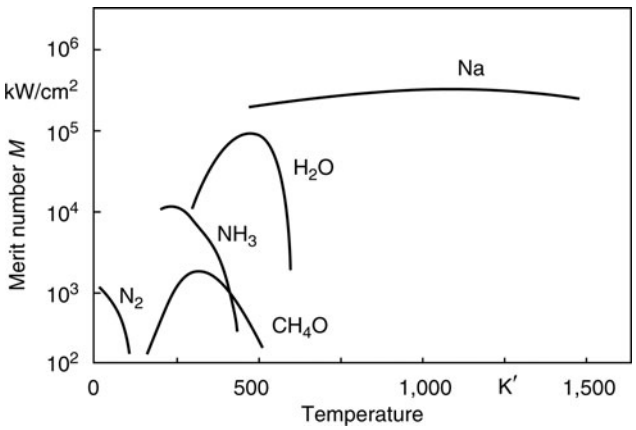
which is not a dimensionless number but has a unit W/m^2 or kW/cm^2. Figure 2 shows the merit number for some fluids that are used in heat pipes. For a given application and its fixed operating temperature range the selection of a fluid with a high merit number is highly desirable. Figure 3 shows further qualified fluids for different temperature ranges.

The selection of the solid material for the container wall and the capillary structure depends not only on its thermal conductivity, which should be rather high, but sometimes even more important on its compatibility with the fluid. Here compatibility comprises (i) good wetting characteristics and (ii) chemical stability to avoid corrosion and the generation of

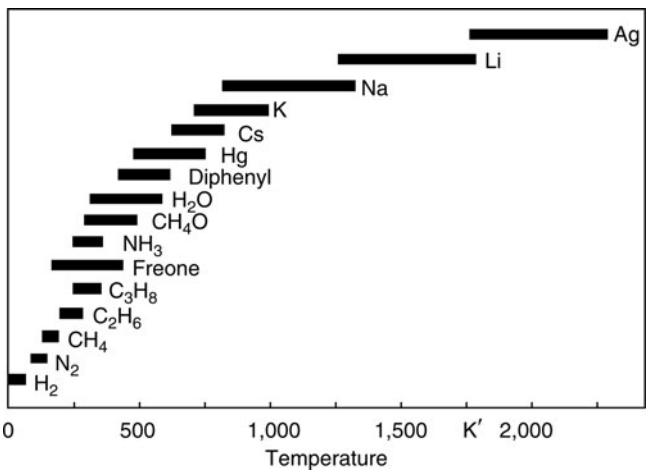
VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_65,



N5. Fig. 1. Principle design of a heat pipe.



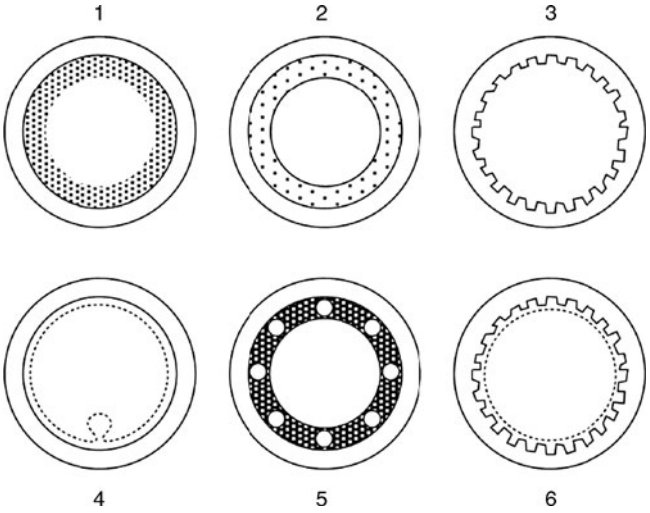
N5. Fig. 2. Merit number for some fluids.



N5. Fig. 3. Qualified fluids for different operating temperature ranges.

noncondensable gases that might block the condenser zone. Long-term tests showed that the following solid–fluid combinations are compatible:

- Freons with aluminum and stainless steel. (However, it should be noted that the use of such chlorofluorocarbons and hydrochlorofluorocarbons is forbidden in many applications today due to their negative effect on the ozone layer of the earth.)
- Ammonia with aluminum, construction steel, stainless steel, and nickel.
- Acetone with copper.
- Methanol with copper.



N5. Fig. 4. Different capillary structures: (1) wick or mesh structure, (2) sinter structure, (3) open axial grooves, (4)–(6) combined structures.

- Water with copper.
- Potassium with copper.
- Sodium with stainless steel, nickel, and inconel.
- Lithium with niobium, tantalum, tungsten, and molybdenum.
- Silver with tantalum and tungsten.

The compatibility also depends on the production and post-cleaning methods which might explain the partly different compatibility observations from different authors using the same material combinations [1–5]. Reay and Kew [1] as well as Brost and Groll [5] have given details about specific production and cleaning methods.

Additionally to the aforementioned compatibility issues, the capillary structure should have the following features:

- Generation of a high capillary pressure in the evaporator region which means it should be a fine structure.
- Low liquid flow resistance or pressure drop along main flow direction which means it should be a gorse structure.
- Insensitivity against vapor bubble generation and growth to avoid a blockage of the capillary structure.
- Large storage capability for the liquid phase.

As can be seen these features are partly controversial and therefore require a compromise for the selection of the capillary structure. In any case the selection of the combination fluid/wall material/capillary structure has to be proved finally by a computation of the performance limits of the selected design and its comparison with the performance requirements (for details see Sect. 4 of this chapter).

Figure 4 schematically shows the cross section of a heat pipe with different capillary structures that were proven in the past. Wick or mesh structures (1) and sinter structures (2) allow a high capillary pressure, but typically generate a high liquid flow resistance and are sensitive to vapor bubble formation. Open axial grooves (3) have a relatively small flow resistance, and bubbles that might be generated can vent to the vapor core, but they allow only low to moderate capillary pressures. Some more

sophisticated structures (4, 5, 6) partly combine positive features of the aforementioned structures (1) to (3).

3 Theory and Design for Steady-State Operation

The heat transfer characteristics are determined by the hydrodynamic flow resistances and the heat resistances. The theoretical background and the equations for a basic thermohydraulic design for the steady-state operation mode are given in the following subsections.

3.1 Pressure Profiles

Figure 5 shows a typical pressure profile in the vapor/gas phase and the liquid phase along the heat pipe. As the fluid circulates in a closed circuit the sum of all pressure drops and differences along a single loop must be zero:

$$0 = \Delta p_c + \Delta p_g + \Delta p_l. \tag{2}$$

Herein, Δp_g is the total pressure drop along the vapor flow, Δp_l the total pressure drop along the liquid flow, and Δp_c the capillary pressure difference that has to equalize these two pressure drops and thereby drive the fluid flow. Equation (2) is the basic equation for the hydraulic design.

As can be seen in Fig. 5, the pressure difference between liquid and gas phases typically is highest at the evaporator end and lowest at the condenser end. Thus, the capillary structure is saturated with liquid at the condenser end and the liquid–vapor interface is almost flat, and the liquid recedes more and more into the capillary structure toward the evaporator end. Both situations are schematically indicated at the bottom of the figure. The location where the capillary structure is flooded is also called "wet-point." Due to the possible pressure recovery along the vapor flow in the condenser the wet-point can also be located in the condenser entrance region. The location where the capillary structure tends to dry out first at the capillary limit is also called "dry-point."

3.1.1 Capillary Pressure Difference

In a steady-state operation mode the curvature of the liquid–vapor menisci at each location along the heat pipe attune to local pressures of the vapor and liquid phases. This means, according to

$$p_c = p_g - p_l = \sigma\left(\frac{1}{R_1} + \frac{1}{R_2}\right), \tag{3}$$

a meniscus will have a curvature K, which in a general 3D case can be expressed by two main radii R_1 and R_2.

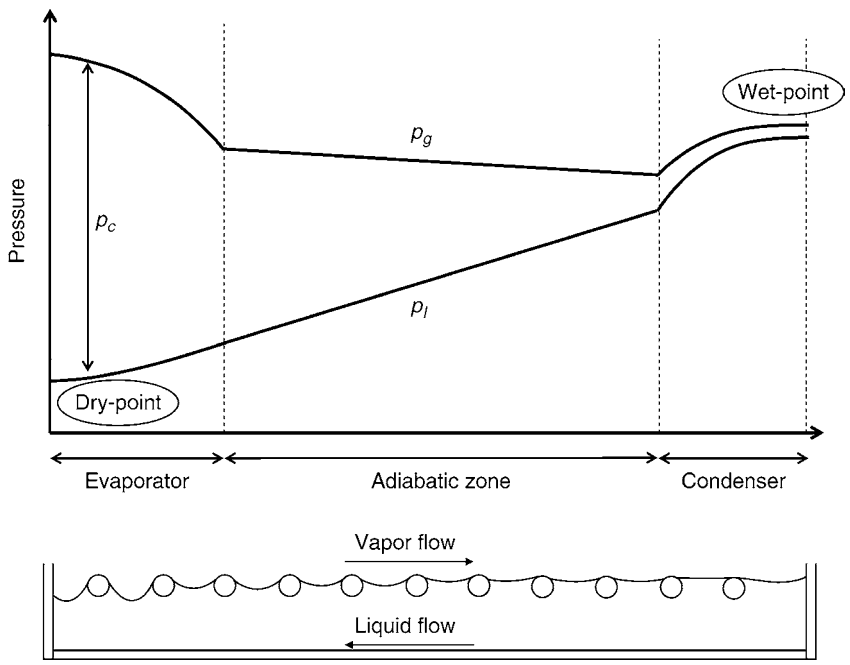
Chi [3] instead defined an effective radius of curvature R_{eff} that characterizes the capillary structure. His definition is based on the assumption of a spherical liquid–vapor phase interface and takes into account the wetting angle of the liquid at the solid structure. It follows

$$p_c = \frac{2\sigma}{R_{eff}} \cos\vartheta. \tag{4a}$$

The maximum capillary pressure that can be generated by a capillary structure for given surface tension σ and wetting angle ϑ depends only on the geometry of the capillary structure or the minimum effective radius of curvature $R_{eff,min}$. It follows

$$p_{c,max} = \frac{2\sigma}{R_{eff,min}} \cos\vartheta. \tag{4b}$$

$R_{eff,min}$ can be derived theoretically, e.g., for open grooves from their geometry or alternatively experimentally for any kind of



N5. Fig. 5. Pressure profiles along a heat pipe.

structures including those with statistical pore size distributions, e.g., sintered metals [4]. Table 1 shows minimum effective radii of curvature $R_{\text{eff,min}}$ for different types of structures.

The capillary pressure difference Δp_c in Eq. (2) equals the difference of the capillary pressure $p_{c,evap}$ at the evaporator end and the capillary pressure $p_{c,cond}$ at the condenser end:

$$\Delta p_c = p_{c,evap} - p_{c,cond.} \tag{5a}$$

Thus, the capillary pressure difference becomes maximal if

(a) $p_{c,evap}$ becomes maximal and
(b) $p_{c,cond}$ becomes minimal.

These conditions are fulfilled if

(a) the liquid is receded as far as possible into the capillary structure at the evaporator end (i.e., $R_{\text{eff,evap}} = R_{\text{eff,min}}$) and
(b) the capillary structure is completely flooded with liquid at the condenser end (i.e., $R_{\text{eff,cond}} \rightarrow \infty$). (Note that the amount of fluid filled into the heat pipe should always be chosen such that there is little excess liquid. This excess liquid accumulates at the condenser end, and therefore, this condition is fulfilled under standard operating conditions.)

It follows

$$\Delta p_{c,max} = \frac{2\sigma}{R_{\text{eff,min}}} \cos\vartheta. \tag{5b}$$

The wetting angle ϑ is the macroscopically apparent contact angle, and it depends on the pairing fluid/capillary material, the surface roughness, the surface state (e.g., oxidation state), and the local heat flux. Typically, the apparent contact angle is measured under isothermal conditions with standardized methods, see e.g., [4]. Here, the influence of the local heat flux in the contact line area is neglected. Wayner [6], Stephan [7], and Khrustalev and Faghri [8] developed numerical methods to compute the apparent contact angle under evaporating conditions. These values are little higher than those under isothermal conditions and increase with the evaporative heat flux, but general correlation still do not exist. If accurate and reliable data for ϑ are not available (e.g., from measurements) the values listed in Table 2 are used for heat pipe design. In case a range of wetting angles is given in the literature the upper value should be chosen for the design to be on the safer side when calculating $\Delta p_{c,max}$.

N5. Table 1. Minimum effective radii of curvature [3]

Capillary structure	$R_{\text{eff,min}}$	Geometric parameter	
Circular artery	R	R	Radius of artery
Rectangular groove	w	w	Groove width
Triangular groove	$w/\cos\beta$	w	Groove width
		β	Opening angle
Screen wicks/ meshes	$(w + d)/2$	w	Mesh width
		d	Wire diameter
	$1/(2N)$	N	Mesh number per unit length
Sintered powders	$0.41R$	R	Particle radius

3.1.2 Liquid Pressure Drop

The pressure drop along the liquid flow comprises the pressure loss due to friction $\Delta p_{l,fric}$ and the hydrostatic pressure difference $\Delta p_{l,stat}$, thus

$$\Delta p_l = \Delta p_{l,fric} - \Delta p_{l,stat.} \tag{6}$$

Since the friction pressure loss is proportional to the mass flow and the mass flow varies in both the evaporator and the condenser zone, an effective length of the heat pipe is defined and used for pressure loss calculation instead of the overall geometrical length. The effective length is defined by

$$l_{\text{eff}} = \frac{1}{\dot{Q}} \int_0^l \dot{Q}(z)\,\mathrm{d}z, \tag{7}$$

where l is the length in axial flow direction z, $\dot{Q}(z)$ is the axial heat flow along the heat pipe at a position z, and $\dot{Q}$ is the total or maximum axial flow. Assuming constant radial heat flux in the evaporator and condenser zone $\dot{Q}(z)$ will rise linearly from the evaporator end toward the adiabatic zone, it will be constant along the adiabatic zone, and it will decrease linearly from the adiabatic zone to the condenser end. With this, Eq. (7) results in

$$l_{\text{eff}} = \frac{1}{2} l_{evap} + l_{ad} + \frac{1}{2} l_{cond}. \tag{8}$$

The liquid flow in a capillary structure is typically laminar; however, the specific flow characteristics in specific capillary structures require specific approaches for the pressure loss calculation.

- The Hagen–Poiseuille equation can be used for open or covered capillary grooves and artery structures:

$$\Delta p_{l,\,fric} = -\frac{32 \nu_l}{A_l \Delta h_v d_{c,h}^2} \dot{Q} l_{\text{eff}}. \tag{9}$$

  Herein, $d_{c,h}$ is the hydraulic diameter of the flow channel and A_l is cross-sectional area of the channel. For heat pipes with N axial grooves with a cross section A_{groove} each, it follows $A_l = N A_{\text{groove}}$.

- For sinter structures or wicks the pressure loss according to Darcy's law is applied:

$$\Delta p_{l,\,fric} = -\frac{\nu_l}{K A_l \Delta h_v} \dot{Q} l_{\text{eff}}. \tag{10}$$

  Herein, K is the permeability of the capillary structure. For homogeneous meshes, it is according to Marcus [10]

$$K = \frac{d^2 \varepsilon^3}{122(1-\varepsilon)^2} \tag{11}$$

  with the porosity ε and the wire diameter d.

N5. Table 2. Wetting angles for various fluids

Fluid	Wetting angle ϑ
Water [9]	40°–45°
Hydrocarbons [9]	35°
Ammonia [6]	20°–25°

For homogeneous sinter metals it is according to Chi [3]

$$K = \frac{r^2 \varepsilon^3}{37.5(1-\varepsilon)^2} \tag{12}$$

with the radius r of the sintered particles.

For nonhomogeneous structures the permeability can be measured [4].

The hydrostatic pressure difference along the liquid flow is calculated by

$$\Delta p_{l,stat} = -\rho_l g\ h, \tag{13}$$

with the height h against the gravitational axis. Figure 6 shows a tilted heat pipe with a tilt angle α against the horizontal line.

Assuming that the geometry of the capillary structure does not allow circumferential liquid flow (e.g., axial grooves), the height is given by

$$h = \pm l \sin\alpha, \tag{14}$$

with the total length l of the heat pipe. The negative algebraic sign is valid if the evaporator is located below the condenser. In this case the hydrostatic pressure difference assists the liquid flow ($\Delta p_{l,stat} > 0$). If the evaporator is located above the condenser, the positive sign is valid, and the gravity opposes the flow ($\Delta p_{l,stat} < 0$).

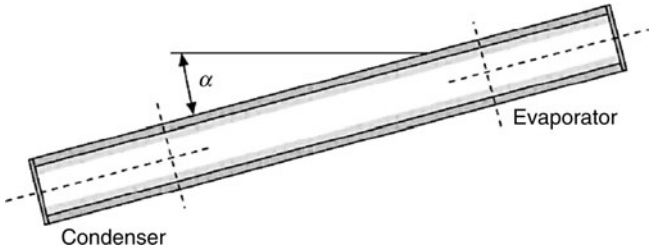
In case the geometry of the capillary structure also allows circumferential liquid flow (e.g., wicks) the height is given by

$$h = \pm l \sin\alpha + d_i \cos\alpha, \tag{15}$$

with the inner diameter d_i of the pipe.

3.1.3 Vapor Pressure Drop

The hydrostatic pressure difference along the vapor channel can be neglected. The hydrodynamic pressure drop along the vapor flow consists of the friction part along the entire vapor channel and an additional inertia part in the evaporator and condenser zone due to the acceleration and deceleration of the vapor flow in these two zones. Many authors have developed analytical or numerical, one- or two-dimensional solutions for the Navier–Stokes equations for several different heat pipe configurations (e.g., [3, 4, 11, 12]). Typically, the Mach number in the vapor flow will be small enough (Ma < 0.3) to assume incompressible flow characteristics. However, some special heat pipes (e.g., high temperature liquid metal heat pipes) or special operating situations (e.g., some start-up procedures) require the consideration of compressible flow characteristics. These special cases are, e.g., described by Faghri [4]. Assuming incompressible flow the following approach for calculating the pressure drop is applied.



N5. Fig. 6. Tilted heat pipe.

The pressure drops in the evaporator zone, the adiabatic zone, and the condenser zone are treated separately. It yields

$$\Delta p_g = \Delta p_{g,evap} + \Delta p_{g,cond} + \Delta p_{g,ad}. \tag{16}$$

The pressure drop in the adiabatic transport zone is governed by friction only. The axial Reynolds number is

$$\mathrm{Re}_a = \frac{\dot{Q} d_{g,h}}{\nu_g \rho_g A_{g,a} \Delta h_v}, \tag{17}$$

with the hydraulic diameter $d_{g,h}$ of the axial cross section $A_{g,a}$.

The flow is laminar for $\mathrm{Re}_a < 2{,}300$. In this case the pressure drop $\Delta p_{g,ad}$ is calculated according to the Hagen–Poiseuille law

$$\Delta \rho_{g,ad} = -\frac{32 \nu_g}{A_{g,a} \Delta h_v d_{g,h}^2} \dot{Q} l_{ad}. \tag{18}$$

For $\mathrm{Re}_a > 2{,}300$ the flow is considered to be turbulent, which means that the transition region between laminar and turbulent flows is omitted. Following the Blasius approach, it is

$$\Delta \rho_{g,ad} = -\frac{0.3164}{\sqrt[4]{\mathrm{Re}_a}} \frac{\dot{Q}^2 l_{ad}}{2 \rho_g A_{g,a}^2 \Delta h_v^2 d_{g,h}}. \tag{19}$$

In the evaporator and condenser zone the vapor velocity has also a radial component. The deformation of the flow profile compared to a purely axial flow is described by the radial Reynolds numbers in the evaporator and condenser. It is defined by

$$\mathrm{Re}_r = \frac{\dot{Q} r_g}{\nu_g \rho_g A_{g,r} \Delta h_v}. \tag{20}$$

Here, r_g is the radius of the vapor channel in the axial cross section and $A_{g,r}$ the surface area where evaporation or condensation takes place. The radial added vapor mass in the evaporator zone has a stabilizing effect to the axial vapor flow for Reynolds numbers $|\mathrm{Re}_r| >> 1$, i.e., the transition from laminar to turbulent flow is shifted to higher axial Reynolds numbers. In the condenser zone, vapor mass is subtracted and a Reynolds number $|\mathrm{Re}_r| >> 1$ has a destabilizing effect to the axial vapor flow. The laminar–turbulent transition is shifted to lower axial Reynolds numbers.

For $|\mathrm{Re}_r| << 1$ the inertia effects originating from the radial velocity components are negligible compared to the friction effects and for $|\mathrm{Re}_r| >> 1$, vice versa.

- For $|\mathrm{Re}_r| << 1$ and $\mathrm{Re}_a < 2{,}300$, i.e., laminar friction dominated flow, the Hagen–Poiseuille law yields

$$\Delta p_{g,evap} = -\frac{32 \nu_g}{A_{g,a} \Delta h_v d_{g,h}^2} \dot{Q} \frac{l_{evap}}{2}. \tag{21}$$

and

$$\Delta p_{g,cond} = -\frac{32 \nu_g}{A_{g,a} \Delta h_v d_{g,h}^2} \dot{Q} \frac{l_{cond}}{2}. \tag{22}$$

- For $|\mathrm{Re}_r| << 1$ and $\mathrm{Re}_a > 2{,}300$, i.e., turbulent friction dominated flow, it is

$$\Delta p_{g,evap} = -\frac{0.3164}{\sqrt[4]{Re_a}} \frac{\dot{Q}^2 l_{evap}}{4\rho_g A_{g,a}^2 \Delta h_v^2 d_{g,h}} \tag{23}$$

and

$$\Delta p_{g,cond} = -\frac{0.3164}{\sqrt[4]{Re_a}} \frac{\dot{Q}^2 l_{cond}}{4\rho_g A_{g,a}^2 \Delta h_v^2 d_{g,h}}. \tag{24}$$

- For $|Re_r| \geq 1$ the inertia effects have to be taken into account. In the evaporator zone and the condenser zone the inertia forces act in contrary direction, i.e., a pressure recovery can be observed in the condenser. According to the model of Cotter [11] the pressure recovery in the condenser is approximately 40% of the pressure drop in the evaporator. The models of Busse [12] and Faghri [4] predict almost 100% pressure recovery which is in accordance with the experimental investigations of Haug [13]. Assuming 100% pressure recovery it follows

$$\langle \Delta p_{g,evap} + \Delta p_{g,cond} \rangle_{|Re_r|\geq 1} = \langle \Delta p_{g,evap} + \Delta p_{g,cond} \rangle_{|Re_r|<<1}, \tag{25}$$

and the aggregated pressure drops in the evaporator and condenser can be calculated using Eqs. (21–24).

Example 1

A heat pipe is used for electronics cooling in a satellite. The required heat flux is 50 W and the operating temperature ϑ_{sat} = 10°C. The heat pipe is made of an aluminum tube with 32 rectangular axial open grooves (w = 0.5 mm, h = 0.8 mm). The grooves are equally distributed around the circumference of the tube (d_i = 9 mm, d_a = 14 mm). The lengths of the evaporator and condenser zone are 100 mm each. The length of the adiabatic transport zone is 780 mm. Ammonia is used as the working fluid. The heat is supplied and rejected homogeneously to the evaporator and from the condenser, respectively (constant heat flux density can be assumed). The questions are:

(a) What is the maximal capillary pressure difference $\Delta p_{c,\,max}$ that the capillary structure can withstand?
(b) What is the capillary pressure difference Δp_c under the given operating conditions?

The required properties of NH_3 at 10°C are

ρ_l = 624.6 kg/m^3,	ν_g = 19.08 · 10^{-7} m^2/s,
ρ_g = 4.865 kg/m^3,	σ = 23.88 · 10^{-3} N/m,
λ_l = 499.6 · 10^{-3} W/(m K),	Δh_v = 1225.5 kJ/kg,
ν_l = 2.490 · 10^{-7} m^2/s.	

Solution

(a) According to Eq. (5b) the maximal pressure difference is

$$\Delta p_{c,max} = \frac{2\sigma}{R_{eff,min}} \cos\vartheta.$$

The minimal effective radius of curvature is taken from Table 1. For rectangular open grooves, we find

$$R_{eff,min} = w = 0.5 \text{ mm}.$$

According to Table 2 the apparent wetting angle ϑ is in the range from 20° to 25°. For a conservative calculation of the maximal capillary pressure difference the upper value has to be considered. With ϑ = 25° it follows

$$\Delta p_{c,max} = \frac{2 \cdot 23.88 \cdot 10^{-3}}{0.5 \cdot 10^{-3}} (\text{N/m}^2) \cos 25° = 86.6 \text{ Pa}.$$

(b) The capillary pressure difference for given operating conditions is calculated using Eq. (2):

$$\Delta p_c = -(\Delta p_g + \Delta p_l).$$

The pressure drop along the liquid flow is given by Eq. (6). For a satellite application (zero gravity) the hydrostatic pressure difference yields $\Delta p_{l,stat}$ = 0. With Eqs. (6) and (9), it follows

$$\Delta p_l = \Delta p_{l,stat} = -\frac{32\nu_l}{A_l \Delta h_v d_{c,h}^2} \dot{Q} l_{eff}.$$

The effective length of the heat pipe is (see Eq. (8))

$$l_{eff} = \frac{1}{2} l_{evap} + l_{ad} + \frac{1}{2} l_{cond} = \left(\frac{100}{2} + 780 + \frac{100}{2}\right) \text{mm} = 880 \text{ mm}.$$

The cross-sectional area of a single groove is

$$A_{groove} = w \cdot h = 0.5 \cdot 0.8 \text{ mm}^2 = 0.4 \text{ mm}^2.$$

Thus, the entire liquid flow cross section is

$$A_l = N \cdot A_{groove} = 32 \cdot 0.4 \text{ mm}^2 = 12.8 \text{ mm}^2.$$

The hydraulic diameter is

$$d_{c,h} = \frac{4 \cdot A_{groove}}{2h + w} = \frac{4 \cdot 0.4}{2 \cdot 0.8 + 0.5} \text{ mm} = 0.762 \text{ mm}.$$

As a result one gets

$$\Delta p_l = \frac{-32 \cdot 2.49 \cdot 10^{-7} \cdot 50 \cdot 880 \cdot 10^{-3}}{12.8 \cdot 10^{-6} \cdot 1225.5 \cdot 10^3 \cdot (0.762 \cdot 10^{-3})^2} \text{ Pa} = -38.5 \text{ Pa}.$$

The pressure drop along the vapor flow is calculated according to Eq. (16):

$$\Delta p_g = \Delta p_{g,evap} + \Delta p_{g,cond} + \Delta p_{g,ad}.$$

First, one has to check whether the axial flow in the adiabatic zone is laminar or turbulent. Equation (17) yields

$$Re_a = \frac{\dot{Q} d_{g,h}}{\nu_g \rho_g A_{g,a} \Delta h_v} = \frac{50 \cdot 9 \cdot 10^{-3}}{19.08 \cdot 10^{-7} \cdot 4{,}865 \cdot 63.62 \cdot 10^{-6} \cdot 1225.5 \cdot 10^3} = 621.8,$$

wherein the hydraulic diameter of the vapor channel is $d_{g,h}$ = d_i = 9 mm and its cross section $A_{g,a} = \pi d_i^2/4$ = 63.62 mm^2.

Thus, the vapor flow is laminar, and the pressure drop in the adiabatic zone follows from Eq. (18):

$$\Delta p_{g,ad} = -\frac{32\nu_g}{A_{g,a}\Delta h_v d_{g,h}^2}\dot{Q}l_{ad} = \frac{-32\cdot 19.08\cdot 10^{-7}\cdot 50\cdot 780\cdot 10^{-3}}{63.62\cdot 10^{-6}\cdot 1225.5\cdot 10^{3}\cdot (9\cdot 10^{-3})^2}\ \text{Pa} = -377\ \text{mPa}.$$

To calculate the pressure drops in the evaporator and condenser zone we have to specify the possible influence of the radial flow components first. As the geometries of the evaporator and condenser are equal, their radial *Reynolds* numbers are – apart from the sign – equal too. It follows from Eq. (20)

$$|\text{Re}_r| = \frac{\dot{Q}r_g}{\nu_g\rho_g A_{g,r}\Delta h_v} = \frac{50\cdot 4.5\cdot 10^{-3}}{19.08\cdot 10^{-7}\cdot 4{,}865\cdot 2{,}827\cdot 10^{-6}\cdot 1225.5\cdot 10^{3}} = 7.0,$$

with the radius of the vapor channel $r_g = d_i/2 = 4.5$ mm and the surface area of the evaporator and condenser zone, $A_{g,r} = \pi d_i \cdot l_{evap/cond} = 2{,}827\ \text{mm}^2$. For $\text{Re}_r = 7$ the inertia effects are not negligible and the pressure drops are calculated according to Eq. (25),

$$\langle \Delta p_{g,evap} + \Delta p_{g,cond}\rangle_{|\text{Re}_r|\geq 1} = \langle \Delta p_{g,evap} + \Delta p_{g,cond}\rangle_{|\text{Re}_r|<<1},$$

and Eqs. (21) and (22)

$$\Delta p_{g,evap} + \Delta p_{g,cond} = -\frac{32\nu_g\dot{Q}}{A_{g,a}\Delta h_v d_{g,h}^2}\left(\frac{l_{evap}}{2}+\frac{l_{cond}}{2}\right) = \frac{-32\cdot 19.08\cdot 10^{-7}\cdot 50\cdot 100\cdot 10^{-3}}{63.62\cdot 10^{-6}\cdot 1225.5\cdot 10^{3}\cdot (9\cdot 10^{-3})^2}\ \text{Pa} = -48.3\ \text{mPa}.$$

The pressure drop along the vapor flow accumulates to

$$\Delta p_g = -(377 + 48.3)\ \text{mPa} = -425.3\ \text{mPa}$$

and the capillary pressure difference under the given operation conditions is

$$\Delta p_c = (0.4253 + 38.5)\ \text{Pa} = 38.93\ \text{Pa}.$$

3.2 Heat Transport

From the point of view of an external observer a heat pipe can be regarded as a thermal conductor with very low heat resistance. With that the temperature difference ΔT between heat source and heat sink simply follows the resistance law

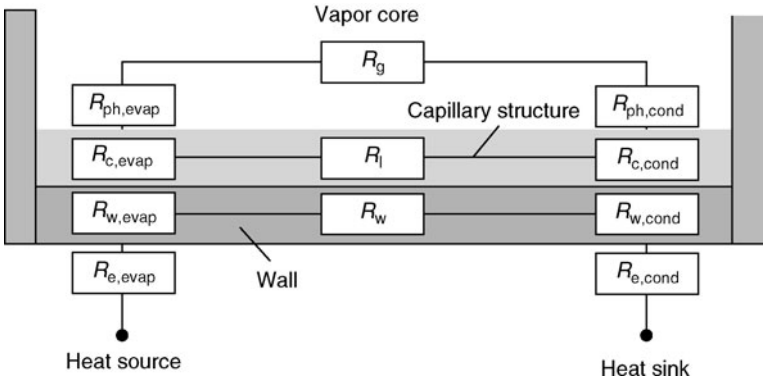
$$\Delta T = \dot{Q}R_{total} \tag{26}$$

with the total heat resistance R_{tot} of the entire heat pipe. This heat resistance includes all single heat resistances that are relevant to the heat pipe system. The single heat resistances are shown in Fig. 7. Some act as parallel resistances and the others as serial resistances in the overall circuit.

The single resistances are:

$R_{e,evap}$	Radial heat resistance between external heat source and outer evaporator wall
$R_{w,evap}$	Radial heat resistance of the evaporator wall
$R_{c,evap}$	Radial heat resistance of the capillary structure in the evaporator zone
$R_{ph,evap}$	Radial heat resistance of the liquid–vapor phase interface in the evaporator zone
R_g	Axial heat resistance along the vapor flow
$R_{ph,cond}$	Radial heat resistance of the liquid–vapor phase interface in the condenser zone
$R_{c,cond}$	Radial heat resistance of the capillary structure in the condenser zone
$R_{w,cond}$	Radial heat resistance of the condenser wall
$R_{e,cond}$	Radial heat resistance between outer condenser wall and external heat sink
R_l	Axial heat resistance along the liquid flow in the capillary structure
R_w	Axial heat resistance in the wall

The heat from the external heat source and the heat to the external heat sink can be transferred by conduction, convection, or radiation. The related heat resistances are typically as high as



N5. Fig. 7. Heat resistances in a heat pipe.

or even higher than the overall internal heat resistance of a heat pipe. If this internal heat resistance is R_{HP} it follows

$$R_{total} = R_{e,evap} + R_{e,cond} + R_{HP}. \quad (27)$$

To calculate the external resistances $R_{e,evap}$ and $R_{e,cond}$ the reader is referred to Parts F (natural convection), G (forced convection), and K (radiation) because no specific heat pipe problems have to be considered here.

Table 3 shows the orders of magnitude of the individual heat resistances that can be observed typically in heat pipes.

Comparing these orders of magnitude it becomes obvious that some of the parallel or serial heat resistances in the circuit can be neglected compared to others. The negligible resistances are R_l and R_w compared to R_g and R_g, $R_{ph,evap}$, $R_{ph,cond}$ compared to $R_{w,evap}$, $R_{w,cond}$, $R_{c,evap}$, and $R_{c,cond}$. Therefore, the overall internal heat resistance of a heat pipe can be approximated by

$$R_{HP} = R_{w,evap} + R_{c,evap} + R_{w,cond} + R_{c,cond}. \quad (28)$$

For circular heat pipes the radial heat resistance of the evaporator wall $R_{w,evap}$ follows from *Fourier*'s law:

$$R_{w,evap} = \frac{\ln(d_{w,o}/d_{w,i})}{2\pi l_{evap}\lambda_w} \quad (29)$$

with the outer wall diameter $d_{w,o}$, the inner wall diameter $d_{w,i}$, and the thermal conductivity λ_w of the wall material.

For planar heat pipes one obtains

$$R_{w,evap} = \frac{s_w}{A_{evap}\lambda_w}, \quad (30)$$

where s_w is the thickness of the wall and A_{evap} the evaporator surface area.

The solid capillary structure is assumed to be saturated with liquid, and the evaporation takes place at the free surface of the liquid. Pool or flow boiling has to be avoided because vapor bubbles might block the capillary action. The radial heat transfer in the capillary structure is dominated by thermal conduction. The heat resistance $R_{c,evap}$ is calculated in analogy to Eqs. (29) and (30). It follows

$$R_{c,evap} = \frac{\ln(d_{k,o}/d_{k,i})}{2\pi l_{evap}\lambda_{eff}} \quad (31)$$

or

$$R_{c,evap} = \frac{s_k}{A_{evap}\lambda_{eff}}. \quad (32)$$

N5. Table 3. Orders of magnitude of individual heat resistances according to Asselman and Green [14]

Heat resistance	K/W
$R_{w,evap}$, $R_{w,cond}$	10^{-1}
$R_{c,evap}$, $R_{c,cond}$	10^{+1}
$R_{ph,evap}$, $R_{ph,cond}$	10^{-5}
R_g	10^{-8}
R_l	10^{+4}
R_w	10^{+2}

Herein, λ_{eff} is the effective thermal conductivity of the capillary structure (composite of solid structure and liquid). According to Chi [3] and Faghri [4] the following equations can be used to calculate λ_{eff} for different capillary structures.

Porous structures:

(a) Considering solid and liquid resistances separately and assuming them in a serial circuit one yields

$$\lambda_{eff} = \frac{\lambda_l\lambda_w}{\varepsilon\lambda_w + \lambda_l(1-\varepsilon)}. \quad (33)$$

(b) Considering solid and liquid resistances separately and assuming them in a parallel circuit one yields

$$\lambda_{eff} = \varepsilon\lambda_l + \lambda_w(1-\varepsilon). \quad (34)$$

In practice the values λ_{eff} for porous structures will be somewhere in between these values given by Eqs. (33) and (34). Thus,

$$\frac{\lambda_l\lambda_w}{\varepsilon\lambda_w + \lambda_l(1-\varepsilon)} \le \lambda_{eff} \le \varepsilon\lambda_l + \lambda_w(1-\varepsilon).$$

Rectangular axial grooves:

$$\lambda_{eff} = \frac{(bh\lambda_l\lambda_w) + w\lambda_l(0.185b\lambda_w + h\lambda_l)}{(b+w)(0.185b\lambda_w + h\lambda_l)}, \quad (35)$$

with the groove width w, the distance b between the individual grooves, and the groove height h.

Triangular axial grooves:

$$\lambda_{eff} = 0.85\left(\frac{\lambda_l}{\lambda_w}\sin\beta\right)^{0.63} \quad (36)$$

with the opening angle β.

Screen meshes:

$$\lambda_{eff} = \frac{\lambda_l[(\lambda_l+\lambda_w) - (1-\varepsilon)(\lambda_l-\lambda_w)]}{(\lambda_l+\lambda_w) + (1-\varepsilon)(\lambda_l-\lambda_w)}. \quad (37)$$

Sintered structures:

$$\lambda_{eff} = \frac{\lambda_l[(2\lambda_l+\lambda_w) - 2(1-\varepsilon)(\lambda_l-\lambda_w)]}{(2\lambda_l+\lambda_w) + (1-\varepsilon)(\lambda_l-\lambda_w)}. \quad (38)$$

Equations (35) and (36) for open grooves are used in engineering practice to calculate the radial heat transfer. However, it should be noted here that the underlying assumptions of one-dimensional heat conduction and a fully saturated structure are not fulfilled in many cases. In the evaporator the liquid is most often receded into the capillary structure to a certain extent. In case that $\lambda_l << \lambda_w$ (which is basically always the case except for liquid metal heat pipes) the heat flux distribution in the capillary structure is nonuniform and strongly two- or even three-dimensional. Stephan [7] developed a numerical method to compute the radial heat resistance for the two-dimensional case. The resulting values for λ_{eff} were higher than those calculated with Eqs. (35) and (36).

The radial heat resistance at the liquid–vapor phase interface $R_{ph,evap}$ describes the molecular interaction at the interface. It is

$$R_{ph,evap} = \frac{2-f}{2f}\frac{T_g\sqrt{2\pi RT_g}}{\rho_g\Delta h_v^2} \quad (39)$$

with the saturation temperature in the gas phase T_g, the individual gas constant R of the fluid, and the accommodation

coefficient f. However, as stated before, this resistance can be neglected in the overall heat resistance analysis.

The axial heat resistance along the vapor flow, R_g, follows from the Clausius–Clapeyron equation and yields

$$R_g = \frac{T_g \Delta\rho_g}{\dot{Q}\rho_g \Delta h_v}. \tag{40}$$

This resistance is directly proportional to the temperature drop along the vapor flow which might be of special interest. However, for the overall heat resistance analysis, it can be neglected too.

The heat resistances in the condenser zone are calculated exactly in the same way than those in the evaporator zone. Equations (29)–(39) therefore hold also for the condenser, with the difference that the geometric data of the condenser section has to be inserted. Another difference is that the capillary structure is typically slightly flooded or at least saturated in the condenser zone, thus the accuracy of Eqs. (33)–(38) is higher in the condenser zone than in the evaporator zone.

Example 2

(a) What is the heat resistance of the heat pipe described in Example 1?

(b) How big is the temperature difference between the outside evaporator surface and the outside condenser surface?

The thermal conductivity of the wall material ammonia is given by $\lambda_w = 221$ W/(m K).

Solution

(a) According to Eq. (28) the heat resistance is

$$R_{HP} = R_{w,evap} + R_{c,evap} + R_{w,cond} + R_{c,cond}.$$

The radial heat resistance in the solid evaporator wall follows from Eq. (29)

$$R_{w,evap} = \frac{\ln(d_{w,o}/d_{w,i})}{2\pi l_{evap}\lambda_w} = \frac{\ln(14/10.6)}{2\pi \cdot 100 \cdot 10^{-3} \cdot 221}\,\mathrm{K/W} = 2.0 \cdot 10^{-3}\,\mathrm{K/W},$$

with the inner diameter of the relevant circumference

$$d_{w,i} = d_i + 2 \cdot h = (9 + 2 \cdot 0.8)\ \mathrm{mm} = 10.6\,\mathrm{mm}.$$

The heat resistance of the capillary structure in the evaporator is calculated according to Eq. (31). The effective thermal conductivity is approximated using Eq. (35) for rectangular grooves

$$\lambda_{eff} = \frac{(bh\lambda_1\lambda_w) + w\lambda_1(0.185b\lambda_w + h\lambda_1)}{(b+w)(0.185b\lambda_w + h\lambda_1)}.$$

It follows

$$\lambda_{eff} = \frac{(0.384 \cdot 0.8 \cdot 0.4996 \cdot 221)\ \mathrm{W/K\,m}}{(0.384 + 0.5) \cdot (0.185 \cdot 0.384 \cdot 221 + 0.8 \cdot 0.4996)} + \frac{0.5 \cdot 0.4996\ \mathrm{W/K\,m}}{(0.384 + 0.5)} = 2.67\ \mathrm{W/mK}$$

with the distance b between the grooves, which is $b = (\pi d_i/N) - w = (\pi\ 9\ \mathrm{mm}/32) - 0.5\ \mathrm{mm} = 0.384$ mm. With the relevant outer diameter for the capillary structure, $d_{c,o} = d_{w,i}$, Eq. (31) gives

$$R_{c,evap} = \frac{\ln(d_{c,o}/d_{c,i})}{2\pi l_{evap}\lambda_{eff}} = \frac{\ln(10.6/9)}{2\pi \cdot 100 \cdot 10^{-3} \cdot 2.67}\,\mathrm{K/W} = 97.6 \cdot 10^{-3}\,\mathrm{K/W}.$$

As the geometry of the condenser zone is equal to that of the evaporator zone, the heat resistances in the condenser are equal too. Thus,

$$R_{w,cond} = R_{w,evap} = 2.0 \cdot 10^{-3}\,\mathrm{K/W}$$

and

$$R_{c,cond} = R_{c,evap} = 97.6 \cdot 10^{-3}\,\mathrm{K/W}.$$

With that, the overall heat resistance of the heat pipe yields

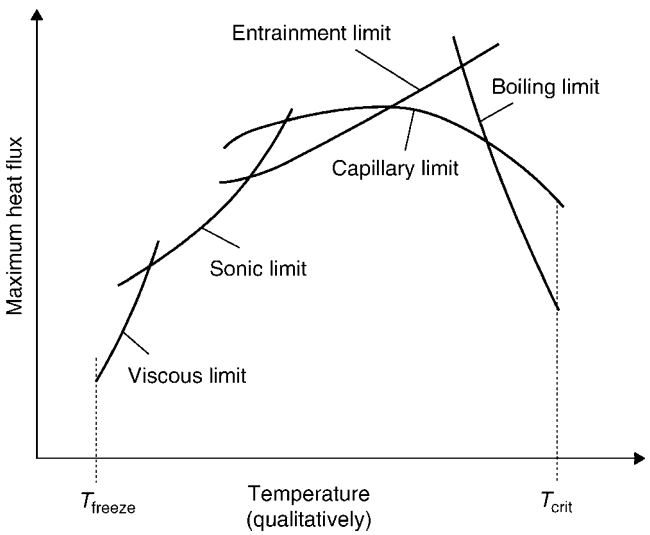
$$R_{HP} = 2 \cdot (2.0 + 97.6) \cdot 10^{-3}\,\mathrm{K/W} = 0.2\,\mathrm{K/W}.$$

(b) The temperature difference between the outer evaporator and the outer condenser surface is calculated according to Eq. (26). With the heating power of 50 W, it follows

$$\Delta T = \dot{Q}R_{WR} = 50 \cdot 0.2\ \mathrm{K} = 10\ \mathrm{K}.$$

4 Heat Transport Limits

The considerations in Sect. 3 of this chapter are valid for the steady-state operation of a heat pipe. In the design phase, it is important to check additionally if a heat pipe can reach such a steady-state operation, or, in other words, if the required heat flux is not too high for a specific design and the heat pipe will fail because a performance limit is reached. Figure 8 shows the performance limits. Generally, the operating temperature must be in the range between the melting temperature and the critical temperature. In this range the maximum heat transport capability $\dot{Q}_{max}$ is limited by different phenomena, indicated by the different curves in Fig. 8. A steady-state operating mode $(\dot{Q}, T)$ can only be reached in the area below these curves. In the following subsections of this chapter the different limits are briefly discussed and calculation procedures are given.



N5. Fig. 8. Heat transport limits.

4.1 Capillary Limit

To keep the fluid circulating, the capillary pressure difference Δp_c must, according to Eq. (2), overcome the sum of all pressure drops in the 2-phase loop. This is only possible if Δp_c is smaller or equal to the maximal pressure difference $\Delta p_{c,max}$ that can be provided by the capillary structure (see Eq. (5b)). Thus, in any steady-state operating mode $(\dot{Q}, T)$ the inequality

$$\Delta p_{c,max} \geq \Delta p_c = -(\Delta p_l + \Delta p_g) \tag{41}$$

must be fulfilled. If an analysis shows that this is not the case the heat pipe design has to be changed (i.e., fluid, capillary structure, geometry, etc.) or the operating mode has to be shifted.

4.2 Viscous Limit

For operating temperatures little above the melting point of the fluid the vapor pressure and vapor density are very low and viscous forces dominate the flow behavior. The vapor pressure drop cannot be higher than the absolute pressure near the evaporator end. In the limiting case, the vapor pressure at the condenser end becomes zero. Busse [15] analyzed this case for heat pipes with circular cross section and the assumption of an isothermal flow of a perfect gas. He derived the maximum axial heat flux

$$\dot{q}_{vis} = \frac{d_g^2 \Delta h_v}{64 \eta_g l_{eff}} \rho_{g,evap} p_{g,evap} \tag{42}$$

with the vapor density $\rho_{g,evap}$ and the vapor pressure $p_{g,evap}$ at the evaporator end. Operating modes $(\dot{Q}, T)$ must be chosen such that the axial heat flux is lower than this value.

4.3 Sonic Limit

The sonic limit might be relevant specifically for high temperature heat pipes with metallic fluids. If one decreases the temperature and thus the pressure in the condenser at a constant evaporator temperature a rising heat flow and rising fluid flow velocities will be the result. Inertia forces dominate the flow. The sonic limit is reached when the vapor velocity at the evaporator exit reaches the sonic velocity. In this case, the heat flow cannot be further increased by a pressure or temperature reduction in the condenser. According to Busse [15] the related maximum axial heat flux is

$$\dot{q}_s = 0.474 \, \Delta h_v \sqrt{\rho_{g,evap} p_{g,evap}}. \tag{43}$$

4.4 Entrainment Limit

In heat pipes with open capillary structures the vapor and countercurrent liquid flow generate a shear force at the fluid interface. With increasing heat flux, the vapor and liquid velocities rise until the shear forces might destabilize the interface and surface waves are generated. As a result, the condensate flow toward the evaporator is partly dammed up and liquid droplets are entrained. Entrainment occurs if the shear forces exceed the surface tension forces. Based on this force balance the maximum axial heat flux follows

$$\dot{q}_e = \Delta h_v \sqrt{\frac{\sigma \rho_g}{2 R_{h,c}}} \tag{44}$$

according to [4] with the hydraulic radius $R_{h,c}$ of the capillary structure:

$R_{h,c} = w$	For axial grooves with the groove width w,
$R_{h,c} = 0.5w$	For screen wicks or meshes with the mesh width w, and
$R_{h,c} = 0.41r$	For sinter structures with the particle radius r.

4.5 Boiling Limit

At high heat fluxes the wall superheat in the evaporator zone might be high enough to activate potential nucleation sites at the solid–liquid interface and as a result vapor bubbles might be generated inside the capillary structure. Bubbles can escape into the vapor space from open capillary grooves, and the boiling limit is typically not critical for open capillary structures. However, covered grooves, sintered structures, or meshes are very sensitive to growing vapor bubbles as they might interrupt the capillary driven condensate flow or even cause a local dry-out. The critical wall superheat is calculated based on the consideration of the thermodynamic equilibrium of a vapor nucleus. It follows

$$\Delta T_{crit} = T_w - T_g = \frac{2 \sigma T_g}{\Delta h_v \rho_g} \left(\frac{1}{R_b} - \frac{1}{R_{eff}} \right). \tag{45}$$

Herein, R_b is the radius of the vapor nucleus, R_{eff} the effective radius of curvature of the capillary structure (Table 1), T_g the vapor temperature which is assumed to be the saturation temperature, and T_w the temperature of the wall next to the vapor nucleus. A vapor nucleus will generate a bubble if the critical wall superheat ΔT_{crit} is exceeded. According to Bergles and Rohsenow [16] the radius R_b can be approximated by

$$R_b = \sqrt{\frac{2 \sigma T_g \lambda_l}{\dot{q}_{evap} \Delta h_v \rho_g}} \tag{46}$$

for a given radial heat flux $\dot{q}_{evap}$ in the evaporator zone. Typical values of R_b range from about 0.1 to 10 µm, and thus lie in the order of magnitude of surface roughness values. The maximum radial heat flux related to the boiling limit is calculated by

$$\dot{q}_b = \frac{\Delta T_{crit}}{A_{evap} R_{c,evap}} \tag{47}$$

with the heat resistance $R_{c,evap}$ of the capillary structure in the evaporator zone according to Eqs. (31) or (32).

Example 3

What is the maximum performance (heating power) that the heat pipe specified in Example 1 can transfer at an operating temperature of ϑ_{sat} = 10°C (referring to p_g = 6.149 bar)? To

answer this question, determine the individual performance limits first.

Solution

(a) *Capillary limit*: The capillary limit follows from Eq. (41)

$$\Delta p_{c,max} \geq \Delta p_c = -(\Delta p_l + \Delta p_g),$$

where the equal sign is relevant in the limiting case. The maximum capillary pressure difference was already calculated in Example 1: $\Delta p_{c,max}$ = 86.6 Pa. Gravitational forces are not relevant in this example (satellite application). Therefore, the liquid pressure drop follows from Eqs. (6) and (9):

$$\Delta p_l = \Delta p_{l,stat} = -\frac{32 v_l}{A_l \Delta h_v d_{c,h}^2} \dot{Q} l_{eff}$$

which yields

$$\begin{aligned}\Delta \rho_l &= \frac{-32 \cdot 2.49 \cdot 10^{-7} \cdot 880 \cdot 10^{-3} \cdot \dot{Q}}{12.8 \cdot 10^{-6} \cdot 1225.5 \cdot 10^3 \cdot (0.762 \cdot 10^{-3})^2} \text{(Pa/W)} \\ &= -0.770 \cdot \dot{Q} \text{ (Pa/W)}.\end{aligned}$$

The pressure drop along the vapor flow follows from Eq. (16):

$$\Delta p_g = \Delta p_{g,evap} + \Delta p_{g,cond} + \Delta p_{g,ad}.$$

As the Reynolds number cannot be calculated a priori without a given heating power, an assumption has to be made first. A useful assumption for a standard heat pipe is $Re_a < 2{,}300$ and $Re_r > 1$. With this, Eq. (19) gives

$$\begin{aligned}\Delta \rho_{g,ad} &= -\frac{32 v_g}{A_{g,a} \Delta h_v d_{g,h}^2{}^2} \dot{Q} l_{ad} \\ &= \frac{-32 \cdot 19.08 \cdot 10^{-7} \cdot 780 \cdot 10^{-3} \cdot \dot{Q}}{63.62 \cdot 10^{-6} \cdot 1225.5 \cdot 10^3 \cdot (9 \cdot 10^{-3})^2} \text{ (Pa/W)} \\ &= -7.54 \cdot 10^{-3} \cdot \dot{Q} \text{ (Pa/W)}.\end{aligned}$$

In analogy to Example 1 the pressure drops in the evaporator and condenser now can be calculated using Eqs. (21), (22), and (25). This yields

$$\begin{aligned}\Delta p_{g,evap} + \Delta p_{g,cond} &= -\frac{32 v_g}{A_{g,a} \Delta h_v d_{g,h}^2} \dot{Q} \left(\frac{l_{evap}}{2} + \frac{l_{cond}}{2} \right) \\ &= \frac{-32 \cdot 19.08 \cdot 10^{-7} \cdot 100 \cdot 10^{-3}}{63.62 \cdot 10^{-6} \cdot 1225.5 \cdot 10^3 \cdot (9 \cdot 10^{-3})^2} \dot{Q} \text{ (Pa/W)} \\ &= -0.967 \cdot 10^{-3} \dot{Q} \text{ (Pa/W)}.\end{aligned}$$

It follows

$$\begin{aligned}\Delta p_g &= -(0.967 + 7.54) \cdot 10^{-3} \cdot \dot{Q} \text{ (Pa/W)} \\ &= -8.51 \cdot 10^{-3} \cdot \dot{Q} \text{ (Pa/W)}\end{aligned}$$

and the capillary pressure difference

$$\Delta p_c = (8.51 + 770) \cdot 10^{-3} \dot{Q} \text{ (Pa/W)} = 778.51 \cdot 10^{-3} \dot{Q} \text{ (Pa/W)}$$

Thus, the capillary limit will be reached at a heating power

$$\begin{aligned}\dot{Q} &= \frac{\Delta p_c}{778.51 \cdot 10^{-3}} \text{ (W/Pa)} = \frac{\Delta p_{c,max}}{778.51 \cdot 10^{-3}} \text{ (W/Pa)} \\ &= \frac{86.6 \text{ Pa}}{778.51 \cdot 10^{-3}} \text{ (W/Pa)} = 111.2 \text{ W}.\end{aligned}$$

Finally the underlying assumptions $Re_a < 2{,}300$ and $Re_r > 1$ have to be validated:

$$\begin{aligned}Re_r &= \frac{\dot{Q} d_{g,h}}{v_g \rho_g A_{g,a} \Delta h_v} \\ &= \frac{111.2 \cdot 9 \cdot 10^{-3}}{19.08 \cdot 10^{-7} \cdot 4{,}865 \cdot 63.62 \cdot 10^{-6} \cdot 1225.5 \cdot 10^3} = 1382.9\end{aligned}$$

and

$$\begin{aligned}|Re_r| &= \frac{\dot{Q} r_g}{v_g \rho_g A_{g,r} \Delta h_v} \\ &= \frac{111.2 \cdot 4.5 \cdot 10^{-3}}{19.08 \cdot 10^{-7} \cdot 4{,}865 \cdot 2{,}827 \cdot 10^{-6} \cdot 1225.5 \cdot 10^3} = 15.6.\end{aligned}$$

Thus, the assumptions were justified.

(b) *Viscous limit*: According to Eq. (42) the maximum axial heat flux related to the viscous limit is

$$\begin{aligned}\dot{q}_{vis} &= \frac{d_g^2 \Delta h_v}{64 v_g l_{eff}} p_{g,evap} \\ &= \frac{(9 \cdot 10^{-3})^2 \cdot 1225.5 \cdot 10^3}{64 \cdot 19.08 \cdot 10^{-7} \cdot 880 \cdot 10^{-3}} 6.149 \cdot 10^5 \text{ (W/m}^2\text{)} \\ &= 5.68 \cdot 10^{11} \text{ (W/m}^2\text{)}.\end{aligned}$$

The performance limit yields

$$\dot{Q} = \dot{q}_{vis} \cdot A_{g,a} = 5.68 \cdot 10^{11} \cdot 63.62 \cdot 10^{-6} \text{ W} = 36.1 \text{ MW}.$$

(Comment: The calculation proves what one could have expected. The viscous limit is extremely high, because the pressure drop along the vapor flow is very small compared to the pressure drop along the liquid flow. Here, the viscous limit will not be relevant.)

(c) *Sonic limit*: The axial heat flux reaching the sonic limit is given by Eq. (43)

$$\begin{aligned}\dot{q}_s &= 0.474 \Delta h_v \sqrt{\rho_{g,evap} \, p_{g,evap}} \\ &= 0.474 \cdot 1225.5 \cdot 10^3 \sqrt{4.865 \cdot 6.148 \cdot 10^5} \text{ (W/m}^2\text{)} \\ &= 1.0 \cdot 10^9 \text{ (W/m}^2\text{)}.\end{aligned}$$

The related performance limit is

$$\dot{Q} = \dot{q}_s \cdot A_{g,a} = 1.0 \cdot 10^9 \cdot 63.62 \cdot 10^{-6} \text{ W} = 63.6 \text{ kW}.$$

(Comment: The sonic limit is very high, because the pressure drop along the vapor flow is quite low for realistic heat fluxes as can be seen, e.g., in Example 1.)

(d) *Entrainment limit*: The entrainment limit follows from Eq. (44) with $R_{h,c} = w$.

$$\begin{aligned}\dot{q}_e &= \Delta h_v \sqrt{\frac{\sigma \rho_g}{2 R_{h,c}}} \\ &= 1225.5 \cdot 10^3 \sqrt{\frac{23.88 \cdot 10^{-3} \cdot 4.865}{2 \cdot 0.5 \cdot 10^{-3}}} \text{ (W/m}^2\text{)} \\ &= 1.32 \cdot 10^7 \text{ (W/m}^2\text{)}\end{aligned}$$

and the performance limit is

$$\dot{Q} = \dot{q}_e \cdot A_{g,a} = 1.32 \cdot 10^7 \cdot 63.62 \cdot 10^{-6} \text{ W} = 840 \text{ W}.$$

(e) *Boiling limit*: The boiling limit is not relevant for the given heat pipe design with open capillary grooves.

With the solutions a) to e) one can summarize the theoretical-limits:

(a) Capillary limit	111.2 W
(b) Viscous limit	36.1 MW
(c) Sonic limit	63.6 kW
(d) Entrainment limit	840 W

Comparing these values one recognizes that the capillary limit is critical at the given operating temperature because the theoretical value is by far the lowest. Thus, the maximum performance (heating power) is

$$\dot{Q} = 111.2 \text{ W}.$$

Above this value the heat pipe will fail because the capillary forces are not high enough to return the condensate to the evaporator.

N6 Pressure Drop and Heat Transfer in Plate Heat Exchangers

Holger Martin
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Introduction: Description of the Apparatus

Plate heat exchangers of the type shown in Fig. 1 are presently offered by many manufacturers worldwide as a standard series production apparatus. They consist of a number of gasketed metal plates clamped between a stationary head and a follower plate by tie bolts. A wavy surface of a special design is stamped on the thin-walled plates (see Fig. 2). The plates are typically rectangular with circular ports at the four corners through which the two heat exchanging fluids may enter and leave. The gaskets are so arranged as to direct the two fluids through alternate flow channels formed by the space between the plates. The corrugated surface pattern of the plates subdivides the flow cross section into a number of interconnected parallel flow channels with multiple changes in direction as well as cross-sectional area. The corrugations on adjacent plates crisscross, providing multiple points of contact and offering mechanical support against pressure differences across the plates. Descriptions of this type of heat exchanger can be found in relevant text and handbooks [1–3], in Chap. O2, or on the websites of manufacturers. The main application area of this type of apparatus is liquid–liquid heat transfer in the lower pressure range (usually below 1.6 MPa) because the construction and the long gaskets are unfavorable for high pressures in general. Due to the small interplate spacing and the high vorticity of the flow, high heat transfer coefficients can be attained. Ease of cleaning, simple adjustment to changed operating conditions by replacement or addition of plates, and the compactness and, correspondingly, a small liquid hold-up are usually cited as the most important advantages of plate heat exchangers.

2 Plates with Chevron-type Corrugations

The most commonly offered shape of the plates is the chevron-type corrugation as shown in Fig. 2. It is characterized by a sinusoidal corrugation pattern with an amplitude $\hat{a}$ and a wavelength Λ. The crests and troughs of this pattern are oriented in an angle φ against the main flow direction (the vertical in Fig. 2) in one, or in several strips of a width B on the plate. The plates in a pack are so arranged (rotation of each second plate around its surface normal by 180°) that the crests of the corrugations of adjacent plates have a regular rhombic pattern of contact points. Manufacturers usually offer series of plates in various sizes with the same chevron pattern in two or more inclination angles, φ (caution: angles given by various manufacturers are partly measured against the horizontal (i.e. $90° - \varphi$), or they give the chevron angle 2φ). The plates with small angles ($0° < \varphi < 45°$) are called "soft" plates (they have lower pressure drop), those with greater angles ($45° < \varphi < 90°$) with correspondingly higher pressure drop are called "hard" plates.

3 Pressure Drop and Heat Transfer

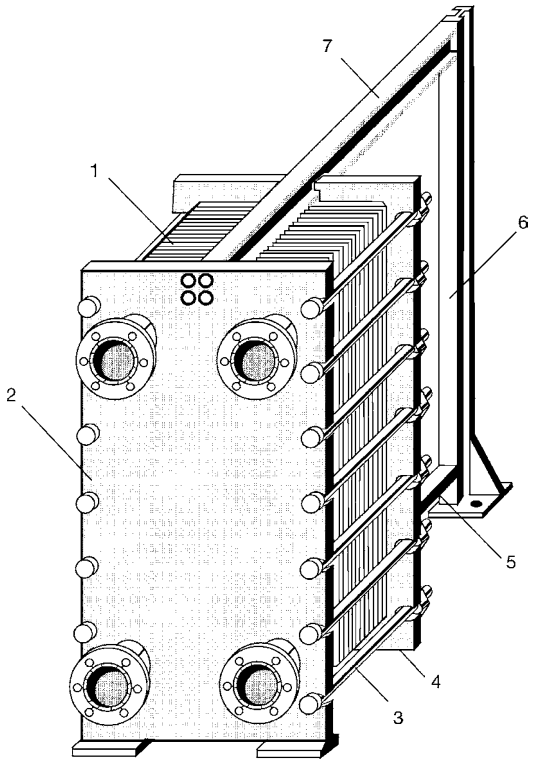
3.1 Definitions

The friction factor, ξ, the Reynolds number, Re, and the Nusselt number, Nu, are defined as

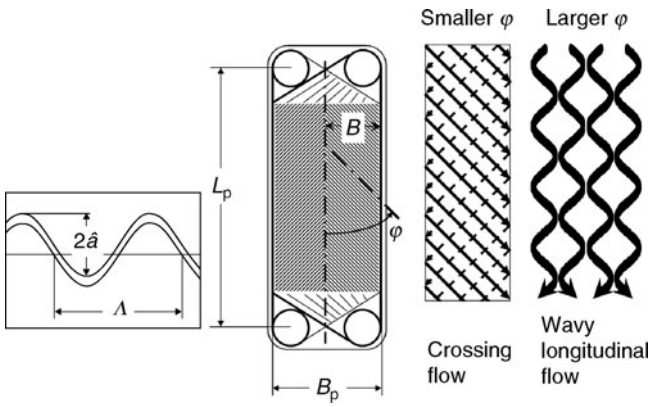
$$\xi = \frac{2\Delta p d_h}{\rho w^2 L_p}, \tag{1}$$

$$\mathrm{Re} = \frac{\rho w d_h}{\eta}, \tag{2}$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_66,



N6. Fig. 1. Plate heat exchanger [2]
1: plate pack, 2: stationary head, 3: tie bolt, 4: follower plate, 5: bottom bar, 6: end support, 7: top bar



N6. Fig. 2. Chevron-type plate. Inclination angle, φ, and the two flow patterns observed

$$\mathrm{Nu} = \frac{\alpha d_h}{\lambda} \tag{3}$$

($\xi = 4f$, if f denotes the Fanning friction factor, which is also often used in the literature) with the pressure drop, Δp, for the (vertical) flow through a gap between two plates over the length, L_p, of a plate (see Fig. 2) (the pressure drop in the distributor and collector channels has to be accounted for separately) and the hydraulic diameter, d_h, defined as

$$d_h = 4\hat{a}/\Phi, \tag{4}$$

where $\hat{a}$ is the amplitude of the sinusoidal corrugation pattern, and Φ is the ratio of the wavy plate surface to its plane projection. The ratio Φ depends on the ratio of amplitude to wavelength, or simpler on the wave number:

$$X = 2\pi\hat{a}/\Lambda. \tag{5}$$

For a sinusoidal corrugation it can be approximately calculated from the formula

$$\Phi(X) \approx \frac{1}{6}\left(1 + \sqrt{1+X^2} + 4\sqrt{1+X^2/2}\right) \tag{6}$$

obtained from a three-point integration over the length of the sine-curve (integration error < 2%).

For $\Lambda/\hat{a} = 2\pi$, that is $X = 1$, the surface enhancement factor becomes $\Phi = 1.22$. Twenty-two percent of surface enhancement is a typical value for technical plates. The fluid velocity, w, in Eqs. (1) and (2) is to be calculated as the volumetric flow rate through the gap between two plates, divided by the average cross section of the gap:

$$w = \frac{\dot{V}_{\mathrm{gap}}}{2\hat{a} \cdot B_p}. \tag{7}$$

The plate width B_p is a certain multiple (mostly an integer multiple) of the width B of the pattern. For the plate shown in Fig. 2, $B_p = 2B$.

As the reference area A_p for the heat transfer coefficients the enlarged surface inside the gaskets is chosen (the plane surface, A_0, is nearly equal to $A_0 \approx B_p L_p$):

$$A_p = \Phi \cdot A_0. \tag{8}$$

There are other definitions used in the literature, so in comparing data from different sources it is always advisable to carefully check the definitions.

The heat transfer coefficient is defined here as

$$\alpha = \frac{\dot{Q}}{A_p \cdot \Delta T_m} \tag{9}$$

that is with the mean difference between fluid and plate surface temperature averaged over the whole surface, A_p (see Chaps. C1 and C2 for the correct mean temperature differences). The physical properties are to be taken at the arithmetic mean of fluid inlet and outlet temperatures:

$$T_m = \frac{1}{2}(T_{\mathrm{in}} + T_{\mathrm{out}}). \tag{10}$$

3.2 Influence of Inclination Angle and Flow Rate

The influence of inclination angle and flow rate on pressure drop and on heat transfer can be approximately found from the following simple flow model, based on available experimental data for pressure drop and heat (or mass) transfer [3–10] and equations for heat transfer based on the Lévêque equation [11, 12] for thermally developing flow [13].

3.2.1 Pressure Drop

Limiting case 0: $\varphi = 0°$, smooth longitudinal flow

Re < 2,000 (laminar),

$$\xi_0 = \frac{B_0}{\mathrm{Re}} \tag{11}$$

Re ≥ 2,000 (turbulent),

$$\xi_0 = (1.8 \lg \mathrm{Re} - 1.5)^{-2}. \tag{12}$$

The constant $B_0 = \xi_0 \mathrm{Re}$ depends on the cross-sectional shape of the channel; for a circular duct, one would get $B_0 = 64$. For sinusoidally shaped ducts B_0 can be calculated numerically [14]. Practically, it may often suffice to use as an average value also

$$B_0 \approx 64. \tag{13}$$

Limiting case 1: ($\sin\varphi = 1$) $\varphi = 90°$, wavy longitudinal flow: The pressure drop in this limit quite sensitively depends on the relative position of the adjacent wave patterns. If the wave patterns are in phase, the wavy longitudinal flow has a friction factor $\xi_{1,0}$, that is much higher than for the smooth longitudinal flow ($\varphi = 0°$).

According to Focke et al. [6] one finds

$$\xi_{1,0} = \frac{B_1}{\mathrm{Re}} + C_1, \quad \mathrm{Re} < 2{,}000, \tag{14}$$

$$\xi_{1,0} = \frac{K_1}{\mathrm{Re}^n}, \quad \mathrm{Re} \geq 2{,}000 \tag{15}$$

with the constants (only determined for $\Lambda/\hat{a} = 4$) $B_1 = 597$, $C_1 = 3.85$, $K_1 = 39$, and $n = 0.289$.

Were the wave patterns, however, phase-shifted by π (= 180°), the wave crests would contact each other, and the flow would be completely blocked:

$$\xi_{1,\pi} \to \infty. \tag{16}$$

The pressure drop for wavy longitudinal flow is therefore approximated by

$$\xi_1(\mathrm{Re}) = a \cdot \xi_{1,0}(\mathrm{Re}) \tag{17}$$

with an empirical factor a ($1 \leq a < \infty$).

Crossed corrugation patterns ($0° < \varphi < 90°$): Two flow patterns have been observed in the gaps between two plates, the wave patterns of which are in pointwise contact with each other [4, 5] (see Fig. 2): For small angles, φ (low pressure drop), the crossing flow along the valleys of the corrugation of the two plates over the whole width of the chevron pattern is mainly observed. For greater angles, φ (high pressure drop), the wavy longitudinal flow between vertically adjacent contact points additionally becomes more important. The combined effects of the longer flow path (by a factor $1/\cos\varphi$) along the furrows, of the flow reversals at the edges of the corrugation pattern ($b \tan\varphi$), the crossing of the streamlets ($c \sin\varphi$), and the smooth change of the crossing flow to the longitudinal wavy flow were taken into account to develop an equation for the friction factor, ξ, as a function of the inclination angle, φ, and the Reynolds number [13]: $\xi = f(\varphi, \mathrm{Re})$

$$\frac{1}{\sqrt{\xi}} = \frac{\cos\varphi}{\sqrt{b\tan\varphi + c\sin\varphi + \xi_0(\mathrm{Re})/\cos\varphi}} + \frac{1-\cos\varphi}{\sqrt{\xi_1(\mathrm{Re})}} \tag{18}$$

with $\xi_0(\mathrm{Re})$ and $\xi_1(\mathrm{Re})$ from the equations for the limiting cases of the smooth ($\varphi = 0°$) and the wavy longitudinal ($\varphi = 90°$) flow, respectively (Eqs. (11–17)).

The empirical constants, a, b, and c, will certainly depend on the geometrical parameters of the corrugation ($\hat{a}$, Λ). From a comparison of published pressure drop data ($\Lambda/\hat{a} \approx 4$–8) with the model Eq. (18), in the form $\xi(\varphi, \mathrm{Re} = 2{,}000)$, as shown in Fig. 3, the approximate values $a = 3.8$, $b = 0.18$, and $c = 0.36$ have been found. These values may be used for an estimation of the pressure drop to be expected in typical chevron-type plate heat exchangers. In case that pressure drop data for a certain plate-type are available as a function of Re for one or several inclination angle, the parameters (a, b, c) can be fitted to these data and used in Eq. (18) to interpolate between the data and even extrapolate into adjacent ranges of inclination angle and Reynolds number. This was done for the data of Heavner et al. [10], as shown in Fig. 4.

3.2.2 Heat (and Mass) Transfer

Because of the periodic structure of the individual flow channels, the heat (and mass) transfer can be determined approximately from the generalized Lévêque equation [13]:

$$\mathrm{Nu} = 1.615\,[(\xi\,\mathrm{Re}/64)\mathrm{Re}\,\mathrm{Pr}\,d_h/L]^{1/3}. \tag{19}$$

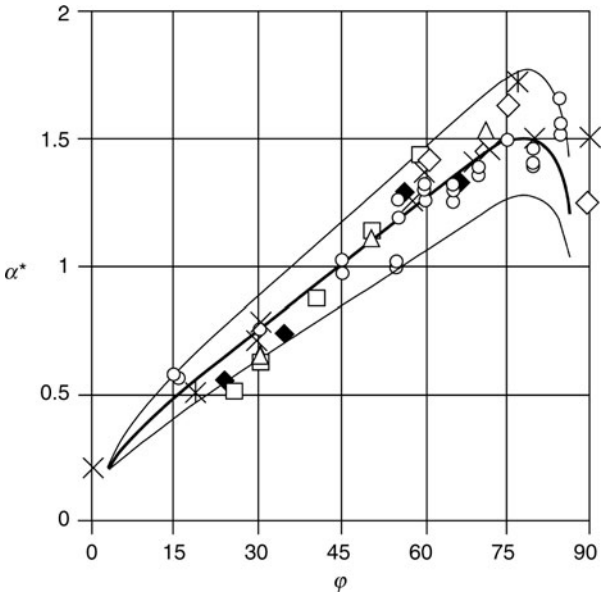
Curves: Eq. (18) with (a, b, c) = (1.6, 0.40, 0.36). *Symbols*: empirical correlations of Heavner et al. (1993), representing their data for technical plates (for Re = 2,000) their data are also shown in Fig. 3 (compared with the other set (a, b, c) = (3.8, 0.18, 0.36))



N6. Fig. 5. Influence of the inclination angle, φ, on heat transfer in plate heat exchangers.
Normalized heat transfer coefficient, $\alpha^* = \alpha(\varphi)/\alpha(45°)$, versus φ for Re = 2,000
Symbols as in Fig. 3 and ○: Rosenblad and Kullendorff [5] (mass transfer, small model plate, Re = 1,880), φ = 15°, 30°, 45°, 55°, 60°, 70°, 75°, 80°, 85°
Curves: Eqs. (19–22) ± 20% with ξ from Eq. (18), parameters as in Fig. 3

For the fully developed laminar tube flow, according to the Hagen–Poiseuille law the term (ξ Re/64) is equal to 1, and Re Prd_h/L is called a Graetz number. Rewritten, and analogously applied to mass transfer as well, Eq. (19) becomes:

$$\mathrm{Nu}/\mathrm{Pr}^{1/3} = \mathrm{Sh}/\mathrm{Sc}^{1/3} = 0.4038\,[\xi\,\mathrm{Re}^2 d_h/L]^{1/3}. \qquad (20)$$

For the length, L, the distance between two crossing points of the corrugation pattern has to be used:

$$d_h/L = (d_h/\Lambda)\sin(2\varphi), \quad 0° < \varphi < 90°. \qquad (21)$$

This generalized form of the Lévêque equation is also applicable to thermally developing boundary layers of short lengths, L, in a turbulent flow (see also [12]).

Is the heat (or mass) transfer coefficient known for one kind of plate, say for an inclination angle of φ = 45° (that is, sin(2φ) = 1), the dependency on the inclination angle can be obtained with a sufficient degree of approximation. A relative heat (or mass) transfer coefficient

$$\alpha^* = \frac{\alpha(\varphi)}{\alpha(45°)} = \frac{\beta(\varphi)}{\beta(45°)} \qquad (22)$$

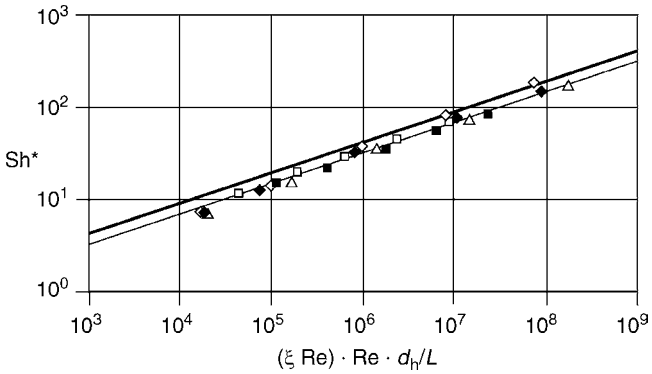
is plotted in Fig. 5 for Re = 2,000 as a curve obtained from Eqs. (20) and (21) together with Eq. (18) for $\xi(\varphi, \mathrm{Re})$ in comparison with the corresponding values obtained from published experimental data for heat (and mass) transfer in chevron-type plate channels. The parameters(a, b, c) have been used as fitted to the pressure drop data (3.8, 0.18, and 0.36) from Fig. 3. For the limiting cases of an uncrossing longitudinal flow, φ = 0° and φ = 90°, the Lévêque equation is not applicable because of $L \to \infty$ (from Eq. (21)). These limits, however, are less important for technical plate heat exchangers, since without the crossing points no mechanically stable plate packs can be formed (at least not without added distance keepers).

Equation (20) describes a special form of analogy between momentum, heat, and mass transfer, which predicts that heat or mass transfer coefficients under these conditions (that is, for short, periodically repeated, thermal, or diffusional boundary layers in laminar, or in turbulent flow) are proportional to the cubic root of the frictional pressure drop. The product

$$\xi\,\mathrm{Re}^2 = 2\frac{\rho \Delta p d_h^3}{\eta^2 L_p} = 2\mathrm{Hg} \qquad (23)$$

is proportional to the Hagen number, Hg, which is directly proportional to the pressure gradient, $\Delta p/L_p$. A check of the validity of the Lévêque analogy for chevron-type plates is shown by comparing the empirical equations based on the experimental data of Focke et al. [6] with the calculations from Eq. (20).

The pressure drop, and mass transfer data, correlated in the work of Focke et al. [6] in the form of friction factors f(Re) and Colburn factors j(Re) are plotted in Fig. 6 as $\mathrm{Sh}^* = \mathrm{Sh}/\mathrm{Sc}^{1/3} = j\,\mathrm{Re}/\Phi^2$ versus [$\xi \mathrm{Re}^2 d_h/L$] with d_h/L from Eq. (21). The values for $\mathrm{Sh}/\mathrm{Sc}^{1/3}$ and [$\xi \mathrm{Re}^2 (d_h/\Lambda)\sin(2\varphi)$] were evaluated for the lowest, the highest, and three intermediate Reynolds numbers for the measurements with inclination angles of φ = 30°, 45°, 60°, 72°, and 80°, respectively. The data for φ = 0° and φ = 90°, because of $L \to \infty$, as mentioned earlier, cannot be compared with the Lévêque equation. The range of Reynolds numbers investigated is about 60 < Re < 30,000. The geometric parameters of the plates used by Focke et al. [6] are Λ = 10 mm, $\Lambda/\hat{a}$ = 4, d_h/Λ = 0.683, and Φ = 1.464. The upper line in Fig. 6 shows the theoretical relationship



N6. Fig. 6. Test of the validity of the Lévêque analogy for chevron-type plates *Symbols*: Sh* = Sh/$Sc^{1/3}$ measured and empirically correlated by Focke et al. [6] versus (ξ Re)Re d_h/L, with $L = \Lambda/\sin(2\varphi)$ (= distance between two crossing points) Calculated from the empirical correlations as given in [6] (Table 3) for the lowest, the highest, and three intermediate Reynolds numbers for the experiments with inclination angles of $\varphi = 30°$(diamond), 45° (full diamond), 60°(triangle), 72°(full square), and 80°(square), with the friction factors measured in the same equipment and also empirically correlated by the authors [6] (Table 2). *Lines*: Sh* = Sh/$Sc^{1/3}$, calculated from Eq. (20), and $\Lambda/\hat{a} = 4$, $\Phi = 1.464$, as given by Focke et al. [6]. *Lower line*: Sh* (theoretical) – 20.6% (fitting curve)

$$(\alpha, \beta) \propto [\Delta p \cdot \sin(2\varphi)]^{1/3}. \tag{24}$$

The lower line is a parallel to this (in a distance of –20.6%) and corresponds to an average curve through the data of Focke et al.

A more detailed comparison with other published data (especially with heat transfer data for technical plates) shows that the dependency of Nusselt numbers on Reynolds numbers can be better represented by a slightly modified form of the Lévêque equation. The exponent 1/3 0 0.333. . . is replaced by a slightly larger value q (present recommendation: $q = 0.374$). The geometric parameter (d_h/Λ), for practical reasons, is included into the modified factor ($c_q = 0.122$), since most of the manufacturers do not publish the geometric details of their corrugation patterns [13]:

$$\mathrm{Nu} = c_q \mathrm{Pr}^{1/3} (\eta/\eta_w)^{1/6} [2\mathrm{Hg}\ \sin(2\varphi)]^q. \tag{25}$$

The constants, c_q and q, can be recommended from the comparison with the data of Heavner et al. [10] to be $c_q = 0.122$ and $q = 0.374$. Equation (25) also contains a correction $(\eta/\eta_w)^{1/6}$, to account for the temperature dependency of the viscosity of the liquid.

Since the product $\xi\ \mathrm{Re}^2$ is directly proportional to the pressure gradient, $\Delta p/L_p$, see Eq. (23), one will get the same heat transfer coefficient for the same pressure gradient with hard plates, $\varphi = (45 + x)°$, and soft plates, $\varphi = (45 - x)°$, $(0 < x < 45)$: The function $\sin(2\varphi)$ is symmetric around its maximum of 1 at $\varphi = 45°$. For $x = 15$, for example, $\sin(2{\cdot}30°) = \sin(2{\cdot}60°) = 0.866$. The flow rates, however, differ by more than a factor of 2 in this case. For the same pressure drop, hard plates, with angles above 45° therefore lead to higher residence times of the fluid (higher NTU) and correspondingly higher changes in fluid temperature.

3.3 Channels between Plates of Different Inclination Angle

Plates of equal size and corrugation parameters, but different inclination angles, φ_1, and φ_2, can be alternately used in one plate pack, in order to meet a certain thermal duty with an economically optimal usage of a given pressure gradient. It was shown that it is simply allowed to calculate, in these cases, with the arithmetic mean of the two angles:

$$\varphi = \frac{1}{2}(\varphi_1 + \varphi_2). \tag{26}$$

3.4 Other Variables of Influence

The sets of parameters determined from the comparison with the relatively few available data in the pressure drop equation, (a, b, c), Eq. (18), and in the heat transfer equation, (c_q, q), Eq. (25) depend on the characteristic length of the corrugation pattern ($\hat{a}$, Λ, B, . . .), which are usually not given by the plate manufacturers. An application of these sets of parameters on ratios of wavelength to amplitude far outside the range of the data used here $4 \leq \Lambda/\hat{a} \leq 8$ is therefore not recommended.

4 Comments on Other Types of Plates and on Multiphase Flow in Plate Heat Exchangers

A plate type apart from the chevron-type, which is still offered by some manufacturers, is the washboard, or intermating trough plate [3], which may be described as a corrugation (not necessarily sinusoidal) with an inclination angle of $\varphi = 90°$, that is with the crests and troughs perpendicularly oriented against the flow direction. The plate spacing that is smaller than twice the amplitude of the corrugation is kept constant by dimples pressed into the crests and troughs to provide contact with those on adjacent plates. The shape of the corrugation waves is usually a multistep trapezoidal one. For this type of plate some empirical equations for pressure drop and heat transfer can be found in the literature [3, 15].

For multiphase flow, evaporation and condensation in plate heat exchangers there are not many published data to be found in the literature. The experimental results of Kreissig and Müller-Steinhagen [16] for the pressure drop in two-phase flow through plate heat exchangers show that a linear interpolation between the two single-phase pressure drops might be a reasonable approximation in this case, while in two-phase tube flow the two-phase pressure drop shows a characteristic maximum between the two single phase pressure drops at gas to massflow ratios of around 90%.

5 Numerical Example

The complete hydrodynamic and thermal design of a heat exchanger requires the determination of an economically optimal flow velocity. Methods to determine such an optimal velocity are found in the relevant textbooks [1, 2]. For low-viscosity liquids (water) this velocity in the tubes of a shell-and-tube heat exchanger is typically in the order of magnitude of 1–3 m/s. For chevron-type plate heat exchangers, because of the higher flow resistance lower velocities of 0.2–0.8 m/s are economically reasonable. The mean temperature difference must also be determined for the kind of flow configuration that is chosen for the apparatus. The logarithmic mean temperature difference is only correct if pure co-current, or countercurrent flow is taking place in the apparatus (see Chap. C1, or [2, 9]).

For technical plate heat exchangers with chevron plates, made of stainless steel, the possible overall heat transfer coefficients, k, and the flow velocities, w, of a water-to-water application (average temperature 40°C) are to be calculated for a given pressure gradient of $\Delta p/L_p = 0.1$ bar/m, if there are plates available with inclination angles of $\varphi = 30°$, and 60°.

Plate data (stainless steel):

Wall thickness	$s_w = 0.75$ mm
Heat conductivity	$\lambda_w = 15$ W/(K m)
Amplitude	$\hat{a} = 2$ mm
Wavelength	$\Lambda = 12.6$ mm

The hydraulic diameter d_h is

with $X = 2\pi\hat{a}/\Lambda$ (Eq. (5))	$X = 0.9973$
with Φ (0.9973) (Eq. (6))	$\Phi = 1.218$
from $d_h = 4\hat{a}/\Phi$ (Eq. (4))	$d_h = 6.568$ mm

The Hagen number $\rho(\Delta p/L_p)\ d_h^3/\eta^2 = (\xi/2)\mathrm{Re}^2$ (Eq. 23) is found with the physical properties of water at 40°C:

$\rho = 992$ kg/m^3	$c_p = 4.179$ kJ/(K kg)
$\eta = 653\ 10^{-6}$ Pa s	$\lambda = 629\ 10^{-6}$ mW/(K m)
	Pr = 4.341

to be Hg = $6.592 \cdot 10^6$.

From this with Eq. (25) with $(\eta/\eta_w) \approx 1$, for $\varphi = 30°$ and 60°, one gets (with $c_q = 0.122$, $q = 0.374$) Nu = 86.76 and from Eq. (3) $\alpha = 8{,}309$ W/(K m^2). From $1/k = (2/\alpha) + (s_w/\lambda_w)$ one gets

$$k(30°) = k(60°) = 3{,}440\,\mathrm{W/(K\,m^2)}.$$

For the mixed channel from two plates with 30° and 60°, that is, from Eq. (26) $\varphi = (30° + 60°)/2 = 45°$, the heat transfer coefficient would be greater by a factor $(1/\sin(2 \cdot 30°))^{0.374} = 1.055$, and the overall heat transfer coefficient is about 4.5% greater:

$$k(45°) = 3{,}596\,\mathrm{W/(K\,m^2)}$$

The flow velocities to be expected are calculated from Reynolds numbers iteratively obtained from Eq. (18):

$$\mathrm{Re}(\mathrm{Hg}, \varphi) = \sqrt{2\mathrm{Hg}}\,\frac{1}{\sqrt{\xi(\mathrm{Re}, \varphi)}}$$

with Eqs. (11–17) and the constants $(a, b, c) = (3.8, 0.18, 0.36)$ one finds with Hg = $6.592 \cdot 10^6$:

Re (60°) = 2,610	$w(60°) = 0.262$ m/s
Re (45°) = 3,951	$w(45°) = 0.396$ m/s
Re (30°) = 5,649	$w(30°) = 0.566$ m/s

The pressure drop in the distributor and collector channels of the plate heat exchanger has to be accounted for separately, which may be a nonnegligible contribution especially for the soft plates ($\varphi < 45°$).

6 Symbols

$\hat{a}$	amplitude of the corrugation (see Fig. 2) (m)
A_0	plane projection of the plate surface (m^2)
A_p	actual plate surface, $A_p = \Phi A_0$ (m^2)
B	width of the corrugation pattern (see Fig. 2) (m)
B_p	plate width (see Fig. 2) (m)
c_q	factor in modified Lévêque analogy (Eq. (25)) (1)
d_h	hydraulic diameter, $d_h = 4\hat{a}/\Lambda$ (m)
j	Colburn factor, $j = \mathrm{Nu}\,\mathrm{Re}^{-1}\,\mathrm{Pr}^{-1/3} = \mathrm{Sh}\,\mathrm{Re}^{-1}\,\mathrm{Sc}^{-1/3}$ (1)
L	length between two crossing points (Eq. (21)) (m)
L_p	plate length (see Fig. 2) (m)
q	exponent in modified Lévêque analogy (Eq. (25)) (1)
X	wave number = $2\pi\hat{a}/\Lambda$ (l)
α^*	normalized heat transfer coefficient $\alpha^* = \alpha(\varphi)/\alpha(45°)$ (Eq. (22)) (l)
φ	inclination angle of the corrugation (see Fig. 2) (1)
Φ	surface enhancement factor = A_p/A_0 (1)
Λ	wavelength (see Fig. 2) (m)
ξ	friction factor (Eq. (1)) (1)

O2 Vibration of Tube Bundles in Heat Exchangers

Horst Gelbe[1] · *Samir Ziada*[2]
[1]Technische Universität Berlin, Berlin, Germany
[2]McMaster University, Hamilton, ON, Canada

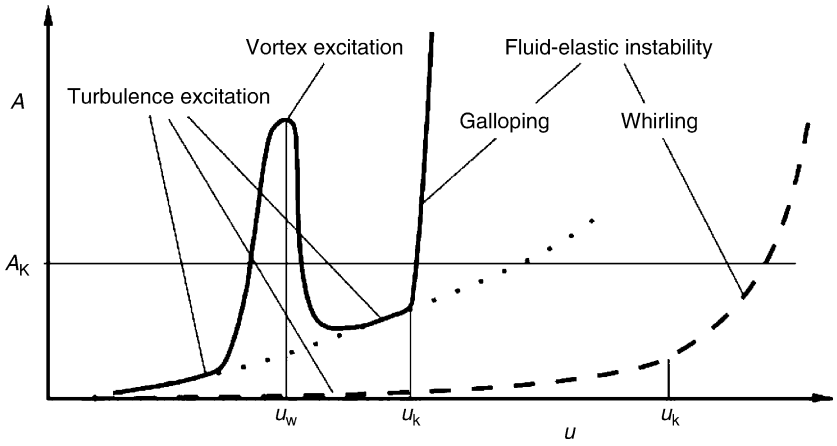
1 Introduction

Flow-induced vibrations are examined for tube bundles with gas, liquid, or gas–liquid mixture cross-flows. The effect of the axial flow or the flow inside the tubes is generally negligible, except in the case of tubes with a long length between the supports and small stiffness, such as thin-walled plastic tubes (of which the procedure to evaluate the vibration is given in [1]). The guidelines in the Sect. 5 deal with the design requirements for standard heat exchangers in chemical and process industries, but not, however, with the additional requirements to ensure long service lives for equipments such as those used in nuclear and conventional power plants.

1.1 Tube Vibration Response and Critical Parameters

Even at relatively low flow velocities, the tube arrays in heat exchangers exhibit turbulent buffeting vibrations due to cross flow. The vibration amplitude increases as fluid density increases. If the amplitude exceeds a critical level A_k, *long-term*

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_68,



O2. Fig. 1. Schematic of the vibration response of a tube as a function of cross-flow velocity, ——— liquid flow, – – – gas flow.

damage can arise, such as material fatigue and/or fretting wear failures due to friction and impact between the tubes and the support baffles. If the flow velocity exceeds a critical value u_k, then the amplitude increases either rapidly or more slowly, depending on the excitation mechanism of fluid-elastic instability, and results in *short-term damage*, such as tearing the tubes from the tube sheets, or causing the tubes to impact against each other. Figure 1 shows two examples of typical tube vibration response as a function of the cross-flow velocity. The causal excitation mechanisms are also highlighted.

1.2 Excitation Mechanisms

The most important design calculation serves to determine the critical flow velocity u_k ($u < u_k$) at which the *fluid-elastic instability* is initiated (Sects. 3 and 5). This instability can produce very fast damage, e.g., within hours of its onset. Fluid-elastic instability is caused by a self-generated fluid force, which is proportional to either the tube vibration displacement (whirling) or vibration velocity (galloping). This force acts against and therefore reduces either the spring stiffness or the damping of the system, respectively [2]. Both excitation types can occur separately or simultaneously.

The second design calculation is for the vibration amplitude A ($A < A_k$), resulting from *turbulence excitation* (Sect. 4.2) at the operating flow velocity $u < u_k$, to avoid long-term damage, especially for liquid and two-phase flows.

Vortex shedding excitation (Sect. 4.3.1) is important only in tube bundles exposed to liquid flows, when the spacing rations are industry relevant, i.e., normally small. This type of excitation can cause either short or long-term failure. It is therefore important to ensure that the vibration amplitude A at the vortex resonance velocity u_w does not exceed the critical amplitude A_k or alternatively, the maximum flow velocity of the equipment can be selected to be less than the vortex resonance velocity, i.e., $u < u_w$.

Acoustic resonance (Sect. 4.3.2) is excited only in tube bundles exposed to gas flows. Standing acoustic waves, normal to the flow and to the tube axis, can be excited by vortex shedding or turbulent fluctuations, leading to loud noise emissions and to an increase in the pressure drop of the shell side flow.

During the design phase, heat exchangers must be checked at the least for possible short-term damage that may be caused by fluid-elastic instability, and in the case of liquid flows, vortex shedding excitation must be assessed as well.

Tube vibrations due to turbulent excitation and whirling cause the tubes to vibrate in the flow direction as well as perpendicular to it, i.e., in the streamwise and transverse directions. However, vortex shedding and galloping vibrations occur predominantly normal to the flow direction. The co-ordinate systems for the tube vibrations and the flow velocities are defined in the following:

- in flow direction and normal to the tube axis — x or u,
- normal to the flow direction and to the tube axis — y or v,
- in tube axis direction — z or w.

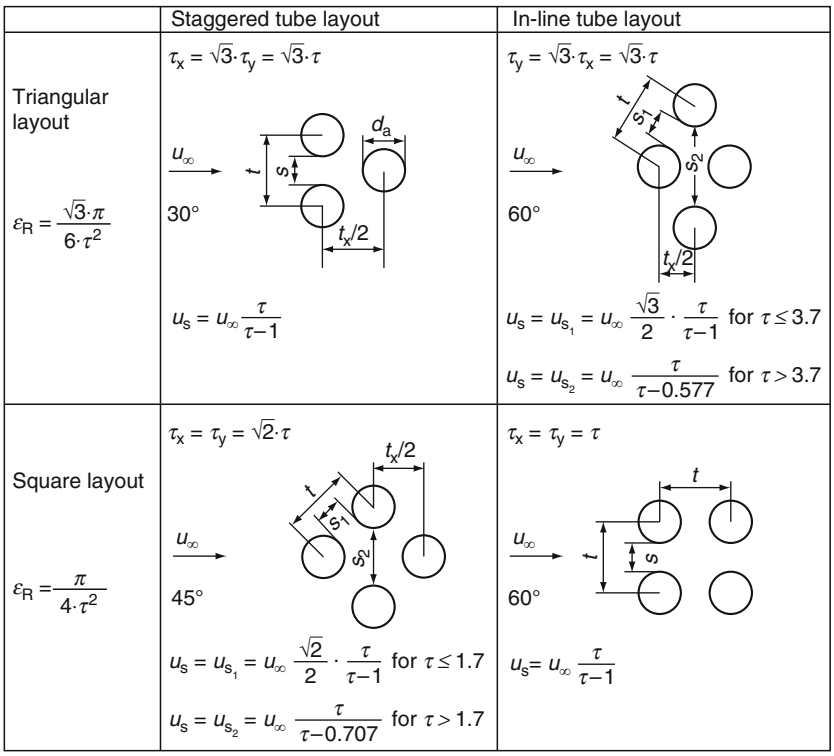
1.3 Tube Bundle Geometries

The characteristics and the effects of all four excitation mechanisms are influenced by the layout geometry and spacing ratio of the tubes. Equations to calculate the maximum gap velocity u_s as well as the solidity ratio ε_R in symmetrical staggered and in-line arrays with a constant layout angle α (the four standard tube layouts) are presented in Fig. 2 as functions of the spacing ratio $\tau = t/d_a$. Based on its geometrical characteristics, the 60° layout seems to belong to the staggered arrays, but from the fluid mechanics point of view, it should be treated in a way similar to that used for in-line arrays.

It is noteworthy that in many publications, the tube bundle velocity is calculated using $u_\tau = u_\infty \frac{\tau}{\tau-1}$, which for the 45° und 60° layouts leads to the following deviations from the gap velocity u_s:

For the 45° layout and $\tau \leq 1.7$: $u_s = 0.707\,u_\tau$,

For the 60° layout and $\tau \leq 3.7$: $u_s = 0.866\,u_\tau$.



O2. Fig. 2. Standard tube layouts with gap velocity u_s and solidity ratio ε_R.

The calculations in the Sects. 3 and 5 are based on u_s, whereas those presented in Sect. 4 are based on u_τ.

2 Structural Parameters

2.1 Definitions

The structural parameters needed to perform the calculations are the total mass per unit length m, the tube natural frequency of mode i f_i, and the logarithmic decrement of damping Λ_i. The vibration of a tube with mass M, damping constant r, and spring stiffness c is described by the linear differential Eq. (1), in which F is a time-dependent force acting on the mass. This force, which is generated by the flow, may include components dependent upon the tube vibration displacement x and vibration velocity $\dot{x}$:

$$M \cdot \ddot{x} + r \cdot \dot{x} + c \cdot x = F(t, x, \dot{x} \ldots). \tag{1}$$

The natural frequency and damping of the tube can be found from the homogeneous differential Eq. (2):

$$\ddot{x} + 2 \cdot \zeta \cdot \omega_0 \cdot \dot{x} + \omega_0^2 \cdot x = 0 \tag{2}$$

with the system undamped circular frequency $\omega_0 = (c/M)^{0.5}$ and the damping coefficient $\zeta = r/(2\,M\,\omega_0)$. The circular frequency of the damped system is

$$\omega = \omega_0 \cdot \sqrt{1 - \zeta^2} \tag{3}$$

and the natural frequency

$$f = \frac{\omega}{2 \cdot \pi}\,(\mathrm{Hz}). \tag{4}$$

The logarithmic decrement Λ of damping is defined by:

$$\Lambda = \frac{1}{n}\ln\left(\frac{\hat{x}(t)}{\hat{x}(t + n \cdot T)}\right) = 2 \cdot \pi \cdot \frac{\zeta}{\sqrt{1 - \zeta^2}}, \tag{5}$$

where $\hat{x}$ represents the maximum mass displacement at the initial time t and after n cycles $(t + nT)$ with period $T = 1/f$. For small damping ratios, $\zeta \ll 1$,

$$\Lambda \approx 2\pi\zeta \tag{6}$$

2.2 Tube Mass

The mass per unit length m is the effective vibrating mass normalized by the length of the tube. It is comprised of the mass of the tube, including the fluid inside it m_R and the hydrodynamic mass m_h:

$$m = m_R + m_h, \tag{7}$$

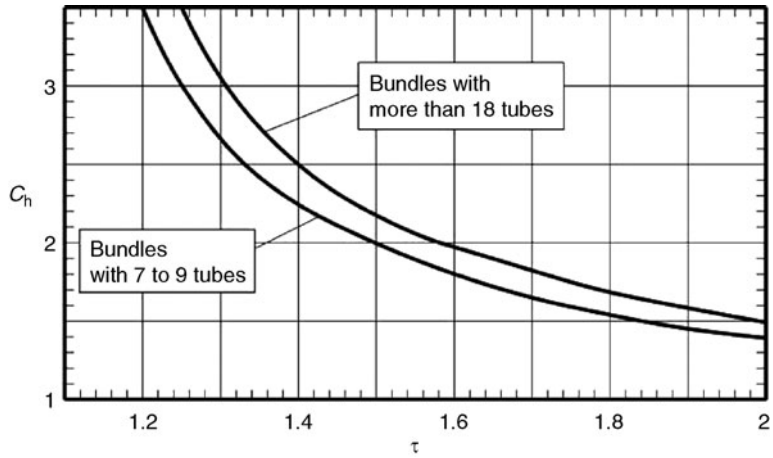
with

$$m_R = \frac{\pi}{4} \cdot \left[\rho_R \cdot \left(d_a^2 - d_i^2\right) + \rho_i \cdot d_i^2\right] \tag{8a}$$

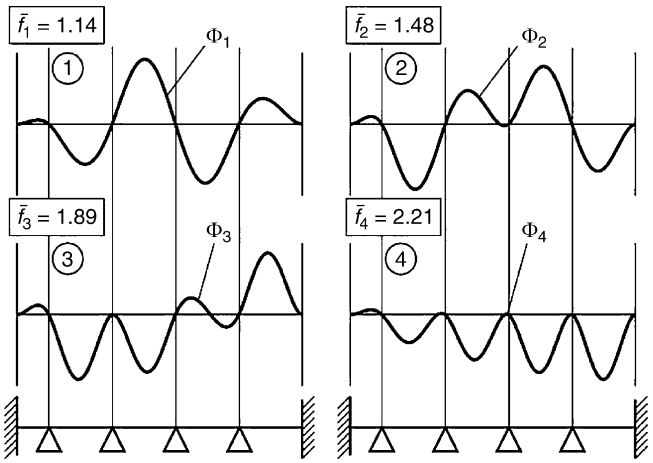
and

$$m_h = c_h \cdot \rho_f \cdot \frac{\pi}{4} \cdot d_a^2. \tag{8b}$$

The hydrodynamic mass coefficient c_h is depicted as a function of the spacing ratio in Fig. 3 [2]. In square tube layouts (45° und 90°), the value of c_h is about 10% lower. The value of m_h is negligible when the density of the fluid medium is small, such as in air.



O2. Fig. 3. Hydrodynamic mass coefficient c_h for triangular arrays (30° and 60°) as a function of tube pitch ratio [2].



O2. Fig. 4. The first four mode shapes and their relative natural frequencies of a multi-supported tube with $N = 5$ and $X = l/2$ (see Table 2 for more details).

2.3 Tube Natural Frequencies and Mode Shapes

2.3.1 Straight Tubes

In tube bundles, many different resonance modes may be excited. Typical examples of these modes, for a tube with five spans, are illustrated in Fig. 4, which shows the first four mode shapes and their relative natural frequencies. To determine the critical conditions for vibration in heat exchangers, it is often sufficient to know the first natural frequency; however, a higher frequency may be the critical one in situations involving uneven flows (e.g., tubes, which are heavily loaded near support plates but elsewhere more lightly impinged by the flow, or in axial flow over U-shaped bundles). Knowledge of the mode shapes is also essential when vortex shedding or turbulence excitations (see Sects. 4 and 6) or when unevenly distributed fluid forces (Sect. 5) have to be taken into consideration.

The natural frequency f_i of a flexible tube is determined from the ratio between the bending stiffness and the mass per unit length. Important tube characteristics, which influence the natural frequencies are the nature of the support at the tube ends, the number of tube spans N, and the span length l. Tables 2 and 3 for $N > 1$ give the relative natural frequency for the first mode shape, Table 1 for $N = 1$ includes also the relative values of the second mode frequency:

$$\bar{f}_1 = \frac{f_1}{f^*} \quad \text{and} \quad \bar{f}_2 = \frac{f_2}{f^*}, \tag{9a, b}$$

whereby f^* represents the first natural frequency of a tube with a length l, simply supported at both ends as reference value:

$$f^* = \frac{\pi}{2 \cdot l^2}\sqrt{\frac{E \cdot I}{m}} \quad \text{and} \quad I = \frac{\pi}{64}\left(d_a^4 - d_i^4\right). \tag{10a, b}$$

Table 1 shows the relative natural frequencies $\bar{f}_1$, $\bar{f}_2$ and the equivalent length for buckling $\bar{l}_k$ (for considering the influence of axial forces), for the standard cases of a tube without intermediate supports along its length. Table 1 also shows the integral average displacement of the mode shape $\bar{\Phi}$ normalized by the maximum displacement for this mode [see comments to Eq. (38)], as well as the corresponding quadratic average $\bar{\Phi}^2$.

When the cross flow velocity is not uniformly distributed along the tube axis (partial admission, see Fig. 24), the flow excitation force can be weighted by means of the partial energy ratio for a tube section of length l_r:

O2. Table 1. Relative natural frequencies, equivalent length for buckling and integral average displacement of the first mode shape for some beams (or tubes) with different types of end supports, and without intermediate supports

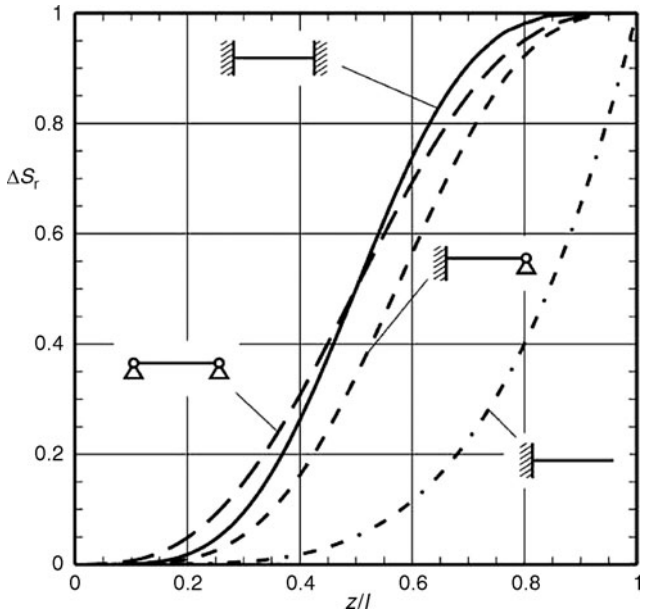
Relative values	Support types for $N = 1$			
	l = L, EI, m	l = L, EI, m	l = L, EI, m	l = L, EI, m
$\bar{f}_1$	1.00	1.56	2.27	0.356
$\bar{f}_2$	4.00	5.06	6.25	2.23
$\bar{l}_k$	1.00	0.7	0.5	2.00
$\bar{\Phi}$	0.637	0.565	0.522	0.392
$\bar{\Phi}^2$	0.500	0.438	0.394	0.250

$$\Delta S_r = \frac{\int_{l_r} \Phi^2(z)\, dz}{\int_0^L \Phi^2(z)\, dz}, \qquad (11)$$

l_r sectional length of a tube with length L (Fig. 24),
$\Phi(z)$ normalized mode shape.

Figure 5 shows the partial energy ratio ΔS_r for the first mode of tubes without intermediate supports as a function of the normalized length, z/l. Depending on the location of the considered tube section, ΔS_r can be determined from the figure.

Table 2 relates to the first mode of a tube with multiple intermediate loose supports and fixed supports at both ends, which gives rise to N spans along the tube. The table gives the relative natural frequency $\bar{f}_1$ and the partial energy ratios ΔS_1 and ΔS_N for the first and last spans. This is relevant to tubes which are welded or riveted to the tube sheets and have a constant span length between the tube support baffles but a different span length X at one end near the tube sheets. Each tube has one natural frequency for the entire tube geometry, meaning that individual spans cannot be treated as independent tubes with their local length and support type.



O2. Fig. 5. Partial energy ratio of a tube with $N = 1$ for the first mode shape as a function of z/l.

Since the sum of all $\Delta S_n = 1$, Table 2 can be used to approximately estimate the partial admission energy ratio for each of the intermediate spans:

$$\Delta S_n = \frac{1 - \Delta S_1 - \Delta S_N}{N - 2}. \qquad (12)$$

These middle span calculations are accurate if the intermediate spans have the same length l_n, as well as same structural and fluid properties and the same flow velocity over all the spans.

Table 3 provides similar information for tubes, which have loose (or pin) supports at both ends. For higher order resonance modes or for other configurations (e.g., elastic boundary at supports, in-active intermediate supports, variable span lengths or other geometries with mixed boundary conditions), the tube resonance modes can be calculated by other means such as standard finite element programs, or other design codes, e.g., the program GOOD VIBRATION [3].

All the values in the tables relate to a single tube in ideal supports. Experience shows that with the assumption of zero moment at the tube supports (i.e., assuming the clearance $\Delta d_B = 0$ und the support thickness $b = 0$), the actual frequency will be within ±5% of the estimated value, given that the value of Δd_B remains within 0.3–0.6 mm and b/d_a is smaller than 0.4. Note that Δd_B and b have opposite effects on the natural frequency, which increases with b and decreases with Δd_B. Small values of Δd_B and larger values of b can increase the damping, esp. for the first mode, and thereby reduce the long-term damage. Too large manufacturing clearances or tolerances at tube supports can eventually cause several supports to become inactive, resulting in a substantial reduction in the natural frequency [4, 5].

In tube bundles, the system natural frequencies can be slightly influenced by the mutual interaction of vibrating tubes. Where tube bundles have multiple supports, the system frequencies lie within frequency bands close to the natural frequencies of the individual tubes [2].

O2. Table 2. Relative natural frequencies and partial energy ratios for the first mode shape of a multi-supported tube, which is *fixed* at both ends. N is the number of spans, X is a variable span length at one side, ΔS_1 is for the first span with length X, and ΔS_N is for the last span with length l

	Relative natural frequencies and partial energy ratios, both ends fixed 																
	$X = 0.4 \cdot l$			$X = 0.8 \cdot l$			$X = l$		$X = 1.2 \cdot l$			$X = 1.4 \cdot l$			$X = 1.8 \cdot l$

2.3.2 U-tubes

It is possible to compute accurate values of the natural frequencies and the corresponding mode shapes of U-bend tubes either analytically [6] or with Finite Element programs. For estimation purposes, the supported straight tube sections and the unsupported U-bend sections can be regarded separately. In the event that only the straight tube sections have cross-flows, then only these are to be taken into consideration. The computation for the supported straight tube sections can be performed with the help of Tables 2 and 3. For the mixed support case, i.e., fixed at one end and pinned at the other, the values from the two appropriate tables should be averaged. When the unsupported U-bend tubes have also cross-flows, then the calculation of the first natural frequency of the U-bend tubes is given in [7].

2.3.3 Effect of Axial Forces on the Natural Frequencies

Axial compressive forces cause a reduction while tensile forces cause a rise in the natural frequencies. The frequency of a tube f_i with an axial force F_R changes according to Eq. (13), whereby the sign of compressive forces is negative and of tensile forces is positive [8]:

$$f_i(F_R) = f_i \cdot \sqrt{1 + \frac{F_R}{F_{R,k}}} \tag{13}$$

and

$$F_{R,k} = \frac{\pi^2 \cdot E \cdot I}{\left(\bar{l}_k \cdot l\right)^2}. \tag{14}$$

$F_{R,\,k}$ is the critical force necessary for the buckling of the tube. The equivalent length (for buckling failure) $\bar{l}_k = l_k/l_n$ depends on the type of the supports, and its value for each span n can be found in Table 1 [9]. The largest value of $l_k = \bar{l}_k \cdot l_n$ should be selected. For firmly fixed tubes, the axial force F_R is calculated from the difference in thermal expansions between the tubes and the shell, as well as from the pressures p_i inside the tube and p_a in the shell side, which, depending upon the construction can cause axial tensile or compressive forces.

O2. Table 4. Recommended plate stiffness X for different types of tube sheets

	X_A	X_I		
Shell diameter in m		<0.6	0.6–1.2	>1.2
Stiff tube sheet, p_a, $p_i \geq 30$ bar	1	0.9	0.8	0.7
Flexible tube sheet, p_a, $p_i < 30$ bar	1	0.7	0.6	0.5
Membrane tube sheet	0.8	0.4	0.3	0.2

The plate stiffness of the tube sheets has a strong effect. Further influences can be attributed to the nature of the tube sheet boundary conditions, the density (or the spacing ratio) of the tube holes, and to an unequal distribution of the tubes. Bundle interior tubes (Index I) are less stressed due to thermal expansions than exterior tubes (Index A), which are positioned in the proximity of the shell at the edge of the plate.

Therefore, the rigidity of the tube sheet is calculated via an empirical rigidity factor X, with $X = 1$ for a rigid plate and $X = 0$ for a flexible membrane. If the bundles exterior tubes (A) are connected rigidly to the tube sheet, then $X_A = 1$, whereas for the tubes in the center of the tube sheet (I), the rigidity factor can be substantially smaller, $X_I < 1$, depending on the tube sheet thickness and the shell diameter. Recommended values can be found in Table 4.

The following equations and recommendations are valid for tubes, which are uniformly distributed at the center of the tube sheet. They are appropriate for the calculations of the compressive stresses (frequency reduction), as well as erring on the safe side for interior tubes with assumed values of X_I, which are too small. For the case of tensile stresses, some lower values may result. But in the vibration analysis, the possible frequency increases from such tensile stresses should not be taken into consideration.

In equipments without stress relief the axial tube force F_R is expressed as:

$$F_R = F_{R\vartheta,v} + F_{Rp}. \tag{15}$$

(a) Axial tube force due to prevention of thermal expansion and lateral contraction:

$$F_{R\vartheta,v} = \frac{A_R \cdot E_R}{1 + \dfrac{n_R^* \cdot A_R \cdot E_R}{X \cdot A_M \cdot E_M}} \cdot \left[\gamma_M \cdot \Delta\vartheta_M - \gamma_R \cdot \Delta\vartheta_R - \frac{\pi}{2} p_a \left(\frac{\nu_R \cdot d_a^2}{A_R \cdot E_R} + \frac{\nu_M \cdot d_i^2}{A_M \cdot E_M}\right)\right]. \quad (16a)$$

The greatest stress occurs at the exterior tubes:
Exterior tubes:

$$X = X_A; \qquad n_R^* = n_{RA}^* = n_{RA0} + (n_R - n_{RA0}) \cdot X_I^3 \quad (16b)$$

Interior tubes:

$$X = X_I; \qquad n_R^* = n_{RI}^* = n_R - n_{RA0}(1 - X_I^3). \quad (16c)$$

For cylindrical shells, the minimal number of load bearing exterior tubes ($X_A = 1$, $X_I = 0$) is:

$$n_{RA0} = \left[e + \frac{d_i - d_H}{3 \cdot \tau \cdot d_a}\right] \cdot \mathrm{NRR} \le n_R. \quad (16d)$$

For tube layout angle α: 60° 45° 30° 90°
Constant e in Eq. (16d): 1.0 1.3 1.6 1.8

(b) Axial tube force due to external forces:

$$F_{Rp} = \frac{\pi}{4 \cdot \left(n_R + X \cdot \dfrac{A_M \cdot E_M}{A_R \cdot E_R}\right)} \cdot \left[\begin{array}{l} p_a \cdot \left(d_i^2 - n_R d_a^2\right) \\ +X \cdot p_i \cdot n_R \cdot d_i^2 - (1 - X)^2 \cdot p_i \cdot \left(d_H^2 - n_R d_i^2\right) \end{array}\right], \quad (16e)$$

X should be given separately for interior and exterior tubes according to Table 4.

For comparatively rigid shell compensators, Eqs. (15), (16a), and (16e) are valid with appropriately reduced values of E_M.

The principal effects of the pressures p_i, p_a, and X_I on the axial tube force $F_{Rp,v}$ for equipments without stress release are described in ([10], Fig. 8). The forces cancel out with equal inner and outer pressures. Considerable axial compressive forces will develop only in the following cases:

- In the exterior tubes for $p_a - p_i > 5$ bar,
- In the interior tubes for $p_i - p_a > 5$ bar and $X_I < 0.5$.(16f).

In equipments with full stress relief $F_{R\vartheta,v}$ is zero and F_{Rp} can be calculated according to Eq. (16e) with $E_M = 0$ and using the parameters cited in Table 5, which shows the critical pressures at which axial compressive forces are to be expected, and the maximally loaded tubes, which are normally the interior tubes (I).

O2. Table 5. Critical pressure values and parameters to be used in Eq. (16e) for equipments with stress relief

Equipment with	Axial pressure force for		X	d_1
Shell compensator	$p_i - p_a > 5$ bar and $X_I < 0.5$	I	X_I	$d_K > d_1$
U-bend tubes	$p_a - p_i > 5$ bar	I ≡ A	1	0
Floating head	$p_a - p_i > 5$ bar, $p_i - p_a > 5$ bar, and $X_I < 0.5$	I	X_I	0
Stuffing box	$p_i - p_a > 5$ bar	I ≡ A	0	d_1

2.4 Acoustic Natural Frequencies of the Shell-side Volume

Gas flows across tube bundles can excite the acoustic resonance modes, which consist of standing waves of the gas column inside the shell-side volume. These standing waves are in a direction perpendicular to the flow and tube axis. The frequencies of these acoustic modes are:

In a rectangular duct

$$f_{ai} = \frac{i \cdot a_{ge}}{2 \cdot W_y}, \quad i = 1, 2, 3 \ldots \quad (17a)$$

and in a cylindrical container

$$f_{ai} = \frac{\lambda_{ij} \cdot a_{ge}}{\pi \cdot d_i}, \quad i, j = 1, 2, 3 \ldots, \quad (17b)$$

where W_y is the duct dimension in the y-direction, λ_{ij} the eigen values of the Bessel function (Table 6), and a_{ge} the effective speed of sound in the bundle. The effective speed of sound in a bank of tubes a_{ge} according to [11] is:

$$a_g > a_{ge} > \frac{a_g}{\sqrt{1 + \varepsilon_R}}, \quad (18)$$

with ε_R is the solidity ratio (percentage by volume of the tubes relative to the total volume of the shell), which is given in Fig. 2 for various tube layouts. The lower value resulting from Eq. (18) seems to give reliable frequency estimates for large size bundles, i.e., bundles with large depth W_x in the direction of the flow. If one assumes $W_x = W_y$ for cylindrical ducts, then measured values for rectangular ducts ([12], Fig. 9) suggest that a_{ge} lies mid-way between the two limit values of Eq. (18).

2.5 Damping

Predicting the damping of vibrating systems is subject to considerable uncertainty. Different levels of damping, up to a factor of 2, can be observed within the very same tube bundle, as a result of manufacturing tolerances. Correlations from published data [13] suggest deviations of about a factor 4. The following guidelines deliver a lower bound of damping, which leads to conservative designs.

In the literature, the damping values are often represented as the Lehr's damping coefficient ζ (given either as an absolute or a percentage). In the following, the logarithmic decrement Λ in absolute value will be used. Some damping types are amplitude dependent and also a function of the natural modes [4], e.g., the higher modes have reduced damping. All the equations presented below are valid for small amplitudes at the critical conditions, e.g., at the initial phase of instability.

O2. Table 6. Eigen values λ_{ij} of the Bessel function [71]

	i				
j	0	1	2	3	4
0	0	1.841	3.054	4.201	5.318
1	3.832	5.331	6.706		

System damping is an additive effect composed of three basic parts:

(a) *Material- and support damping* of tubes without any effect from intermediate supports. The material damping is negligible. The damping of fixed, or rigid, supports at the tube ends depends on the support design and the tube length, e.g., $\Lambda_M = 0.01 \ldots 0.04$. Without intermediate supports, the lower value applies to long tubes ($L > 2$ m), and a higher value is more appropriate for shorter tubes. Supports with O-rings or clamps produce higher damping, which is also amplitude dependent [4]. For loose end supports structural damping is dominant [1] [see (c)] and $\Lambda_M = 0$.

When the tube has intermediate supports, the importance of material and end-support damping decreases as the number of intermediate supports increases, so that, for $N > 2$, it can be ignored relative to the other damping components. For $N = 2$, then 50% of the values for $N = 1$ should be taken into consideration.

(b) *Viscous damping* due to the fluid surrounding the vibrating tube. In the case of gas flow with low density, this can be neglected. The damping formula given in [14] has been adjusted such that even for small Stokes number, the estimated damping values are on the safe side:

$$\Lambda_v = \pi \cdot \frac{\rho_f \cdot d_a^2}{m \cdot \mathrm{ST}^{0.42}} \cdot \frac{1 + \left(\frac{1}{\tau'}\right)^3}{\left(1 - \left(\frac{1}{\tau'}\right)^2\right)^2} \tag{19}$$

with the Stokes number $\mathrm{ST} = \dfrac{\pi \cdot f_i \cdot d_a^2}{2 \cdot \nu_f} > 30$,

$\tau' = 1.7\tau > 2$ for a standard triangular layout,
$\tau' = 1.9\tau > 2$ for a standard square layout.

(c) *Structural damping*. In multiple support tube bundles ($N > 2$), most of the total damping comes from this source; practically 100% in gases and from 70 to 90% in liquids (the remainder being viscous damping). The sources of structural damping are Coulomb friction as well as impact and squeeze film processes in the gaps between tubes and support plates. For loose or pinned supports at both tube ends, the value N in Eqs. (20) and (21) should be increased to $N^1 = N + 2$.

When tube bundles are exposed to gas flow, friction and impact processes are dominant. From the work of Pettigrew et al. [13], the following equations can be derived:

$$\Lambda_{Sg} = \frac{\pi}{10} \cdot \frac{N-1}{N} \cdot \sqrt{\frac{b}{0.8\,[\mathrm{m}]}} \quad \text{for } l_{am} < 0.8 \text{ m}, \tag{20a}$$

$$\Lambda_{Sg} = \frac{\pi}{10} \cdot \frac{N-1}{N} \cdot \sqrt{\frac{b}{l_{am}}} \quad \text{for } l_{am} \geq 0.8 \text{ m}, \tag{20b}$$

with b thickness of support plate, l_{am} the arithmetic mean of the three longest tube sections. At boring clearances Δd_B = 0.4–0.7 mm, the effect of Δd_B is small. With further reductions in the support clearance, the damping increases – so for this and other reasons, the value of Δd_B should be kept as small as possible.

When tube bundles are exposed to liquid flow, the impact damping processes in combination with squeeze film damping are dominant. According to [14]:

$$\Lambda_{Sl} = 44 \cdot \pi \cdot \frac{N-1}{N} \cdot \frac{1}{f_i} \cdot \left[\frac{\rho_l \cdot d_a^2}{m}\right] \cdot \left[\frac{b}{l_{am}}\right]^{0.6}. \tag{21}$$

(d) Total damping values are the sum of the three basic parts:

Gases (at low pressures):

$$\left.\begin{array}{ll} N = 1 & \Lambda_g = \Lambda_M \\ N = 2 & \Lambda_g = \Lambda_M/2 + \Lambda_{Sg} \\ N \geq 3 & \Lambda_g = \Lambda_{Sg} \geq 0.03/i^{0,2} \end{array}\right\} \tag{22}$$

Liquids :

$$\left.\begin{array}{ll} N = 1 & \Lambda_l = \Lambda_M + \Lambda_V \\ N = 2 & \Lambda_l = \Lambda_M/2 + \Lambda_V + \Lambda_{Sl} \\ N \geq 3 & \Lambda_l = \Lambda_V + \Lambda_{Sl} \geq 0.04/i^{0,2} \end{array}\right\} \tag{23}$$

3 Fluid-elastic Instability

3.1 Introduction

The phenomen of fluid-elastic instability is described in [1, 2, 15, 16]. It can be seen from Fig. 1 that there are some differences between whirling and galloping. According to [1, 17], the following stability equation for the dimensionless critical gap velocity u_k^* for whirling can be derived:

$$u_k^* = \frac{u_{sk}}{f_i \cdot d_a} = K \cdot \sqrt{\Delta} \tag{24}$$

with u_{sk} as the critical gap velocity, $K(\tau)$ the stability constant, and $\Delta = \frac{m \cdot \Lambda}{\rho_f \cdot d_a^2}$ the mass-damping parameter.

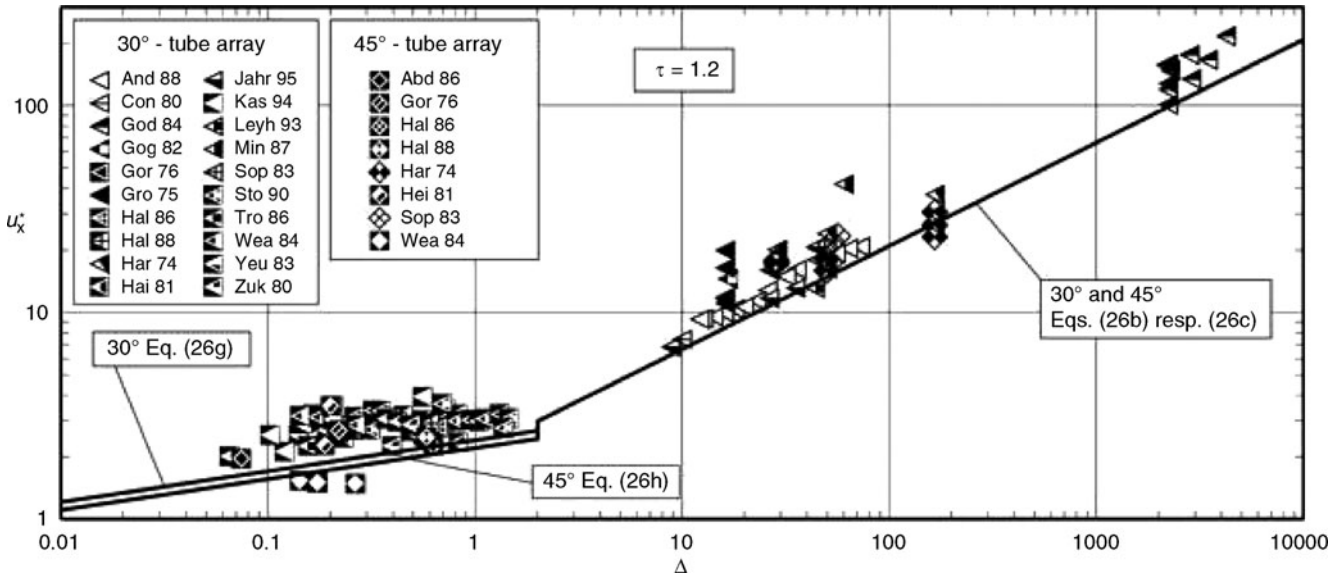
Whirling is caused by a soft self-excitation mechanism [15], in which all the tubes of the bundle participate. These vibrate on elliptical trajectories in both the x and y directions. The coupling effect weakens as the spacing ratio becomes larger. For gas flows ($\Delta > 2$) across staggered tube bundles (30° und 45° layouts), the fluid-elastic instability is initiated by whirling. In such cases, Eq. (24) as well as the exponent 0.5 of the mass-damping parameter Δ are confirmed (Fig. 6).

Galloping is caused by a hard self-excitation mechanism [15] involving single tubes or individual tube rows, which vibrate exclusively in y-direction and independently of the movements of the remaining tubes. Galloping leads to steep amplitude increases and arises particularly in in-line tube bundles (60° and 90° layouts) with free flow lanes and in liquids. In these cases, galloping can occur before the onset of whirling, which then leads to low K-constants, to smaller exponents of the mass-damping parameter and to weak dependence on the spacing ratio.

Since the stability equation ought to be valid for both excitation types, its general form is:

$$u_k^* = K(\tau) \cdot \Delta^P. \tag{25}$$

$K(\tau)$ as well as P are functions of the tube layout, the spacing ratio, and of the fluid flow across the array.



O2. Fig. 6. Stability diagram: dimensionless critical gap velocity as a function of the mass-damping parameter for tube layout geometries of 30° and 45° with the stability constants for $\tau = 1.20$ [21].

The suggested equations described in Sect. 3.2 for single-phase flows are based on a re-valuation of the data reported in the original works of Chen and Jendrzejczek [2, 18], Weaver and Fitzpatrick [19], and Pettigrew and Taylor [20], as well as in more recent publications. They reproduce the lower limits of the scatter in all measured data points. In comparison with previous guidelines, the recommended equations show smaller deviations and reduce the scatter of the measured data points for all tube layout geometries and all fluid flow conditions [21].

3.2 Single-phase Flow

The stability equation is

$$u_k^* = \frac{u_{sk}}{f_i \cdot d_a} = K(\tau) \cdot \left[\frac{m \cdot \Lambda}{\rho_f \cdot d_a^2}\right]^P \qquad (26)$$

with $P = 0.5$ for gas flow across 30° and 45° layouts as well as for single rows,
$P = 0.4$ for gas flow across 60° and 90° layouts,
$P = 0.15$ for liquid flow and all layouts.

The stability constant $K(\tau)$ for *ideal tube bundle situations* can be taken from Figs. 8 and 9 or Tables 7 and 8. It is clear from these figures that the 30° layout is the least susceptible to instability, and the 60° layout has the smallest critical flow velocity without any influence of the pitch ratio. The second and third tube rows, relative to the other rows, are at greater risk to vibrate; however, in [22], the last tube row of square bundles (90° layout) exposed to liquid flows was most susceptible to instability.

Figures 6 and 7 show the stability diagrams for $\tau = 1.20$, i.e., at the practically smallest values of τ, with all experimental data. Reference [23] gives further information and [21] offers all data sources, additional correlations and comparisons with previous guidelines. The demarcation between gases and liquids is approximately at $\Delta = 2$.

In the liquid range, the coincidence of different excitation mechanisms (whirling, galloping, vortex excitation) is possible.

O2. Table 7. Stability constants for standard tube layout geometries subjected to *gas flow* [21]

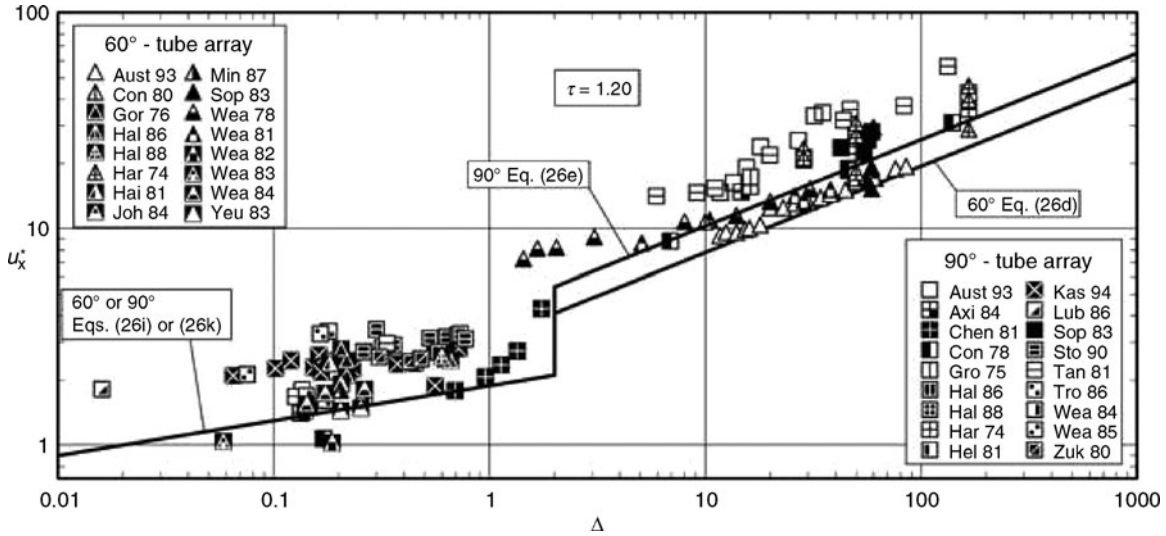
Tube layout geometry	K_{min}	$K(\tau)$	P	Δ	Eqs.
Tube row [2]	4.4	6.0 (τ − 0.375)	0.5	3 . . . 300	(26a)
30°[a]	2.1	7.0 (τ − 0.9)	0.5	2 . . . 4000	(26b)
45°[a]	2.1	5.3 (τ − 0.8)	0.5	2 . . . 300	(26c)
60°[a]	3.1	3.1	0.4	2 . . . 200	(26d)
90°[a]	4.1	2.9·τ	0.4	2 . . . 200	(26e)

[a]Smaller values are realistic in real heat exchangers due to variations in the approach flow angle [see Sect. 5.2, Eq. (46) and Table 9]

O2. Table 8. Stability constants for standard-tube layout geometries subjected to *liquid flow* [21], $P = 0.15$

	K_{min}	$K(\tau)$	Δ	Eqs.
Tube row [18]	2.2	3.1 (τ − 0.375)	0.05 . . . 3	(26f)
30°[a]	2.4	1.5 (τ + 0.5)	0.05 . . . 2	(26g)
45°[a]	2.2	1.2 (τ + 0.6)	0.05 . . . 2	(26h)
60°	1.8	1.8	0.05 . . . 2	(26i)
90°	1.9	1.0 (τ + 0.7)	0.05 . . . 2	(26k)

[a]Smaller values are realistic in real heat exchangers due to variations in the approach flow angle [see Sect. 5.2, Eq. (46) and Table 9]



O2. Fig. 7. Stability diagram: dimensionless critical gap velocity as a function of the mass-damping parameter for tube layout geometries of 60° and 90° with the stability constants for $\tau = 1.20$ [21].

Therefore, it is essential for liquid flows that the selected operating velocity does not coincide with that for tube resonance by vortex shedding (Sect. 4.3). This is because vortex resonance can hasten the onset of fluid-elastic instability. This was the case in some test measurements by Weaver et. al., reported in Figs. 6 and 7, which though they lie below the stability boundary, are included as a helpful warning.

The stability diagrams are valid under the following major boundary conditions:

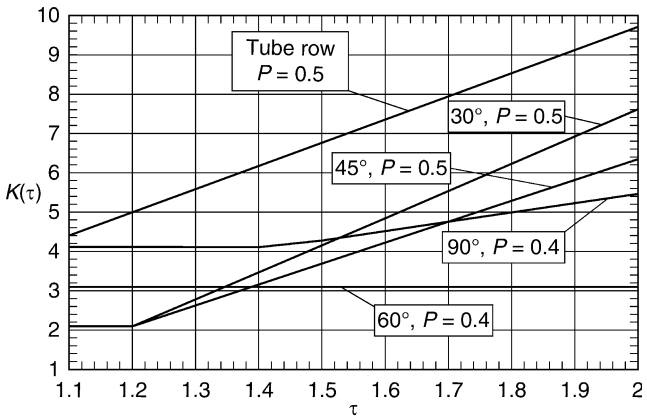
1. For tubes starting from the second tube row, in bundles with *ideal conditions,* i.e.,
   - for homogeneous bundles with constant cross section, uniform distribution of the tubes without free channels or boundary gaps,
   - for tubes with evenly distributed flow along the entire length and in the *y*–direction.
2. The structural parameters m, Λ_i, and f_i are determined from tube tests in quiescent fluid with density ρ_f.

For more details and conditions see [10, 21]. The effects of various deviating boundary conditions, which normally arise in real (circular) heat exchangers, are described in Sect. 5. For *nonideal flow conditions* (i.e., with nonuniform flow), the appropriate *equivalent gap velocities* (Sect. 5.3) should not exceed the critical values.

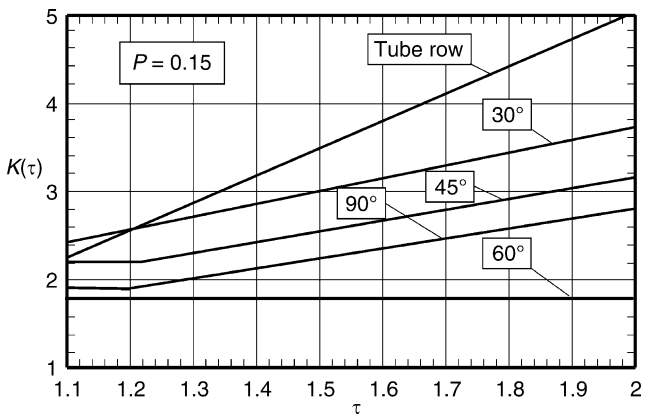
Figure 8 and Table 7 give the stability constants $K(\tau)$ and the exponents P for gas and steam flow, and Fig. 9 and Table 8 for liquid flow across *standard tube layout geometries.*

In *nonstandard tube layouts*, i.e., with deviations in the layout angle α, which is no more than $\pm 5°$, the equations for the standard situation can be used [24].

Should the deviations be greater than $\pm 5°$, then the stability constants for staggered arrays can be obtained from interpolations between the values for 60°, 45°, and 30° as well as from the limiting instability curve for a tube row ($\tau_x = \infty$). Suitable diagrams can be found in [10], for gas flow also in [21].



O2. Fig. 8. Stability constants for gas flow and standard tube layout geometries as a function of the pitch ratio.



O2. Fig. 9. Stability constants for liquid flow and standard tube layout geometries as a function of the pitch ratio.

The 30° layout bundles react very sensitively to *changes in the approach flow angle* when these are larger than ±8° [25]. Then the stability constant declines and the value for the 60° layout bundle can be attained already at deviations of ±12° [26, 27]. Because of the prevalence of changes in the approach flow direction in real heat exchangers with 30° and 45° tube layouts, it is recommended to select smaller values of u_{sk} for tubes in the endangered regions (Sect. 5.2, Table 9). The 45° layout is less sensitive than the 30° layout, because the angle deviations can be larger (approximately ±15°) before an influence has been observed and the changes of the stability constants are smaller.

3.3 Two-phase Flow

At present, compulsory design guidelines for two-phase flows of gases and liquids do not exist. The addition of another fluid phase changes the nature of the interaction mechanism between the tubes and the fluid. Therefore, the stability equations developed for single-phase flows cannot be used without taking further parameters into consideration.

In Figs. 10 and 11, some results are presented for measurements of the 30° as well as the 60° and 90° tube layouts, which can help in estimating the critical velocities. For the sake of comparison, the corresponding stability equations for the single-phase flow case with $\tau = 1.20$ are also included. In order to make comprehensive rough estimates possible, the measured data were normalized using the structural data corresponding to pure liquid phase instead of the locally measured two-phase parameters. Therefore:

- Mass per unit length m, frequency f, and damping Λ are the values *in pure liquid*.
- The fluid density ρ_{gl} results from the linear average of ρ_g and ρ_l:

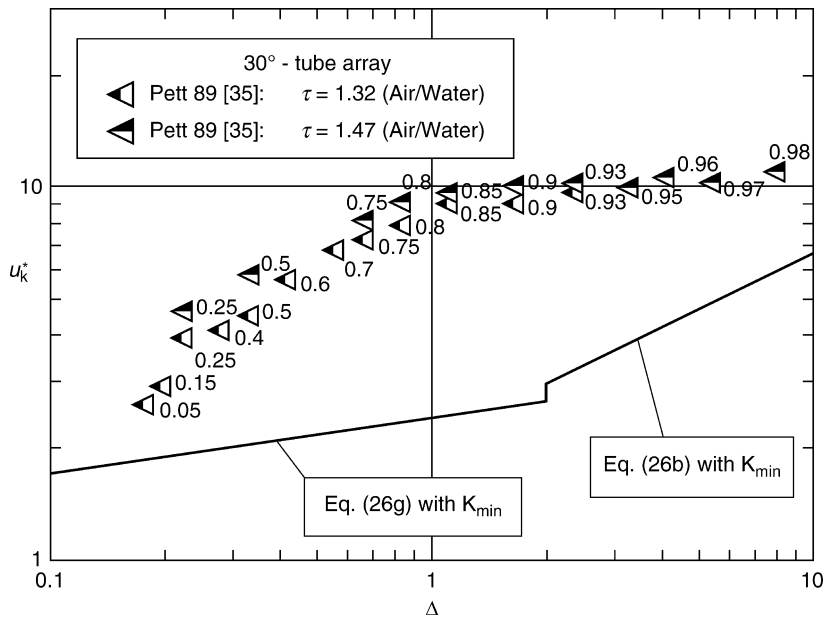
$$\rho_{gl} = \dot{\varepsilon}_g \cdot \rho_g + (1 - \dot{\varepsilon}_g) \cdot \rho_l \quad \text{and} \quad \dot{\varepsilon}_g = \frac{\dot{V}_g}{\dot{V}_g + \dot{V}_l}. \quad (27a, b)$$

- $\dot{\varepsilon}_g$ is the gas volume flow fraction, which, if available, is printed next to the data points.
- The effect of the pitch ratio has not been considered in the shown data points [28, 29]. However, the pitch ratio is indicated in the figures.
- The velocity parameter is determined from the gap velocity u_s, which is based on the average two-phase flow density ρ_{gl}.

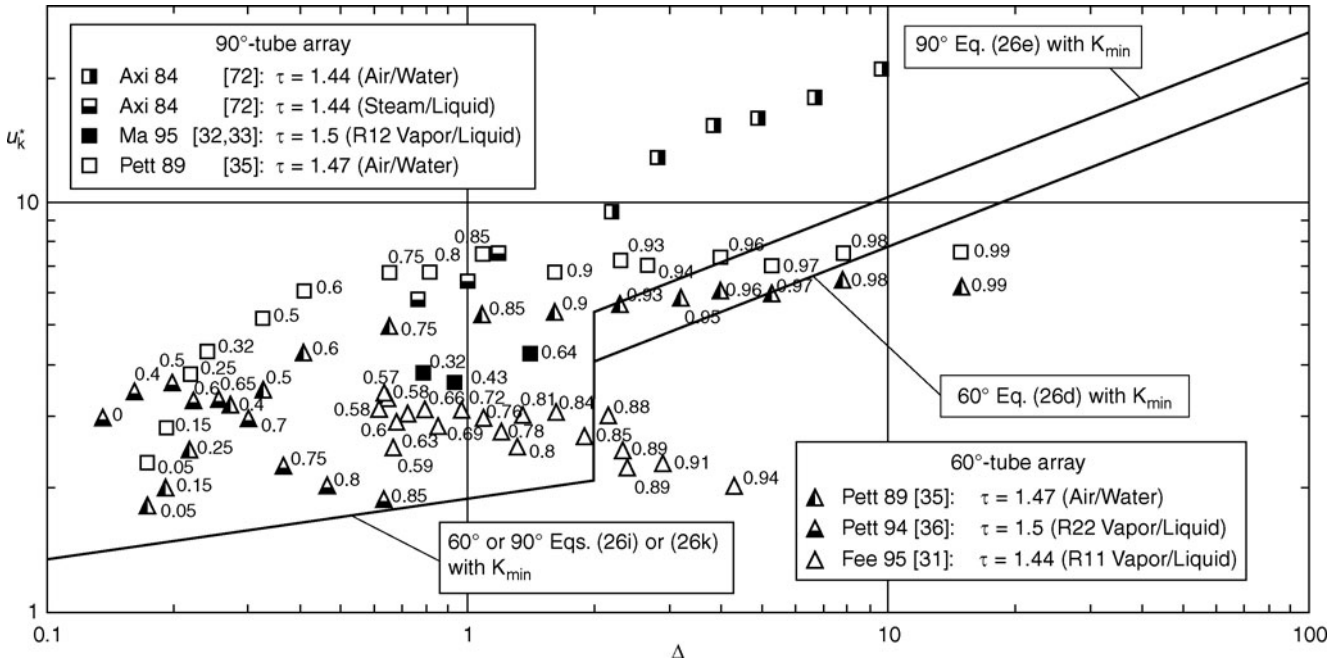
Several publications [28–37] show that u_k^* is dependent on the two-phase flow regime. For bubbly flows, the dimensionless critical gap velocity increases with $\Delta^{0.5}$. For higher values of $\dot{\varepsilon}_g$, for which dispersed flow predominates, the value of u_k^* seems to be independent of Δ in air–water flows [31, 35, 36]. If refrigerant flow is used [31, 36], the value of u_k^* for $\dot{\varepsilon}_g > 0.6$ decreases with increasing $\dot{\varepsilon}_g$.

The locally measured two-phase flow data for $\dot{\varepsilon}_g = 40 \ldots 70\%$ show that viscous damping Λ_V reaches a maximum value of about 5 times higher than the corresponding single-phase value [35, 37]. This is obviously the reason that the measured critical velocities for two-phase flows, as shown in Figs. 10 and 11, are higher than those obtained from the equations for single-phase flows. Formulas to determine the hydrodynamic mass coefficient and the fluid damping from the local void fraction can be found in references [34, 37].

References [28, 29, 37] give additional information regarding the effect of the tube layout geometry and the spacing ratio as well as the influence of the two-phase flow regime on the dimensionless critical gap velocity u_k^*.



O2. Fig. 10. Dimensionless critical gap velocity as a function of the mass-damping parameter for the 30° tube layout geometry. The stability lines shown are for the single- phase flow with the lowest stability constant.



O2. Fig. 11. Dimensionless critical gap velocity as a function of the mass-damping parameter for the 60° and 90° tube layout geometries. The stability lines shown are for the single-phase flow with the lowest stability constant.

4 Turbulence and Vortex Shedding Excitations

4.1 Introduction

The tubes of heat exchangers are inherently exposed to turbulence excitation at all flow velocities. In addition, periodic excitations due to vortex shedding also exist and must be assessed at critical ranges of flow velocity. Small amplitude vibrations excited by flow turbulence, also called turbulent buffeting, are often the cause of fretting wear damage of the tubes. This mechanism should therefore be carefully considered for power plant heat exchangers, e.g., steam generators, because of their long service life expectation.

The nature of these two flow excitations is depicted in Fig. 12, which shows the normalized power spectral density of the fluid force S_F [see Eq. (28)] acting on the tubes of an in-line tube bundle with a relatively large tube spacing ratio (τ = 3.0). The turbulent excitation extends over a wide frequency range and is represented by the two straight lines, which approximate the bound spectrum of turbulent forces, i.e., the spectrum enveloping the highest turbulent forces. On the other hand, the spectral peak near a Strouhal number of 0.2 is caused by vortex shedding excitation. The presence of this excitation and the amplitude of its spectral peak depend on the spacing ratio of the tube layout. For example, this vortex shedding excitation does not exist in tube bundles with small spacing ratios, $\tau \leq 1.5$ [38, 39].

Turbulent flow excitation will be dealt with in Sect. 4.2 without any considerations to the vortex shedding excitation. The latter will be separately addressed in Sect. 4.3. The flow parameters in these two sections are based on the bundle velocity $u_\tau = u_\infty \cdot \tau / (\tau - 1)$, which is different from the gap velocity u_s used in Sect. 3. Conversion to u_s for tube layouts with 45° and 60° can be easily derived with the aid of Fig. 2 or Eq. (66b).

4.2 Turbulent Buffeting

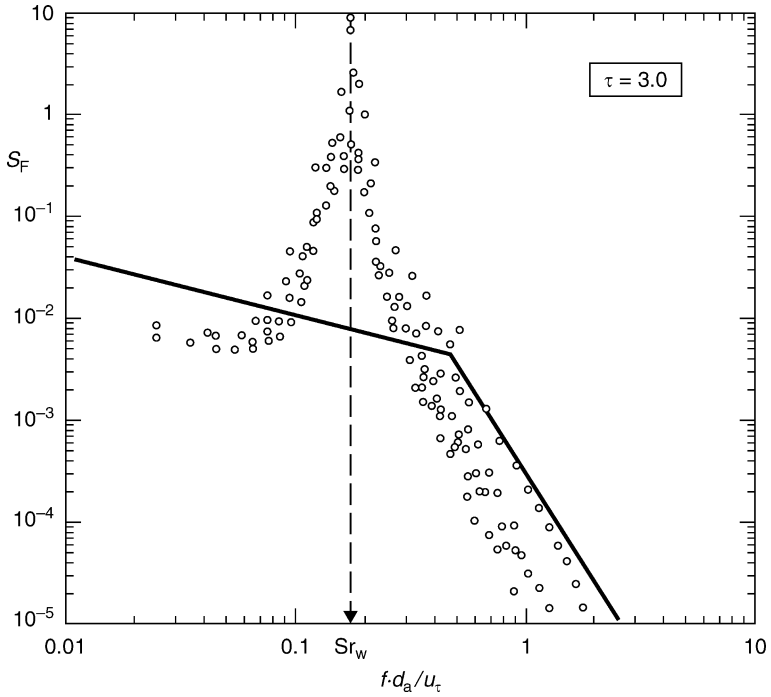
4.2.1 Power Spectral Density of Turbulence Excitation

The bound spectrum shown in Fig. 12 is used to estimate the maximum amplitude of turbulent buffeting vibration. Introductory material on this topic can be found in [1], whereas recent measurements and a brief review can be found in [40] and [41], respectively. The normalized form of power spectral density of the fluid force is given by [39, 42]:

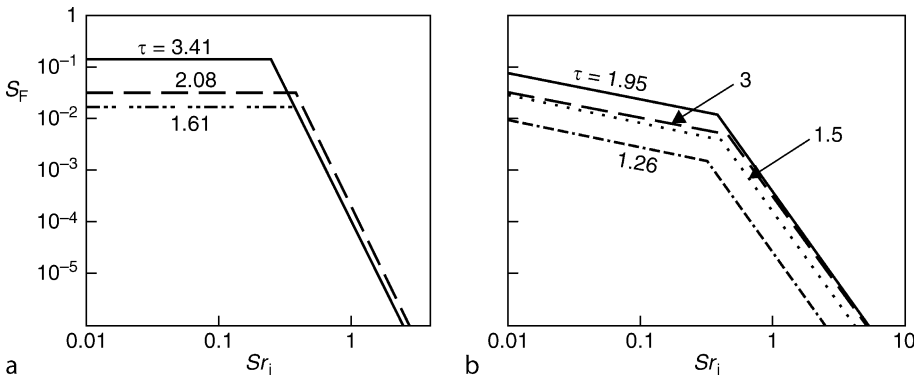
$$S_F = S_y \cdot \frac{4 \cdot u_\tau}{d_a \cdot \left(\rho \cdot u_\tau^2 \cdot l \cdot d_a\right)^2}, \qquad (28)$$

where S_y is the measured power spectral density of the fluid force in y-direction, which is substantially higher than that measured in x-direction. The normalization procedure shown in Eq. (28) collapses the values of S_F for different Reynolds numbers on a single curve when plotted against the dimensionless frequency of turbulence excitation $f \cdot d_a / u_\tau$.

Design bound spectra of S_F for different tube layouts are given as functions of Sr_i in Fig. 13a for staggered (30°, 45° and 60°) and in Fig. 13b for in-line (90°) tube arrangements. The normalized power spectral densities S_F given in Fig. 13 are valid for single-phase flows, whether gas or liquid. The tube with natural frequency f_i will be excited by the turbulence fluid



O2. Fig. 12. Normalized power spectral density of the fluid force as a function of the dimensionless frequency for an in-line tube bundle, $\tau = 3.0$; Re = 10^4– $5 \cdot 10^4$; data for tube rows 1–6 [38]; Sr_w Strouhal number of vortex resonance frequency.



O2. Fig. 13. Bound spectra of normalized power spectral densities of turbulence excitation force as functions of the dimensionless turbulence resonance frequency [39, 42], (a) for staggered tube layouts (30°, 45°, and 60°), (b) for in-line tube layouts (90°).

force at the frequency $f = f_i$. Therefore, the *dimensionless turbulence resonance frequency* is defined by:

$$\mathrm{Sr}_i = \frac{f_i \cdot d_a}{u_\tau}. \tag{29}$$

The bound spectra of Fig. 13 can also be expressed by the following equations, which are given for staggered and in-line bundles separately:

Staggered tube layouts:

For $1.25 \le \tau \le 2.1$

$$0.01 \le \mathrm{Sr}_i < 0.36 : S_F = 4.2 \cdot \tau^{2.8} \cdot 10^{-3}, \tag{30a}$$

$$0.36 \le \mathrm{Sr}_i \le 3.0 \ : S_F = 2.7 \cdot \tau^{2.8} \cdot 10^{-5} \cdot \mathrm{Sr}_i^{-5}, \tag{30b}$$

and for $2.1 \le \tau \le 3.5$

$$0.01 \le \mathrm{Sr}_i < 0.65\,\tau^{-0.8} : S_F = 4.2 \cdot \tau^{2.8} \cdot 10^{-3}, \tag{30c}$$

$$0.65\,\tau^{-0.8} \le \mathrm{Sr}_i \le 3.0 \ : S_F = 5 \cdot \tau^{-1.2} \cdot 10^{-4} \cdot \mathrm{Sr}_i^{-5}. \tag{30d}$$

In-line tube layouts:

For $1.25 \le \tau \le 2.1$

$$0.01 \le \mathrm{Sr}_i < 0.36 : S_F = \left(2.4 \cdot \tau^{2.3} - 3\right) \cdot 10^{-3} \cdot \mathrm{Sr}_i^{-0.5}, \tag{31a}$$

$$0.36 \le \mathrm{Sr}_i \le 3.0 : \ S_F = \left(1.2 \cdot \tau^{2.3} - 1.8\right) \cdot 10^{-4} \cdot \mathrm{Sr}_i^{-3.5}, \tag{31b}$$

and for $2.1 \le \tau \le 3.5$

$$0.01 \le \mathrm{Sr}_i < 0.23\,\tau^{0.6} : S_F = \tau^{-3.1} \cdot 10^{-1} \cdot \mathrm{Sr}_i^{-0.5}, \tag{31c}$$

$$0.23\,\tau^{0.6} \le \mathrm{Sr}_i \le 3.0 \ : S_F = 1.4 \cdot \tau^{-1.4} \cdot 10^{-3} \cdot \mathrm{Sr}_i^{-3.5}. \tag{31d}$$

4.2.2 Turbulence Vibration Response for Single Phase Flow

The amplitude of turbulent buffeting is determined by means of random vibration theory. The Root Mean Square (RMS) amplitude, or the effective amplitude, of the tube turbulent buffeting can be calculated from the formula given by Blevins [1]. This formula gives the effective amplitude A_{RMS} of a simply supported beam of length l and excited by homogenous turbulence at its resonance frequency f_i:

$$\frac{A_{RMS}(z)}{d_a} = \sum_i \Phi_i(z) J_i \cdot \frac{\sqrt{2}}{16 \cdot \pi} \left(\frac{1}{Sr_i}\right)^{1.5} \frac{\rho \cdot d_a^2}{m} \left(\frac{S_F}{\Lambda_i}\right)^{0.5}. \quad (32)$$

$\Phi_i(z)$ is the normalized mode shape of vibration, for which the maximum vibration amplitude is $\Phi_i = 1$.
$J_i = (2 \cdot l_c/l)^{0.5}$ is the joint acceptance coefficient, which is given by Eq. (49). The maximum value of J_i for vibration mode i is $J_i = 1/\sqrt{i}$. More information on the joint acceptance coefficient and on the effect of l_c/l can be found in [43].
l_c is the correlation length: $l_c = 6\ d_a$ [1, 40] up to $8\ d_a$ [44, 45] for the first two tube rows. In the inlet flow region, the correlation length can be taken as $l_c = (11 - 2N_{RR})\ d_a \geq 3\ d_a$ (where N_{RR} is the row number of the bundle), and in other flow regions, $l_c = 3\ d_a$.

If the approach flow is highly turbulent, the turbulence power spectral density S_F for the first tube row could be up to 5 times higher [41, 46]. The average peak vibration amplitude A can be calculated from the RMS amplitude as follows:

$$A = \sqrt{2} \cdot A_{RMS}. \quad (33)$$

The *weighted amplitude* $\tilde{A}$ (or $\tilde{A}_{RMS}$) for nonuniform flow distribution and multiple support situations can be calculated at the operating velocity $u_\tau < u_{\tau k}$ from the Eqs. (62) and (63) and the maximum amplitude $\hat{A}_t$ from Eq. (64) in Sect. 5.3.3. It should then be compared with the critical amplitude A_k, which is based on the expected life span and the fretting wear properties of the tube material. More information on estimating A_k can be found in [46, 47]. If A_k is unknown, an upper limit for $\hat{A}_{t,RMS}/d_a$ of 1% is recommended.

4.2.3 Turbulence Excitation in Two-phase Flow

Estimation of the vibration amplitude for two-phase flows is described in [28, 29, 37, 44–46]. Accordingly, for gas volume flow fraction of $\dot{\varepsilon}_g < 25\%$, the liquid flow data can be used. In the ranges of $\dot{\varepsilon}_g = 25$–90% and 90–100%, the power spectral density of the fluid force at constant mass flow rates increases steeply.

4.3 Vortex Shedding

Vortex shedding in the interstitial space between the tubes of bundles constitutes a narrow band excitation and is treated in the literature as a periodic excitation at the vortex resonance frequency $f_w = f_i$. The vortex shedding frequency f_w changes linearly with the flow velocity and its dimensionless form is called the Strouhal number Sr_w:

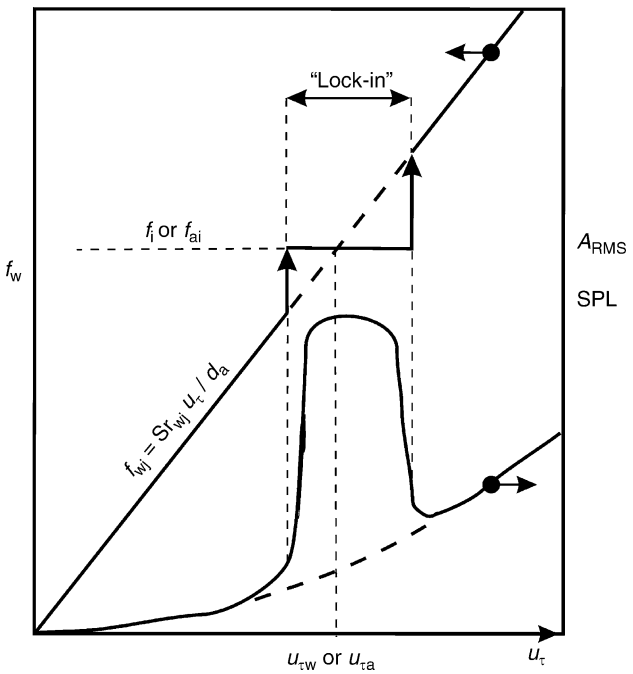
$$Sr_w = \frac{f_w \cdot d_a}{u_\tau}. \quad (34)$$

For the Reynolds number range, which is relevant to industrial applications, Sr_w is independent of the Reynolds number. The flow velocity u_τ is the velocity component perpendicular to the tube axis [48]. For tube bundles exposed to dense fluid flow (small mass-damping parameter), vortex shedding excitation can cause mechanical resonance of the tubes, and for those exposed to gas flow, vortex shedding can cause acoustic resonance in the shell-side volume, see Fig. 14.

Recent studies showed that periodic vortex formation in tube bundles is generated and controlled by the hydrodynamic instability mechanism of one or more of the following inherently unstable flows: (a) the wakes of the tubes; (b) the jets issuing between adjacent tubes; and (c) the shear layers separating from the tube shoulders. Therefore, the Strouhal number of vortex shedding is a function of the tube layout pattern, the spacing ratio between the tubes, and the location of the tubes within the bundle (i.e., front or middle tube row). A recent review of this topic can be found in [49].

As can be seen in Fig. 14, tube or acoustic resonance occurs when the vortex shedding frequency f_w becomes close to either the tube natural frequency f_i or the acoustic natural frequency f_{ai}, respectively. When the tube vibration amplitude of any mode exceeds 2% of the tube diameter, i.e., when

$$A \geq 0.02\ d_a, \quad (35)$$



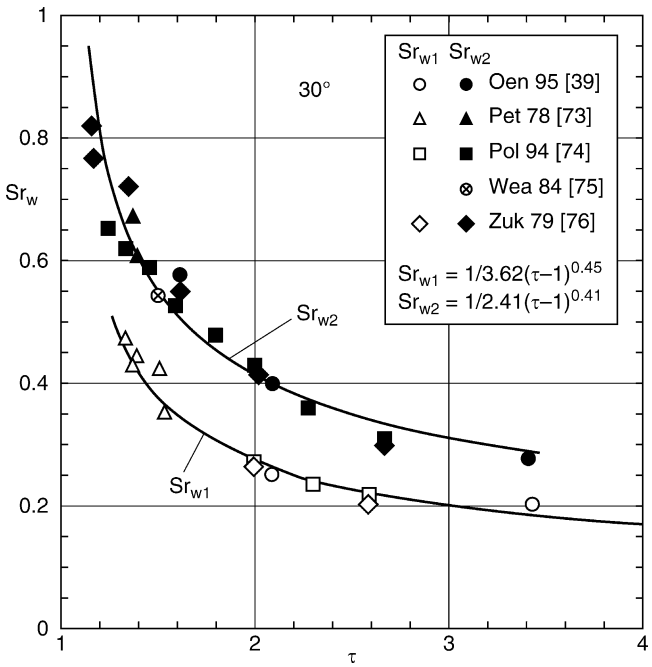
O2. Fig. 14. Illustration of the excitation mechanism of tube and acoustic resonances as the flow velocity is increased. f_{wj} is the vortex shedding frequency, A_{RMS} is the tube vibration amplitude, *SPL* is the sound pressure level.

the tube response to flow excitation becomes substantially stronger due to the mutual interaction and enhancement mechanism between the vortex shedding process and the tube vibration [1]. Under these conditions, the vortex shedding frequency jumps to the tube resonance frequency and remains constant (i.e., $f_w = f_i$) within a velocity range, which is known as "*the lock-in range*." Short-term failures are expected to occur if this lock-in mechanism takes place.

The most recently developed design charts of Strouhal numbers [39, 50, 51] are given in Figs. 15–17. It is noteworthy that up to three vortex shedding frequencies f_{wj} (or Strouhal numbers Sr_{wj}) can appear simultaneously in some tube bundles. In general, the Strouhal numbers Sr_{w2} und Sr_{w3} appear at the front rows at low Reynolds numbers, especially for closely packed tube bundles. Periodic flow excitations at these higher Strouhal numbers are capable of exciting acoustic resonances, but seem relatively weak to excite strong tube resonances. On the other hand, the lower Strouhal number Sr_{w1} is the strongest and can cause intense acoustic resonances and/or large amplitude tube vibrations. It also becomes dominant over the whole tube bundle at high Reynolds numbers and in bundles with large spacing ratios.

In addition, this lower Strouhal number can negatively affect the fluid-elastic instability because its vortex resonance flow velocity $u_{\tau w}$ is often close to the critical velocity, $u_{\tau k}$ or u_{sk}, for fluid-elastic instability (see Sect. 3.1).

Recent work showed that tube and acoustic resonances are caused by the same excitation mechanism in staggered tube bundles (30°, 45°, and 60° layouts). Therefore, the same Strouhal number charts Sr_w can be used for either excitation mechanism, i.e., for acoustic or tube resonance. However, for in-line tube bundles with 90° tube layout, acoustic resonances are not caused by the vortex shedding excitation f_w. Therefore, two different Strouhal number charts ($Sr_w \neq Sr_{wa}$) must be developed; one for the tube resonance Sr_w and the other for the acoustic resonance Sr_{wa}. Note that there is only one dominant Strouhal number Sr_w for in-line tube bundles, which is given in Fig. 18 as a function of τ_x and τ_y [38, 52, 53]. The Strouhal numbers Sr_w and Sr_{wa} are shown together in Fig. 19 for the 90° standard tube layout bundles.

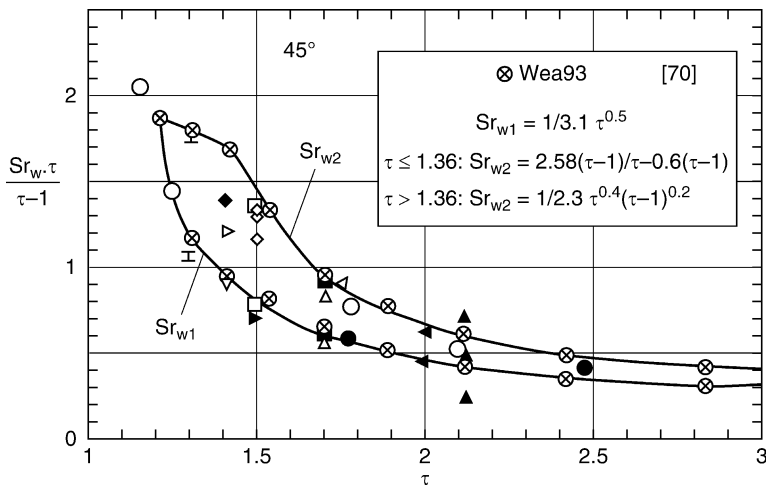


O2. Fig. 15. Strouhal numbers of vortex shedding as a function of the pitch ratio for tube bundles with 30° tube array [39].

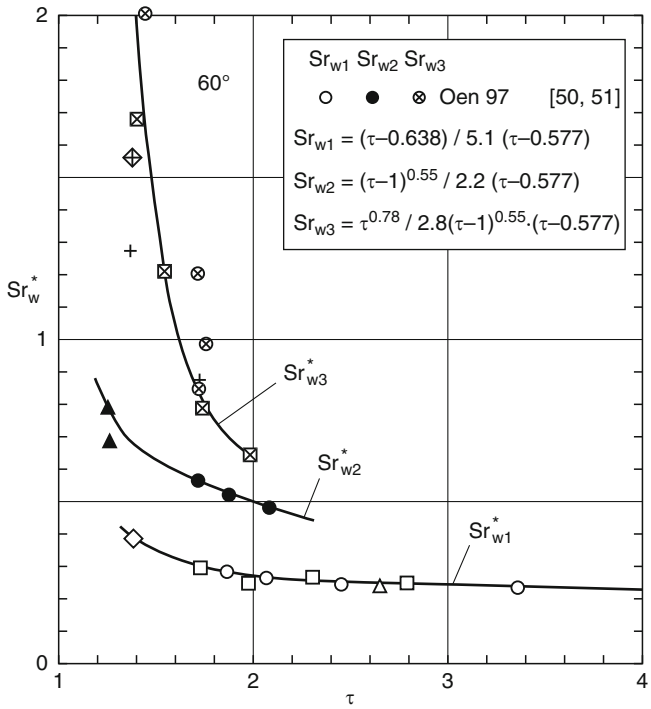
4.3.1 Tube Vibration Response

Tube resonance due to vortex shedding excitation is only significant for single-phase flows of dense fluids, and especially within the inlet region of heat exchangers. In gas flows, vortex shedding excitation is too weak to cause excessive tube vibration.

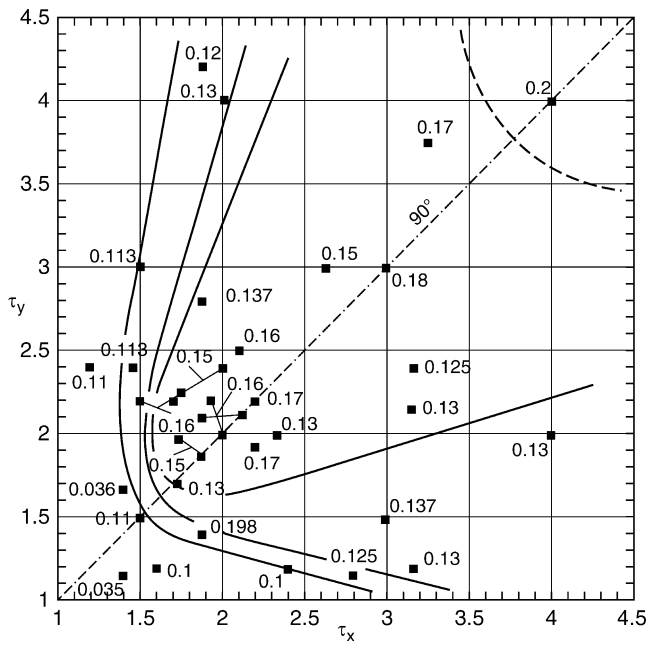
In general, vibration amplitudes less than 1% of the tube diameter are considered acceptable (see also [47]). This amplitude, which can be calculated from Eq. (38), is normally, i.e.,



O2. Fig. 16. Strouhal numbers of vortex shedding as a function of the pitch ratio for tube bundles with 45° tube array [70].



O2. Fig. 17. Strouhal numbers of vortex shedding $Sr_w^* = Sr_w \cdot (\tau - 0.577)/(\tau - 1)$ as a function of the pitch ratio for tube bundles with 60° tube array [50, 51].



O2. Fig. 18. Strouhal numbers of vortex shedding in in-line tube bundles with 90° tube layout arrangement as a function of the transverse and streamwise pitch ratios [38].

when complying with the recommendations in Sect. 5.5 and observing a stability ratio $K^* < 0.9$, below the value of 1%, if the following parameter limits for the 30° and 60° tube layouts are not exceeded (limits of Δ for 45° and 90° layouts are given in brackets):

	$N = 1$ or 2	$N \geq 3$
in gas flow	$\tau \leq 1.7$ and $\Delta > 6$ (10/20)	$\tau \leq 1.8$
in liquid flow	$\tau \leq 1.3$ and $\Delta > 0.35$ (0.8/10)	$\tau \leq 1.4$

In two-phase flows, vortex shedding excitation has not been observed for $\dot{\varepsilon}_g > 20\%$ [28, 29, 43].

If the above-mentioned conditions are not met, the critical flow velocities $u_{\tau wji}$ must be estimated. At these critical velocities, i.e., when $f_{wj} = f_i$, tube resonance and lock-in with vortex shedding can occur. From Eq. (34), the following equation is obtained for the critical velocities:

$$u_{\tau wji} = \frac{f_i \cdot d_a}{Sr_{wj}}. \tag{36}$$

In estimating the critical velocity, u_τ must be divided by k_α (Eq. (46)) to obtain the gap velocity u_s.The values of Sr_{wj} can be obtained from Figs. 15 to 19.

Based on the data of single cylinder in cross flow, it is advisable to maintain a 30% margin below the critical flow velocity, i.e.,

$$u \leq 0.7\, u_w. \tag{37}$$

But this margin leads to overly conservative design in tube bundles, because the operating velocity is often above u_w and variable along the full length of the tubes. Therefore, a more useful and accurate approach to assess vortex-induced vibration is to calculate first the maximum tube vibration amplitude A at the critical flow velocity u_w and hence the amplitude A for the operating velocity $u(z)$.

The following equation can be used to estimate the vibration amplitude of a tube with length l and simply supported at both ends with baffle plates at the critical flow velocity [54]:

$$\frac{A(z)}{d_a} = \sum\nolimits_i \Phi_i(z) c_y \cdot \frac{\bar{\Phi}}{8 \cdot \pi} \cdot \frac{\sqrt{2}}{Sr_{wj}^2 \cdot \Delta_i} \tag{38}$$

c_y is the dynamic lift coefficient, which is shown in Figs. 20 and 21. These are the maximum values for row 2 in Fig. 20 and for row 3 in Fig. 21.

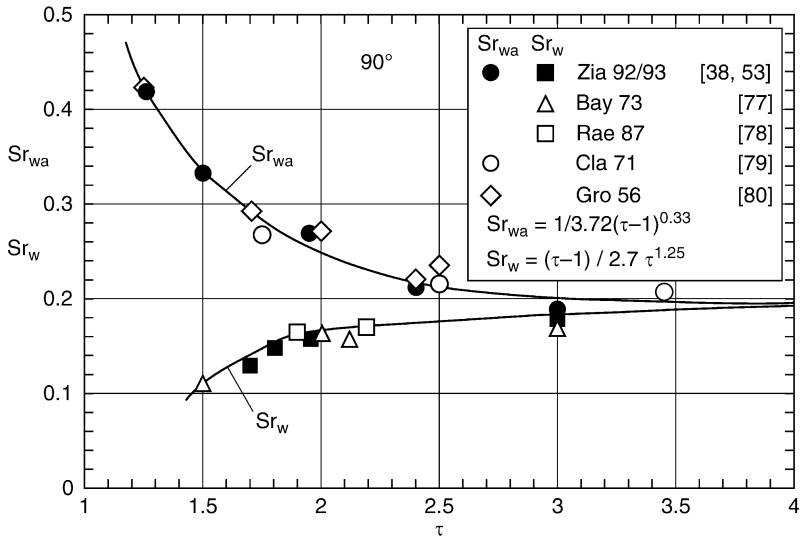
$\Delta_i = m \cdot \Lambda_i / \rho_f \cdot d_a^2$ is the mass-damping parameter,

$\Phi_i(z)$ is the normalized vibration mode shape with $\Phi_i = 1$ corresponding to the maximum vibration amplitude,

$\bar{\Phi} = \frac{\int_0^l |\Phi_i(z)| dz}{l}$ considers the support conditions on the mode shape and is obtained from Table 1.

Equation (38) is valid for tube vibration amplitude ratios A/d_a less than 10%. Additional models to calculate the correlated lift coefficient ($c_y \cdot \sqrt{2} \cdot \bar{\Phi}$) can be found in [1].

The lift coefficient c_y depends on the tube layout geometry, the tube row within the bundle, the spacing ratio, and the Reynolds number, which is based on the gap velocity u_s. Note that the maximum lift coefficient for staggered bundles is at approximately $\tau = 2$ and also that the effect of Reynolds number for staggered bundles (Fig. 20) is opposite to that for in-line bundles (Fig. 21). For staggered bundles, the lift coefficient becomes smaller after the third row [55]; after the sixth row c_y is only 30% of the values from Fig. 20. The lift coefficient for small spacing ratios, $\tau \leq 1.5$, is very small, approximatly $c_y = 0.1 \cdot (\tau - 1.1)$.



O2. Fig. 19. Acoustic and vortex shedding Strouhal numbers as functions of the pitch ratio for square bundles (90° tube layout).

The proximity to the condition of maximum tube resonance can be assessed by considering the frequency ratio from Eqs. (34) and (38):

$$\eta_{i,j} = \frac{f_{w,j}}{f_i} = \frac{u}{u_{w,i,j}}. \tag{39}$$

If the velocity u and therefore the value of $\eta(z)$ changes between η_u and η_o along the length or a sectional length l_r of a tube (see Fig. 24), then the *amplitude weighting factor*

$$k_{A,i,j} = \frac{1}{\eta_o - \eta_u} \cdot \int_{\eta_u}^{\eta_o} f_{VA}(\eta)\, d\eta \tag{40}$$

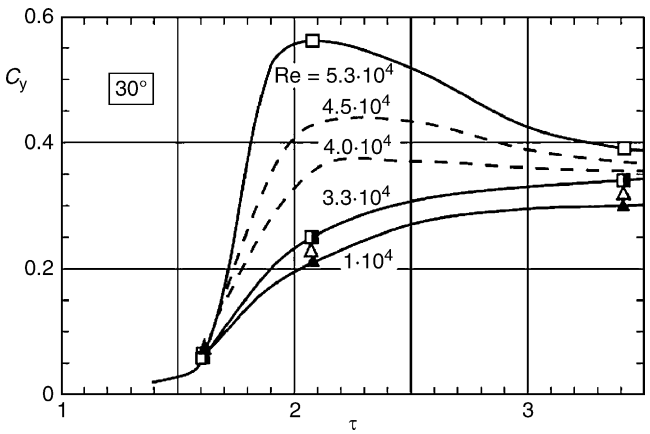
can be used to estimate the reduction in the amplitude from that maximum, which would occur at the frequency coincidence ($\eta = 1$). $f_{VA}(\eta)$ is the dynamic response amplification function which, for example, can be approximated for tube bundles by the following linear triangle function:

$$\begin{aligned} f_{VA} &= 0 && \text{for } \eta < 0.78 \text{ and } \eta > 1.22, \\ f_{VA} &= 4.54 \cdot \eta - 3.54 && \text{for } 0.78 \le \eta \le 1, \\ f_{VA} &= 5.54 - 4.54\,\eta && \text{for } 1 < \eta \le 1.22. \end{aligned} \tag{41}$$

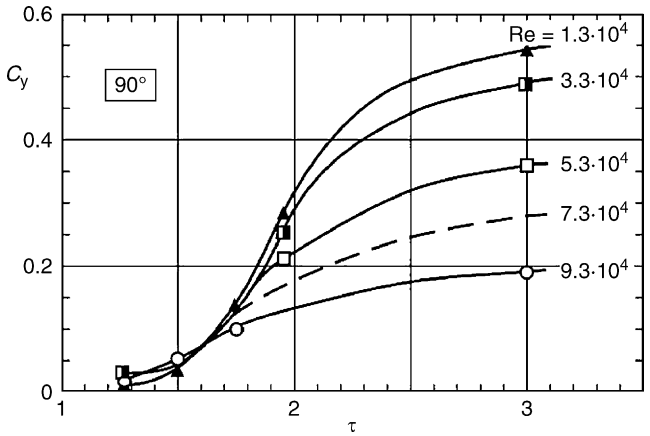
For tubes with different levels of flow excitation along sectional tube spans, the vibration amplitude can be calculated by taking into account the tube vibration mode shape Φ_i, according to Eqs. (62) or (63), which give the weighted vibration amplitude $\tilde{A}_i$ (see Sect. 5.3.3).

If the estimated maximum amplitude for any mode is less than 2% of the tube diameter, then the lock-in phenomenon is not expected to occur [56], see also [1, p 55]. In addition, lock-in normally does not occur in bundles ($N \ge 3$) exposed to liquid flows if $\tau \le 1.5$, in bundles exposed to gas flows if $\tau \le 2.0$, nor in bundles subjected to two-phase flows if $\dot{\varepsilon}_g > 15\%$.

The estimated maximum vibration amplitude $\hat{A}_w$ according to Eq. (64) should be less than the acceptable value A_k based on fretting wear considerations and the expected life span of the equipment [46, 47]. This value should be less than 2% of the tube diameter to avoid short-term damages. If A_k is unknown, an upper limit for $\hat{A}_w/d_a$ of 1% is recommended. If the



O2. Fig. 20. Dynamic lift coefficient for the first two tube rows in staggered tube bundles (30° tube array) as a function of the pitch ratio. The data are also valid for the 45° and 60° tube arrays [39], Re = $u_s\, d_a/\nu$.



O2. Fig. 21. Dynamic lift coefficient for the 90° tube array as a function of the pitch ratio. The data are for tube rows $N_{RR} \ge 3$ [42], Re = $u_s\, d_a/\nu$.

amplitude $\hat{A}_w$ is too large, structural modifications should be considered (see Sects. 5.5 and 6.3), or otherwise the operating flow velocity of the equipment must be reduced.

4.3.2 Acoustic Resonance

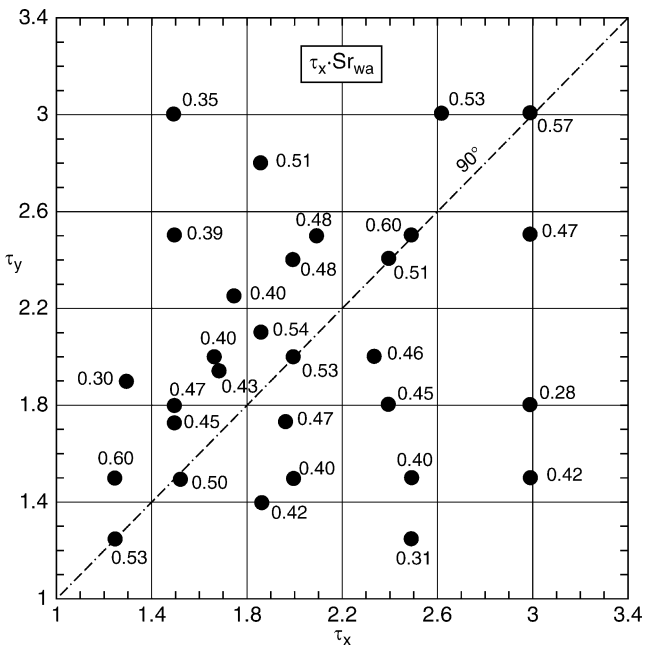
The mechanism of acoustic resonance of tube bundles is similar to the mechanism of tube resonance, which is addressed in the previous section (Fig. 14). For in-line bundles, the Strouhal numbers at which acoustic resonances occur, Sr_{wa}, differ from the Strouhal numbers for tube resonance Sr_w [52, 57, 58].

Therefore, acoustic Strouhal numbers for in-line bundles are provided in Fig. 22, which give the value of $\tau_x \cdot Sr_{wa}$ as a function of the streamwise and transverse spacing ratios, τ_x and τ_y, respectively. The difference between Sr_{wa} und Sr_w is highlighted in Fig. 19, which shows both values against the pitch ratio for the case of 90° tube layout geometry.

For staggered tube bundles, acoustic resonances occur at the Strouhal numbers of vortex shedding, i.e., $Sr_{wa} = Sr_w$, and therefore Figs. 15–17 can be used to determine the critical flow velocity for acoustic resonance excitation. This critical velocity can be obtained from the following equation:

$$u_{\tau aji} = \frac{f_{ai} \cdot d_a}{Sr_{waj}}. \tag{42}$$

As in the case of tube resonance, coincidence between the frequency of vortex shedding and that of acoustic resonance, i.e., when $f_{ai} = f_{wj}$ or $f_{ai} = f_{wa}$, does not necessary mean that lock-in will actually occur. Whether lock-in will occur, or not, depends on the acoustic attenuation (damping) relative to the excitation energy provided by vortex shedding.



O2. Fig. 22. Acoustic Strouhal number multiplied by the streamwise pitch ratio for in-line tube bundles with 90° tube layout arrangement. τ_x and τ_y are the streamwise and the transverse pitch ratios [38].

Several damping criteria exist in the literature that can be used to predict whether acoustic resonance will, or will not, occur [59–61]. According to Blevins [1], acoustic resonance will occur if $u_\tau / (f_{ai} \cdot d_a) > 2$. Chen and Young [59, 62] developed a damping parameter, G, for in-line tube bundles:

$$G = \frac{\mathrm{Re}}{\mathrm{Sr}_{wa}} \cdot \frac{1}{\tau_y} \left(1 - \frac{1}{\tau_x}\right)^2 \leq 2000 \tag{43}$$

with $\mathrm{Re} = u_\tau \cdot d_a / \nu$. Chen states that resonance will occur if $G > 2000$.

Eisinger et al. [63] reported that this criterion is suitable for large size bundles and for both in-line and staggered tube layout geometries. However, he recommended the following limits:

$G > 2700$: Always resonance,
$G < 1300$: Always no resonance.

A reliable general criterion for the range $1300 < G < 2700$ does not exist, and must await further studies. The criteria of Fitzpatrick [60] and Ziada et al. [61] are based on small scale model tests and appear to be less reliable for large size industrial applications. Additional information and other criteria based on Chen's method can be found in [55, 64].

To avoid acoustic resonance, it is recommended to maintain the maximum flow velocity in the equipment below 80% of the critical velocity for acoustic resonance, i.e.,

$$u_\tau \leq 0.8\, u_{\tau a} \tag{44}$$

where $u_{\tau a}$ is the lowest possible acoustic resonance velocity. However, if u_τ is found to be larger than the critical velocity $u_{\tau a}$, then the damping parameter, G, must be calculated to assess the liability of the heat exchanger to acoustic resonance. If several critical velocities for acoustic resonances are found to be within the operating velocity range, i.e., if

$$u_{\tau aji} < 1.25\, u_\tau, \tag{45}$$

then the value of G must be based on the highest critical velocity. Resonance is not expected to occur if $G < 1300$. If this is not the case, countermeasures must be implemented. For example, acoustic baffle plates can be added in the shell side between the tubes such that the lowest critical velocity for acoustic resonance is increased to at least 20% higher than the maximum flow velocity of the equipment.

5 Design of Heat Exchangers against Vibration Excitation

5.1 Introduction

The design equations presented in Sects. 3 and 4 are based on *ideal conditions*, as they normally exist in wind tunnel experiments. Real conditions in heat exchangers require additional considerations:

- Altering of the critical velocity for fluid-elastic instability (Sect. 5.2), e.g., regarding a change of the radial velocity distribution, which generates a variable approach flow direction in the bundle or possibly higher velocities in the gaps between the exterior tubes and the shell.

- Calculation of equivalent velocities and amplitudes (Sect. 5.3), e.g., for tubes with a varying cross flow velocity and with variable fluid or structural properties along the entire length.
- Estimation of the velocity distribution in critical sections of the heat exchanger bundle (Sect. 5.4), e.g., in the inlet, the outlet, or in the window region.

Guidelines for appropriate engineering design to avoid vibration damages are given in Sect. 5.5.

5.2 Adjusted Critical Velocities for Fluid-elastic Instability

It is not possible to calculate the risk of vibration excitation for an individual tube in the bundle, only the risk for a tube row can be determined with the assumption that the radial velocity distribution is constant. If this is not the case, the most endangered tube in the tube row, i.e., for the inlet or outlet flow region the tube at the center of the nozzle, should be considered.

Three factors influence the critical velocity in heat exchangers:

$$u_{sk} = u_{sk,min} \cdot k_{IF} \cdot k_{RS}. \tag{46}$$

$u_{sk,min}$ is the *reduced critical velocity* due to varying approach flow directions, as shown in Table 9 [26, 27]. It has to be used in all sections of heat exchangers with cylindrical shells.
k_{IF} is the *inlet flow factor* for the first two tube rows in the inlet section, which can be taken from Table 9. This factor accounts for the lower approach flow velocity and excitation force for the first tube row [4, 15, 16]. For the second tube row, it includes an adjustment to the velocity distribution model of Mohr [26], as described in Sect. 5.4.2.
k_{RS} is the *boundary stream factor*, which considers the higher risk of outer tubes because of the smaller gaps between them and the shell and the higher velocity in comparison to the mean velocity of the considered tube row. k_{RS} is relevant in heat exchanger sections with an accelerated flow, e.g., in the inlet flow region of windows and in the exit region of cylindrical shells. In the following, k_{RS} is described briefly.

CFD-simulations of the velocities in boundary gaps show a marked increase of the approach flow velocity of the outer tubes. This is especially the case when the distance between shell and tube is small and the boundary gaps of the upstream tubes are greater. In addition, the flow must accelerate due to the reduction in the flow area as the chord of the circular boundary becomes smaller [26].

This situation can be seen for gap A in (Fig. 23). The outer tube in tube row i with the smallest boundary gap width $s_{RS,i}$ is exposed to higher flow velocity and therefore higher level of vibration excitation. The approach flow velocity is taken to be the RMS-value of the two velocities in the boundary gap and in the gap adjacent to the next tube in row i. The boundary stream factor for tube row i in sections with accelerated flow is:

$$k_{RS,i} = \sqrt{\frac{2}{1 + \left(\frac{s_{RS,i-1}}{s_{RS,i}}\right)^n}} \le 1, \tag{47}$$

where $s_{RS} = 0.5(d_1 - d_a) - \sqrt{x_{RR}^2 + y_{Ra}^2}$, index $i-1$ refers to the upstream tube row and the exponent n is:

$$n = 10/(10 + d_1/d_a)^{0.5} \ge 1.4 \tag{47a}$$

Equation (47) is valid for

$$\frac{s_{RS,i}}{d_a \cdot (\tau - 1)} \ge 0.4 \text{ and } 1 < \frac{s_{RS,i-1}}{s_{RS,i}} \le 4.0, \tag{47b}$$

otherwise the boundary stream factor becomes $k_{RS} = 1$. Some more details and limitations are described in [10, 26].

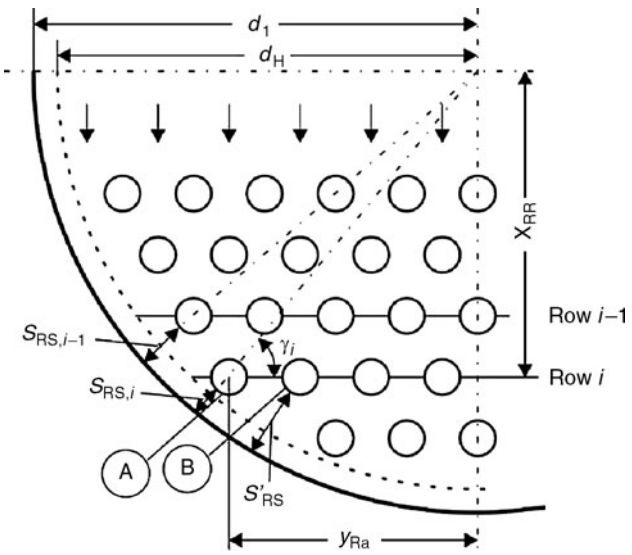
It is assumed in Eq. (46) that the vibration risk for the outer tube is proportional to the gap flow velocity, which is the usual assumption for inner tubes of the bundle. Whether an influence of the adjacent wall exists or not has not yet been proven by experiments. Nevertheless, if a tube row becomes critical due to the high approach flow velocity of its outer tube, which may happen for the first tube rows in the window, then this tube should be removed.

For the decelerated flow sections, the boundary stream factor can be assumed $k_{RS} = 1$. Since only every second section has an accelerated flow, the correction for the whole tube length is about 50% smaller than the calculated correction from Eq. (47).

O2. Table 9. Reduced critical velocities and inlet flow factors for all fluids in heat exchangers

Tube array	Reduced critical velocity $u_{sk,min}$	Eqs.	Inlet flow factor k_{IF}	
			Tube row one	two[a]
30°	$1.3 \cdot u_{sk60} \le u_{sk30}$	(46a)	$(1 + 0.4\tau)/\tau$	1.0
45°	$u_{sk90} \le u_{sk45}$	(46b)		0.9
60°	$u_{sk60} \le u_{sk30}$	(46c)		1.0
90°	u_{sk90}	(46d)		0.8

[a]In conjunction with the use of Eqs. (69–73)



O2. Fig. 23. Influence of the boundary gap velocities at accelerated flow conditions on endangered outer tubes.

If the curvature of the shell is small, i.e., if the shell diameter is large, the tube row is located in the center of the shell or if there are "no tubes in the window," then k_{RS} increases to the limit case:

$$k'_{RS} = 0.3 + 0.7\, k_{RS} \tag{48}$$

5.3 Influence of Partial Fluid Force Admission

The correlation of the unevenly distributed lateral forces $F(z)$ with the mode shape of the tube is usually described by the joint acceptance coefficient J_i, e.g., [1, Eqs. (7–44)]:

$$J_i = \frac{\int_0^L F'(z) \cdot \Phi_i(z)\, \mathrm{d}z}{\int_0^L \Phi_i^2(z)\, \mathrm{d}z}, \tag{49}$$

with J_i being a correlation factor and $F'(z) \leq 1$ is the normalized distribution function of the lateral forces. The basic approach to calculate the fluid forces acting on tube arrays was presented by Connors [65] for Whirling and by Blevins [1] for vortex shedding with lock-in:

$$F(z) \sim \hat{u}^2 \cdot \Psi^2(z) \cdot \Phi_i(z), \tag{50}$$

where $\hat{u}$ is the maximum velocity as shown in Fig. 24, $\Psi(z) \leq 1$ is the normalized distribution function of the velocity and $\Phi_i(z) \leq 1$ is the normalized mode shape function of the i^{th} mode.

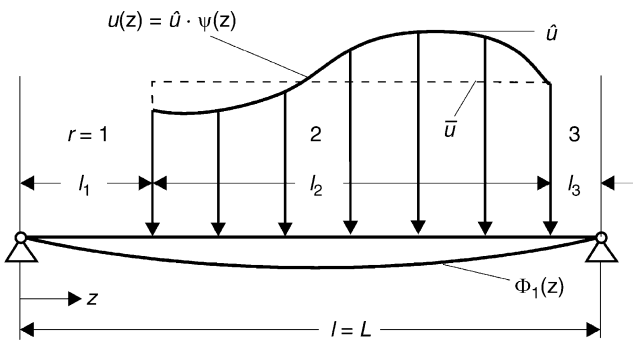
The *energy ratio* S_i results from Eqs. (49) and (50) and is used to correlate the forcing function when the flow distribution is not uniform along the tube:

$$S_i = \frac{\int_0^L \psi^2(z) \cdot \Phi_i^2(z) dz}{\int_0^L \Phi_i^2(z) dz} \leq 1. \tag{51}$$

5.3.1 Equivalent Velocity and Energy Ratio

Equations (49–51) yield the *equivalent velocity* $\tilde{u}_i$ for the whole tube length, which can be compared with the critical velocity $u_{k,i}$:

$$\tilde{u}_i = \hat{u} \cdot \sqrt{S_i}. \tag{52}$$



O2. Fig. 24. Partial admission of a tube with variable velocities.

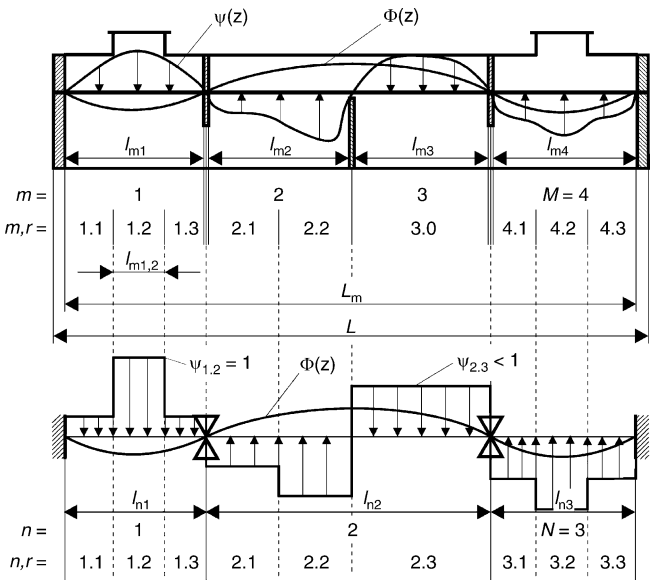
For bundles with homogeneous fluid flow ($S_i = 1$ for $\Psi = 1$), i.e., for tubes with approximately constant forces along the entire length, it is always the first mode (with the lowest frequency), which becomes critical. However, in the majority of cases the detailed velocity distribution is not known. Therefore, it is normally sufficient to divide the tube length into sections with average constant velocities. If the velocity (or amplitude) in the section r for a simply supported tube with the length l_r is constant (see Fig. 24), then the energy ratio from Eq. (51) becomes:

$$S_i = \sum_{r=1}^{R} \psi_r^2 \cdot \Delta S_{i,r}, \tag{53}$$

where Ψ_r is constant. $\Delta S_{i,r}$ is the partial energy ratio for the section r due to Eq. (11) and can be obtained from Fig. 5 for the first mode.

In heat exchangers with multi-supported tubes, the excitation forces in the sections with the greatest spans (or partial energy ratios) in conjunction with maximum fluid velocities are dominant, but the sections with lower or no force admission contribute to an energy dissipation of the vibrating tube. Therefore, it would be too conservative to consider only the section with maximum velocity (e.g., the inlet flow region), because the *equivalent*, i.e., the *weighted velocity* is the true indicator of the excitation level of the whole tube.

The tube shown in Fig. 25 is a window tube with four flow paths and three tube spans ($M = 4$, $N = 3$). It is advantageous to perform the calculation according to various sections, either per flow path (m, r) or per tube span (n, r). Beside variable velocities, other fluid or structural data, e.g., mass, density, damping, or changing of the fluid state and the mass flow, which depend on the tube length, can be included too. These values are assumed constant per flow path m [66]. Values for partial



O2. Fig. 25. Subdividing the tube length in sections of constant velocities. m, r is the numeration of the flow paths and n, r the numeration of the tube spans.

energy ratios can be taken from Tables 2 or 3 or by means of computer programs [3].

For a constant velocity in the whole section m, the energy ratio is similar to Eq. (53):

$$S = \sum_{m=1}^{M} \psi_m^2 \cdot \Delta S_m. \tag{54}$$

Here in Eq. (54) and in the following, the subscript i referring to the mode shape has been omitted. ΔS_m is the partial energy ratio for the flow path length l_m, as defined by Eq. (11).

When the velocity in the section m is subdivided, then

$$S = \sum_{m,r=1,1}^{M,R} S_{m,r} = \sum_{m,r=1,1}^{M,R} \psi_{m,r}^2 \cdot \Delta S_{m,r}, \tag{55}$$

$$\Delta S_{m,r} = \int_{l_{m,r}} \Phi^2(z)\mathrm{d}z \Big/ \int_0^L \Phi^2(z)dz \text{ and } \sum_{m,r=1,1}^{M,R} \Delta S_{m,r} = 1. \tag{55a}$$

An approximate calculation – without the use of a computer program – is only possible for the first mode, by means of Eq. (12), Fig. 5 and Tables 2 and 3 in Sect. 2.3. For this purpose $\Delta S_{m,r}$ can be split up into two parts:

$$\Delta S_{m,r} = \Delta S_m \cdot \Delta S'_{m,r} \quad \text{and} \quad \sum_{r=1}^{R} \Delta S'_{m,r} = 1, \tag{55b}$$

where $\Delta S'_{m,r}$ or $\Delta S'_{n,r}$ are, contrary to Eq. (55a), not related to the tube length L, but to the flow path length l_m or span length l_n. The values of $\Delta S'_{m,r}$ or $\Delta S'_{n,r}$ can be taken from Fig. 5, the values of ΔS_m or ΔS_n from Tables 2 or 3 and from Eq. (12).

The calculation should be executed practically in table form for the partial sections m,r (see Table 11 in Sect. 6.2).

5.3.2 Stability Ratio for Fluid Elastic Instability

The stability equation (25) can be written as:

$$u_k^* = \frac{u_{sk}}{f \cdot d_a} = \frac{\hat{u}_{sk} \cdot \sqrt{S}}{f \cdot d_a} = K(\tau) \cdot \Delta^P. \tag{56}$$

The resultant maximum critical velocity in the case of constant fluid and structural data is:

$$\hat{u}_{sk} = u_{sk} \Big/ \sqrt{S}. \tag{57}$$

The stability ratio K^* defines the risk of the vibration excitation by fluid-elastic instability. It is the ratio of the equivalent velocity divided by the critical velocity:

$$K^* = \frac{\tilde{u}_s}{u_{sk}} = \frac{\hat{u}_s \cdot \sqrt{S}}{u_{sk}}. \tag{58}$$

Variable fluid properties or structural data:

Based on the knowledge of the different sectional critical velocities u_{skm}:

$$u_{km}^* = \frac{u_{skm}}{f \cdot d_a} = K_m(\tau) \cdot \left[\frac{m_m \cdot \Delta_m}{\rho_m \cdot d_a^2}\right]^{P_m} \tag{59}$$

it is possible to obtain the general equation for the maximum critical veöocity ($K^* = 1$), which is analogous to Eq. (57):

$$\hat{u}_{sk} = \frac{1}{\sqrt{\sum_{m=1}^{M} \frac{S_m}{u_{skm}^2}}} \tag{60}$$

with S_m from Eq. (55). It should be mentioned that the accuracy of these calculations depends on the knowledge of Φ_i. So in most cases, computer programs [3] are necessary for the design.

The critical volume flow in section m can be calculated from the following equation, which uses the notation indicated in Fig. 25:

$$\dot{V}_{k,m} = \hat{u}_{sk} \cdot \sum_{r}^{R} \frac{\psi_{m,r} \cdot A_{qsm,r}}{k_{LF} \cdot k_{PF}}, \tag{61}$$

where m may be any flow path and $A_{qsm,r}$ is the cross sectional area corresponding to $\Psi_{m,r}$. The two factors in the denominator k_{LF} for leakage flow and k_{PF} for partial flow will be explained in Sect. 5.4.1, Eqs. (67) and (68). The critical inlet volume flow $\dot{V}_{k,IF}$ can be obtained by multiplying Eq. (61) by ρ_m/ρ_{IF}.

5.3.3 Weighted Turbulence and Vortex Amplitudes

The maximum amplitudes A_i resulting from Eqs. (38–41) for vortex shedding [or $A_{i,RMS}$ from Eq. (32) for turbulent buffeting] in the partial sections r have to be weighted by the partial energy ratio $\Delta S_{i,r}$. For the simply supported tube in Fig. 24, the weighted maximum amplitude is approximately [1, 43]:

$$\tilde{A}_i = \sqrt{\sum_{r=1}^{R} A_{i,r}^2 \cdot \Delta S_{i,r}}. \tag{62}$$

In heat exchangers with multi-supported tubes and constant fluid properties and structural data, the weighted maximum amplitude for the mode i is:

$$\tilde{A}_i = \sqrt{\sum_{n=1}^{N} \Delta S_{i,n} \cdot A_{i,n}^2 \cdot J_{w,i,n}^2}. \tag{63}$$

$A_{i,n}$ must be weighted by means of Eq. (62), when the velocity in span n is subdivided. $J_{w,i,n}$ is a correlation factor and is $J_{w,i,n} \leq 1$ for vortex shedding and $J_{w,i,n} = 1$ for turbulent buffeting.

In the case of *vortex excitation*, $J_{w,i,n}$ considers the forces, which act out of phase or opposing directions at different tube spans l_n. In the following, it is recommended to consider – in the normal case – only the two spans n with the maximum loadings in Eq. (63) for every mode:

$J_{w,i,,n} = 1$ for the most severely loaded span, i.e., when $\Delta S_{i,n} \cdot A_{i,n}{}^2$ is maximal for a span n or "for all spans and all modes where lock-in cannot be avoided" [1, p. 458],

$J_{w,i,,n} = 0.5$ for the span with the second highest value of $\Delta S_{i,n} \cdot A_{i,n}{}^2$,

$J_{w,i,,n} = 0$ for all other spans.

This recommendation will lead to conservative results.

For the case, in which the fluid or structural data vary over the length of the tube, which leads to changing values of $A_{i,n}$ as well as $\Delta S_{i,n}$, the weighting of the amplitudes is described in [1, 43].

From the summation of the mode shapes $A_i(z)$ [resp. $A_{i,\mathrm{RMS}}(z)$], the course of the Amplitude $A(z)$ can be obtained as:

$$A_i(z) = \tilde{A}_i \cdot \Phi_i(z) \quad \text{and} \quad A(z) = \sum_i A_i(z). \tag{64}$$

From Eq. (64), the maximum value of the vortex shedding amplitude $\hat{A}_w$ or of the turbulent buffeting amplitude $\hat{A}_t = \sqrt{2} \cdot \hat{A}_{t,\mathrm{RMS}}$ can be identified for a tube.

5.4 Approximation of the Axial Velocity Distribution

With the aid of CFD simulations [26, 27, 67, 68], the influence of the bundle geometry on the velocity distribution could be determined and thereby the energy ratio and the instability ratio K^* for the most endangered tube rows could be quantified. The following tube rows are particularly endangered and should be always analyzed:

- The first and the second tube rows of the bundle approached by the inlet flow, because of the nozzle jet flow and possible turbulent buffeting and vortex excitation,
- the first and the second tube rows in the windows, because they are exposed to the maximum cross flow velocity in all sections over the whole tube length.

Furthermore, some tubes adjacent to vertical free flow lanes or to impinging plates may have a much greater excitation risk in those cases, when the design recommendation in Sect. 5.5 have not been followed.

The following equations provide *equivalent* axial distributions of flow velocity with sectional constant values, primarily derived to assess the influence of fluid-elastic instability. Their application to calculate the amplitudes caused by vortex shedding and turbulent excitations is described in Sect. 6.3.

5.4.1 Volume Flow and Distribution Function

The total volume flow in any flow path m is given by Eq. (61):

$$\dot{V}_m = \dot{V}_{\mathrm{IF}} \cdot \rho_{\mathrm{IF}}/\rho_m = \hat{u}_s \cdot \sum_{r=1}^{R} \frac{\psi_{m,r} \cdot A_{\mathrm{qsm},r}}{k_{\mathrm{LF}} \cdot k_{\mathrm{PF}}}. \tag{65}$$

$\dot{V}_{\mathrm{IF}}$ is the inlet volume flow. The gap of cross-sectional area $A_{\mathrm{qsm},r}$ should be calculated according to Eq. (66a), without consideration of possible small free flow lanes, i.e., as if the cross-section area were to be completely filled with tubes within the inner diameter of the shell. This leads to a conservative design for tubes in the bundle. Tubes adjacent to free flow lanes have to be considered separately.

$$A_{\mathrm{qsm},r} = s' \cdot l_{m,r} \cdot \frac{\tau - 1}{\tau} \cdot k_\alpha, \tag{66a}$$

s' is the chord length of the tube row in the shell cross section, $l_{m,r}$ the length of the flow path and k_α considers the gap flow velocity dependence on the tube layout according to Fig. 2:

$$\begin{aligned}
&30^\circ\text{- and } 90^\circ\text{-tube layout}: && k_\alpha = 1 \\
&45^\circ\text{-tube layout}: && k_a = 1.414 \text{ for } \tau \le 1.7; \\
& && k_\alpha = \frac{\tau - 0.707}{\tau - 1} \text{ for } \tau > 1.7; \\
&60^\circ\text{-tube layout}: && k_a = 1.155 \text{ for } \tau \le 3.7; \\
& && k_\alpha = \frac{\tau - 0.577}{\tau - 1} \text{ for } \tau > 3.7.
\end{aligned} \tag{66b}$$

The values of the correction factors k_{LF} and k_{PF} in Eq. (65) depend on the considered flow path m and on the tube row:

- $k_{\mathrm{LF}} \le 1$ considers the axial leakage flow through the gaps between support plates and tubes and between the plates and the shell in all sections m, except the inlet and outlet regions.

$$k_{\mathrm{LF}} \approx \left(1.1 - \frac{0.1 \cdot \Delta d_{\mathrm{B}}}{[\mathrm{mm}]}\right) \cdot \sqrt{f_{\mathrm{L}}} \text{ for } \Delta d_{\mathrm{B}} \le 1.0 \text{ mm}. \tag{67}$$

  When the boring clearance is $\Delta d_{\mathrm{B}} > 1$ mm, then the bracket value becomes 1.0. The factor f_{L} will be calculated from Subchap. L1.5 [Fig. 5 or Eqs. (23) and (24), as well as Eq. (5), also for bundles with gaps]. The radial bypass flow between bundle and shell should not be considered here. When fouling is possible, k_{LF} will approach to 1.0.
- $k_{\mathrm{PF},\,i} \le 1$ considers the partial flow, which approaches the window tube row in cross flow:

$$k_{\mathrm{PF},i} = 1.1 \cdot A_{\mathrm{qF},i}/A_{\mathrm{qF\,max}}, \tag{68}$$

  $A_{\mathrm{qF},i}$ is the partial free axial cross section of the window, downstream of tube row i (see Fig. 30), A_{qFmax} is the whole free axial cross section of the window [see Subchap. L1.5, Eqs. (50)–(53)].

The correction factors k_{LF} and k_{PF} can also be used to consider added or reduced mass flow, e.g., in conjunction with condensation or vaporization.

5.4.2 Inlet and Outlet Regions with Nozzles

Basically, the velocity distribution at tube rows near the inlet and outlet nozzles is influenced by the geometric data of the heat exchanger, the pitch ratio of the bundle, the nozzle diameter, and the distance bundle/nozzle. A velocity peak normally appears at the nozzle center line and decays within the first tube rows due to the large pressure drop in the bundle. In staggered tube arrays, this peak decays after three to four tube rows and in in-line tube arrays after five to six tube rows.

The model of Mohr [26] describes the equivalent velocity distribution at the second tube row of 30° – and at the third tube row of 60° – arrangements. The approximate calculation

for the other tube layouts are also feasible, when the inlet flow factors k_{IF} in Table 9 are taken into consideration.

The basis of the model is the worst case scenario, in which the maxima of the velocity and of the mode shape are coincident, as shown in Fig. 26. A further criterion is the equivalence of the energy ratios in the model and in the corresponding CFD-simulation for every partial flow path. An unsymmetrical position of the nozzle can also be considered, which would shift the velocity profile by the eccentricity of the nozzle position Δl_S [3, 26].

The velocity distribution for the tube in the center line of the nozzle will be divided into five flow path lengths with three flow areas, as shown in Fig. 26:

(I) Flow path with maximum velocity: $\psi_1 = 1$ (for one tube span)

$$l_1 = d_S \cdot Y \cdot \frac{l}{s'} - \left| l_S - \frac{l}{2} \right|, \quad d_S \le l_1 \le l_2, \quad \text{and} \quad \frac{l}{s'} \ge 1. \tag{69a}$$

$$s_1 = d_S \cdot Y \cdot f\left(\tau, \frac{d_1}{d_S}, \frac{l}{d_1}\right), \quad 0.5 d_S \le s_1 \le s_2, \tag{69b}$$

$$A_{qs1} = \frac{\tau - 1}{\tau} \cdot (l_1 \cdot s_1 - 0.215 \cdot s_1^2) \cdot k_\alpha \text{ for } s_1 \le l_1. \tag{69c}$$

The jet expansion factor Y is a function of h/d_a:

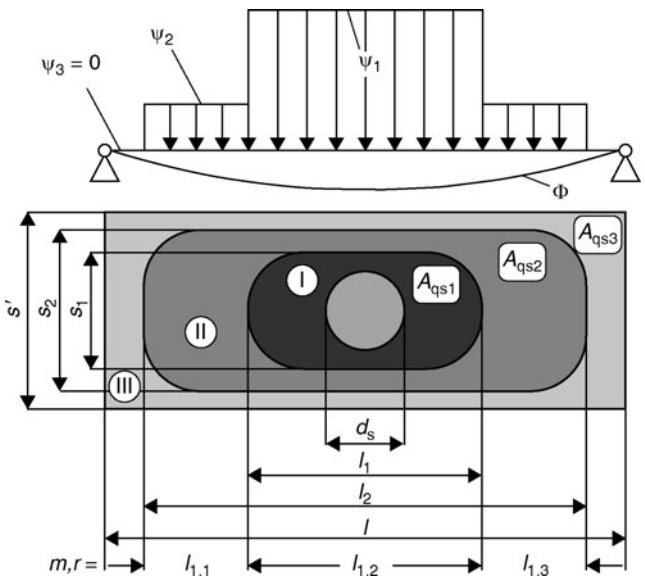
$$Y = 1.1 \cdot \left(\frac{h}{d_a}\right)^{0.25} \ge 0.9. \tag{70}$$

The geometry function reads as follows:

$$f\left(\tau, \frac{d_1}{d_S}, \frac{l}{d_1}\right) = 0.4 \cdot \frac{\tau}{\tau - 0.95} \cdot \frac{1 - 0.09 \cdot (d_1/d_S)}{(l/d_1)^{0..3}}. \tag{71}$$

(II) Flow path with reduced velocity:

$$l_2^* = 0.9 \cdot l \cdot \frac{\tau}{\tau - 0.5} \cdot \left(\frac{d_S}{l} + 0.2\right)^{0.7}, \tag{72a}$$



O2. Fig. 26. Model of the inlet velocity distribution by Mohr and Gelbe [26, 67, 68].

$$l_2 = l_2^* \le l, \tag{72b}$$

$$s_2 = 1.35 \cdot s' \cdot f\left(\tau, \frac{d_1}{d_S}, \frac{l}{d_1}\right) \cdot \left(\frac{d_S}{s'} + 0.2\right)^{0.7} \le s' \tag{72c}$$

$$A_{qs2} = \frac{\tau - 1}{\tau} \cdot (l_2 \cdot s_2 - l_1 \cdot s_1) \cdot k_\alpha, \tag{72d}$$

$$\psi_2 = 1.2 \cdot \frac{l_2^* - l_1}{l}. \tag{72e}$$

(III) Flow path with reverse flow: $\psi_3 = 0$

$$A_{qs3} = \frac{\tau - 1}{\tau} \cdot k_\alpha \cdot s' \cdot l - A_{qs1} - A_{qs2}. \tag{73}$$

The scope of application for this model has been validated for:

$$\frac{h}{d_a} > 0.5; \frac{d_1}{d_S} \le 7.5; \frac{l}{d_1} \le 3; \frac{d_S}{l} \ge 0.1; \tau \le 2.$$

The critical volume flows determined by the model with Eq. (61) are on the safe side in the range of 80–100% from the real values [26].

For a *quick and rough estimate*, it is recommended to use the *jet flow model* given in Eqs. (74a) and (b) to check the second tube row and primarily the first tube row, when considering the inlet flow factor k_{IF} in Table 9. This model is for $\frac{h}{d_a} > 0.5$ more accurate than a model using the projected area of the nozzle cross-section, which should be used for $\frac{h}{d_a} < 0.5$.

$$l_1 = s_1 = 1.20 \cdot d_S \cdot \left(\frac{h}{d_a}\right)^{0.25} \ge 0.9 \cdot d_S; \; l_1 \le l; \; s_1 \le s', \tag{74a}$$

$$A_{qs1} = l_1 \cdot s_1 \cdot \frac{\tau - 1}{\tau} \cdot k_\alpha \quad \text{and} \quad \Psi_2 = \Psi_3 = 0. \tag{74b}$$

When the *jet flow model* is used to calculate the vibration amplitude caused by vortex shedding or turbulent excitation, then the length l_1 from Eq. (74a) should be divided into three sections and the flow path length l into five sections as shown in Fig. 26. An example is given in Sect. 6.3.

In the *outlet flow region*, the last tube row, which is directly facing the nozzle, can be calculated with the model by Mohr [Eqs. (69–73)]; for the penultimate tube row, a similar approach can be used, with the exception, that a value $\psi_2 = 0.8$ should be used instead of ψ_2 from Eq. (72e). For all other tube rows, the velocity is usually considered uniform [10].

5.4.3 Window Region with Tubes

If the span length between the support plates is small compared with the shell diameter, i.e., for

$$l_m < d_1 \cdot 0.3/(\tau - 1), \tag{75a}$$

then it is acceptable to assume u = constant for the section m. If in contrast

$$l_m > d_1 \cdot 0.3/(\tau - 1), \tag{75b}$$

then velocity peaks appear in regions with *accelerated flow* at the edge of the support plate, i.e., at the peak of the mode shape of the window tube (see Fig. 25, Sect 2.2), which increase the level of vibration excitation [26]. The flow path length for the

first three tube rows in the window should be divided into two parts:

$$l_{m,2} = l_{m,1} = l_{m/2}. \tag{76}$$

The ratio of the two velocities is:

$$\Psi_{m,2}/\Psi_{m,1} = 1 + \frac{1.6 \cdot m^{1.6}}{d_1^{1.6}} - \frac{0.46 \cdot m^{1.6}}{d_1^{1.6}} \cdot \frac{d_1}{l_m \cdot (\tau - 1)}, \tag{77a}$$

and

$$1 \le \Psi_{m,2}/\Psi_{m,1} \le 2. \tag{77b}$$

If $l_m > 1.5\ d_1$, which occurs in some rare cases, then the length approached by flow l'_m is smaller than l_m:

$$l'_m = 0.2 \cdot l_m + 1.2 \cdot d_1 \le l_m. \tag{78}$$

Then l_m is divided into three partial sections and Eq. (76) can be used: $l_{m,3} = l_{m,2} = l'_m/2$. The value of $\Psi_{m,3}/\Psi_{m,2}$ can be calculated from Eqs. (77a) and (b) with l'_m instead of l_m; $\Psi_{m,1} = 0$.

The velocity can be assumed constant, u = constant, in sections with a decelerated flow (e.g., outlet flow region of a window) and for window tube rows after the third row.

5.5 Engineering Design Recommendations

Special attention for an effective engineering design is necessary in heat exchangers working near the critical velocity (stability ratio $K^* > 0.8$) or whose capacity is to be enlarged. The designer's goal should be to avoid peaks of velocity, especially in sections with maximum mode shapes or to reduce the mode shape maxima by the installation of additional support plates. A detailed vibration analyses should provide hints to the necessary measures.

5.5.1 General Remarks

The influence of the geometric and structural data on the critical velocity for fluid-elastic instability is described by the stability equation (26):

For gases:

$$u_{sk} \sim K(\tau) \cdot \frac{d_m^{1.5}}{l^2} \cdot E^{0.5} \cdot \left(\frac{s_R}{\rho_f}\right)^{0.5} \cdot \Lambda^{0.5}, \tag{79a}$$

for liquids:

$$u_{sk} \sim K(\tau) \cdot \frac{d_m^{1.5}}{l^2} \cdot E^{0.5} \cdot \left(\frac{s_R}{\rho_f}\right)^{\approx 0.35} \cdot \Lambda^{0.15}, \tag{79b}$$

with $d_m = 0.5 \cdot (d_a + d_i)$ average tube diameter,
$s_R = 0.5 \cdot (d_a - d_i)$ tube wall thickness.

Effective measures therefore include the reduction of the span length l or increase of d_m or s_R. A span length reduction normally leads only to an approximate linear increase of the critical volume flow $\dot{V}_k$. Raising Λ is also feasible, e.g., by reducing the boring clearances and increasing the thickness of the support plates, but this measure is only effective when the first or second modes (with large span lengths) are critical. If possible, the boring clearance at the tube supports should be $\Delta d_B \le 0.3$ mm [4]. But also in uncritical exchangers, Δd_B should be smaller than 0.6 mm, since otherwise tube supports tend to become inactive; this may result in fretting wear failures [5].

The proposed measures also provide a risk prevention of turbulence or vortex shedding excitations. Tie rods outside the bundle may be endangered by vortex shedding excitation and should be checked. They should not be installed at the center line of the nozzles.

5.5.2 Nozzle Inlet and Outlet Flow Region

The inlet flow should be as equally distributed as possible, especially when this section is critical, e.g., for flow paths $N \le 3$. This basically holds also for the outlet flow region, where the flow conditions are somewhat better. Some general recommendations are listed in the following:

- The distance between the bundle and nozzle h (see Fig. 27, point A) should be sufficiently large. Increasing this distance up to $h = 2.5 \cdot d_a$ leads to a substantial increase in the critical volume flow, whereas for $h > 2.5 \cdot d_a$ this influence becomes smaller [67, 68]. The model by Mohr describes the influence of h/d_a [see Sect. 5.4.2 and Eq. (70)]. For critical inlet flow regions without a partial support plate, this value is recommended:

$$\frac{h}{d_a} \ge 2. \tag{80}$$

- If a bundle shall include the maximum number of tube rows (i.e., fully packed with tubes), some tube rows with a chord length $s' < d_S$, resp. $h/d_a < (\tau - 0.5) \le 1$, should be removed.
- A louvre distributor can be installed under the nozzle (see Chap. O1, Fig. 21d), which divides the flow in axial or radial direction, depending on the geometric parameters [69]. It additionally provides a protection from the impingement of liquid droplets and is therefore a much better vibration design, than an impingement plate.
- The nozzles can be enlarged to reduce the inlet velocity and their minimum diameter can be chosen to avoid recirculation at the baffle plates. For example Eq. (72) gives:

$$\begin{aligned} \tau = 1.28 &: \ d_S \ge 0.37 \cdot l_m, \\ \tau = 1.40 &: \ d_S \ge 0.42 \cdot l_m, \\ \tau = 2.0 &: \ d_S \ge 0.57 \cdot l_m. \end{aligned} \tag{81}$$

If the above-mentioned measures are not feasible or not effective, it will be necessary to implement additional supports for the endangered tube rows:

- A partial support plate can be installed at the center of the nozzle, e.g., with the height H_1 and an overlap with the baffle plate as shown in Fig. 27. This is also advisable, when the baffle plate edge is positioned normal to the nozzle cross-section (point C in Fig. 27). In this case, the partial support plate protects the exterior tubes in the first tube rows (point B in Fig. 27) against the intensified diagonal flow.

5.5.3 Impingement Plates

Impingement plates protect the bundle from the impingement of liquid droplets (Chap. O1, Sect. 2.4), but normally they increase the risk of vibration excitation [69]. Therefore circular impingment plates should have a diameter of $d_P > 1.2 \cdot d_S$ and holes like a perforated plate. High local velocities arise at the radial edge of the plate (point A in Fig. 28), which coincides with the maximum amplitude of the mode shape. This endangers the exterior tubes in the first tube rows (point B in Fig. 28). In this case also, a partial support plate can provide additional support to these tube rows (point E in Fig. 28).

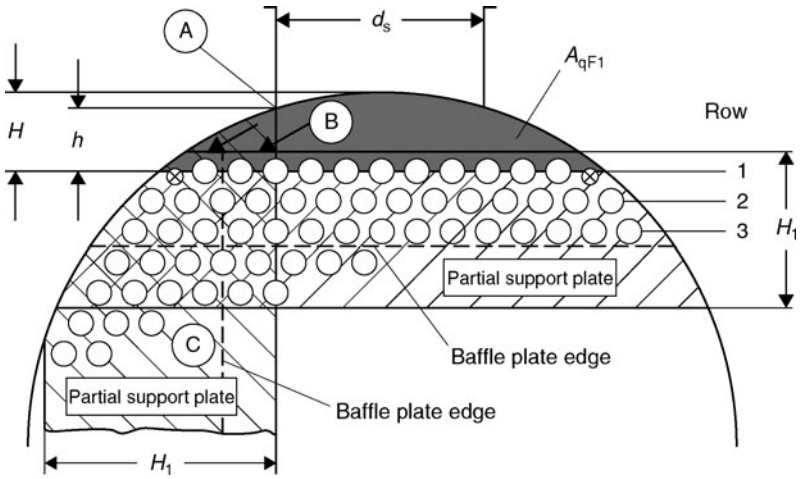
Additional measures are described below:

- The impingement plates with rectangular shape should be brought close to the shell wall (point C in Fig. 28) to avoid high radial velocities. Instead, high axial velocities arise at the supports, which can be beneficial for the reduction of the vibration excitation.
- Strengthened tubes or solid rods can be used in the first two or three tube rows. This solution is more advantageous with regard to vibration prevention than impingement plates.
- The above-mentioned louvre distributor is suitable for impingement prevention as well as for flow distribution.

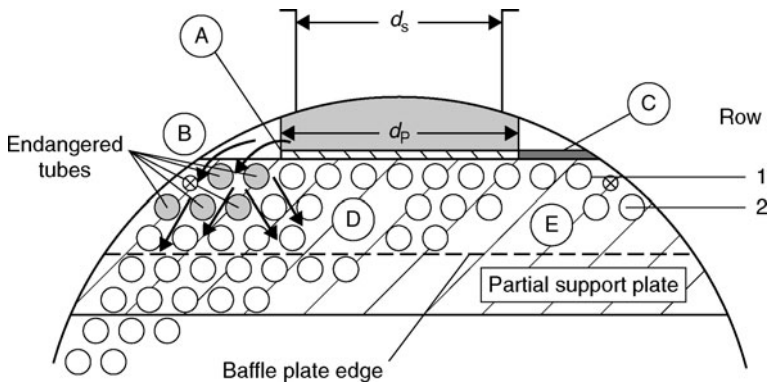
5.5.4 Endangered Window Tubes

If window tubes are critical, then the following measures are feasible:

- Partial support plates bearing three or more of the first window tube rows and optionally overlapping with the baffle plate.
- Supporting grids (see Chap. O1, Fig. 22) to increase the damping and avoid high vibration amplitudes. They are



O2. Fig. 27. Partional tube support plates in the inlet and outlet flow region.



O2. Fig. 28. Impingement and partial support plates.

often installed in heat exchangers bundles with axial flow and large tube spans. The contraction of the cross-section area can be kept low by an axial offset of the grids. But greater clearances and the risk of inactive supports have to be considered.

- In especially critical cases, window tubes should be avoided altogether (see Chap. O1, Figs. 12 and 13).
- To prevent fretting wear, the distance between baffle plate and the first window tube row should be about $0.05 \cdot d_a$ and when the baffle plate overlaps the first tube row, the boring diameter of the half-round holes should be $d_B \geq 1.1 \cdot d_a$.

5.5.5 Bypass Flow through Open Flow Lanes

Open flow lanes in the center part or between bundle and shell wall (see Chap. O1, Fig. 16) cause a directional change of the flow; owing to the high flow resistance of the bundle, the flow velocity in these gaps can be substantially higher than within the bundle. Tubes adjacent to these gaps are therefore exposed to a higher vibration risk, especially the tubes at the end of the gaps, where a constriction leads to local high velocities.

- Boundary gaps can be considered by the boundary stream factor k_{RS} (see Sect. 5.2). In rectangular plane channels, the maximum loads of the exterior tubes have been measured at a gap width of $d_a(\tau - 1)/2$; these tube loads are found to be approximately 25% higher than the average of the considered tube row [26]. Therefore, the following difference between the shell and the outer tube limit d_H is recommended:

$$d_1 - d_H > 2d_a \frac{\tau - 1}{\sqrt{\tau}}. \qquad (82)$$

  The influence of the boundary gap width on the critical load of the outer tubes will be smaller with an increase in the difference $d_1 - d_H$, but the by pass flow will also increase.
- Vertical gaps should be avoided or closed by dummy tubes. The velocity in open flow lanes can be approximately estimated using the equation of continuity.
- Sealing strips or dummy tubes should be placed at the beginning of the open flow lanes and consecutively at distances of two or three tube rows (as described in Chap. O1 with regard to Fig. 16).
- In particular critical cases, endangered outer tubes with small gap widths (see point A in Fig. 23) should be removed.

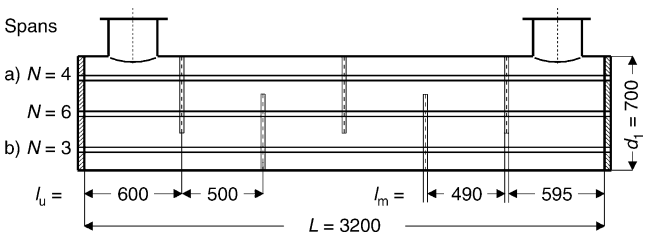
6 Example Calculation

The critical shell-side volume flow of water has to be calculated for a heat exchanger, sketched in Figs. 29 and 30. The cold water on the shellside has an overpressure of $p_a = 10$ bar, the hot medium in the tubes $p_i = 5$ bar. The medium tube temperature is $\vartheta_R = 64°C$, i.e., $\Delta\vartheta_R = 44$ K higher than 20°C (stress free fitting condition), $\Delta\vartheta_M = 0$. The tubes are fixed in the tube sheets.

6.1 Fluid and Structural Data

Geometric data:

Inner diameter of the shell	$d_1 = 700$ mm
Outer diameter of the shell	$d_2 = 720$ mm
Cross-sectional area of shell wall	$A_M = 22\,305$ mm^2
Outer diameter of the tubes	$d_a = 25$ mm
Inner diameter of the tubes	$d_i = 21$ mm
Cross-sectional area of the tube wall	$A_R = 144.5$ mm^2
Tube layout angle	$\alpha = 30°$
Pitch ratio	$\tau = 1.4$
Tube support width	$b = 10$ mm
Boring diameter of holes in tube support plates	$d_B = 25.6$ mm
Window cutout height: baffle edge to shell	$H_u = 244$ mm
Distance: bundle to nozzle	$h = 60.9$ mm
Diameter of the baffle plates	$d_u = 695$ mm
Outer tube limit	$d_H = 690$ mm
Nozzle diameter	$d_S = 211$ mm
Distance: tube sheet to nozzle center	$l_S = 297.5$ mm
Cross-sectional flow area of the nozzle	$A_{qS} = 34\,967$ mm^2
Number of tube rows	$NRR = 18$
Number of tubes in the bundle	$n_R = 294$
Material and fluid data	
Tube sheet stiffness, interior tubes	$X_I = 0.5$
Tube sheet stiffness, exterior tubes	$X_A = 1.0$
Density of tube material	$\rho_R = 7850$ kg/m^3
Modulus of elasticity for tubes and shell	$E = 210{,}000$ N/mm^2
Poisson's ratio	$\nu = 0.3$
Thermal expansion coefficient	$\gamma_R = 1.18 \cdot 10^{-5}$ 1/K
Density of fluid in the tubes	$\rho_i = 900$ kg/m^3
Density of fluid in the shell	$\rho_f = 1000$ kg/m^3
Viscosity of water	$\nu_f = 1.0 \cdot 10^{-6}$ m^2/s



O2. Fig. 29. Sketch of the heat exchanger; dimensions are in mm.

Structural data:

Tube mass per unit length	Eq. (8a)	m_R = 1.446 kg/m
Hydrodynamic mass coefficient	Fig. 3	c_h = 2.5
Hydrodynamic mass per unit length	Eq. (8b)	m_h = 1.227 kg/m
Mass per unit length	Eq. (7)	m = 2.673 kg/m
Thermal expansion		$\gamma_R \cdot \Delta\vartheta_R = 51.92 \cdot 10^{-5}$
The exterior tubes are critical	Eq. (16f)	
Load bearing exterior tubes	Eq. (16b)	$n^*_{RA} = 63$
Minimal number of load bearing tubes	Eq. (16d)	$n_{RA0} = 30$
Axial force due to thermal expansion	Eq. (16a)	$F_{R\vartheta v} = -12\,434$ N
Axial force due to external forces	Eq. (16e)	$F_{Rp} = 650$ N
Total axial force	Eq. (15)	$F_R = -11\,784$ N

O2. Table 10. Influence of the support conditions on the fluid and structural data

Support conditions (see Fig. 29)	Support type:	a	b

Reduced critical velocity for 30°-layout, Table 9, Eq. (46a)	u_{sk} (m/s)	1.72	1.53

6.2 Fluid-elastic Instability

Endangered tube rows are RR 1 and RR2 due to the high inlet velocity and RR 13 due to the lowest frequency and with approximately constant loads in all flow paths (i.e., $\Delta S \approx 1$). Therefore, a first estimate of the critical volume flow is possible when analyzing tube row 13:

Tube row 13 *for the first mode, support type (b)*

Lowest cross-section flow area, Fig. 30	$A_{qs} = 0.092$ m^2
Reduced critical velocity, Table 10	$u_{sk} = 1.53$ m/s
Leakage flow factor, Eq. (67)	$k_{LF} = 0.85$
Partial flow factor, Eq. (68)	$k_{PF} = 1$
Boundary stream factor, Eq. (46)	$k_{RS} = 1$
Critical volume flow $\dot{V}_k \approx (1.53 \cdot 0.092)/0.85$, Table 10	$\dot{V}_k = 0.166$ m^3/s
A more accurate computation with the program [3] gives	$\dot{V}_k = \dot{V}_{k,IF} = 0.175$ m^3/s

Tube row 14 is unproblematic in relation to row 13, since $k_{PF} < 1$ and $k_{RS} = 1$ (no narrow boundary gap).

Tube row 2 *for the first mode, support type (a)*:
Tube row 2 is endangered by fluid-elastic instability, first by the inlet jet flow and secondly by the smallness of the boundary gap width of the outer tubes in rows 2 and 17 (see Fig. 30). In Fig. 31, the velocity distribution, due to the equations described in Sect. 5.4, are shown. In the following, the use of these equations will be demonstrated, but more details can be found in [10].

Inlet flow region, section $m = n = 1$ (see results in Table 11)

Eq. (70)	Y = 1.374
Eq. (69a)	$l_{1Mo} = l_{1,2} = 341.7$ mm
Eq. (71)	$f = 0.9165$
Eq. (69b)	$s_{1Mo} = s_{1,2} = 265.7$ mm
Eq. (69c)	$A_{qs1Mo} = A_{qs1,2} = 21603$ mm^2
Eq. (72a) and Fig. 26	$l_{2\,Mo} = 551.4$ mm $< l_1 = 595$ mm
	$l_{1,1} = l_{1,3} = 104.9$ mm

Outlet flow region, section n = 4 (or m = 6)

$k_{LF} = k_{PF} = 1$; $\Psi_{4,1} = 0.470$; $u_{sk} = 1.0$ m/s

The results are summarized in Table 11. Values of $\Delta S_{m,r}$ for the first mode in column eight were roughly estimated by using Eq. (55b), Table 2, Eq. (12), and Fig. 5. The partial sections, which have the greatest influence on the excitation, are given in column 9 of the table:

The inlet flow region is uncritical, but the window regions with accelerated flow, *m*, *r* = 2,1/4,1, have the greatest influence, caused by the maximum mode shape in these regions and by the endangered outer tubes in the tube rows two and 17. But removing these tubes, i.e., $k_{RS} = 1$, is not necessary in this case, because the tube row 13 is the critical one and not tube row two.

From Eqs. (60) and (61), the maximum critical velocity and the critical volume flow of tube row two for the first mode are:

$$\hat{u}_{sk} = 1/0.1718 = 5.82 \text{ m/s},$$
$$\dot{V}_k = \dot{V}_{k,IF} = 0.234 \text{ m}^3/\text{s}.$$

Due to the low energy ratio S_1 it should be examined, whether higher modes could be critical for tube row two. A more accurate computation with a computer program [3] shows that the first mode is critical.

Tube row 1:

Tube row 1 is not endangered by fluid-elastic instability, due to the relative large distance of the bundle from the nozzle, h/d_a = 2.44 [Eq. (80)], and the inlet flow factor k_{IF} = 1.114 (from Table 9). But the influence of turbulent buffeting and vortex shedding has to be examined at the critical and the operating volume flows, as shown in Table 12, because the nozzle diameter d_S = 211 mm is smaller than the recommended value by Eq. (81): $d_S \geq 0.42 \cdot l_m$ = 250 mm.

Summing up of the results:

The operating volume flow should be about 85% of the critical volume flow: $\dot{V}_k = 0.175$ m^3/s, i.e., $\dot{V}_B = 0.15$ m^3/s. The stability ratios K^* [Eq. (58)] for the tube rows one, two, and 13 are shown in Table 12 at the volume flows of 0.15 and 0.17 m^3/s. The maximum amplitudes for turbulent buffeting $\hat{A}_t = \sqrt{2} \cdot \hat{A}_{tRMS}$ and vortex shedding $\hat{A}_w$ (computed by [3]) are also inserted in this table. The critical values have been grey shaded.

When using a heat exchanger with a shell compensator or a floating head, i.e., with a tube frequency of 50.5 instead of 32.3 Hz for tube row 13, then the capacity could be increased by a factor 50.5/32.3 = 1.56 to $\dot{V}_k = 0.26$ m^3/s and $\dot{V}_B = 0.22$ m^3/s. A similar effect could be achieved by swapping the working fluids, i.e., the cold water inside the tubes and the hot fluid in the shellside.

O2. Table 12. Stability ratios and amplitudes for the tube rows 1, 2, and 13 [3]

Operating volume flow			$\dot{V}_B = 0.15$ m^3/s			$\dot{V}_B = 0.17$ m^3/s

6.3 Vibration Amplitudes Caused by Vortex and Turbulence Excitations

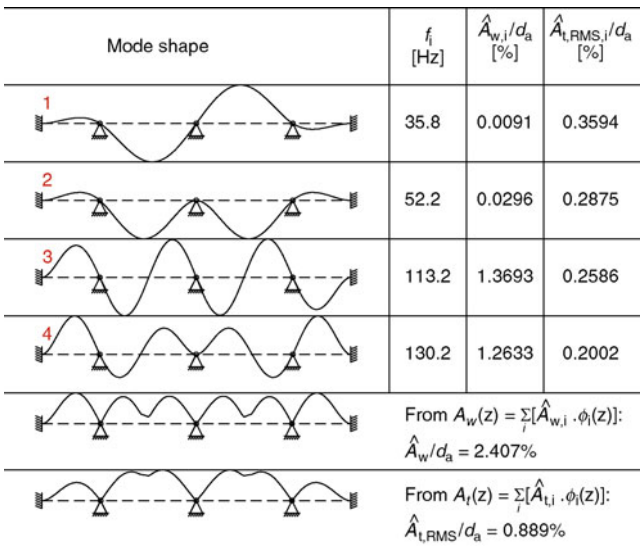
With a pitch ratio τ = 1.4 and the number of spans $N \geq 3$, the vibration amplitudes should be lower than 1% of the tube diameter (Sect. 4.3.1). Table 12 shows the vibration amplitudes excited by vortex shedding and turbulent buffeting: For the small nozzle diameter d_S = 211 mm, the amplitudes in the first tube row approach the danger limit for lock-in when the volume flow comes up to the critical flow rate of 0.17 m^3/s. At this flow rate, both tubes, row one by vortex shedding ($\hat{A}_w/d_a$ = 2.4%) and tube row 13 by fluid-elastic instability (K^* = 97%) are endangered.

As shown in Fig. 32, the third and the fourth modes are dominant for vortex shedding in this case. The amplitudes are too high to avoid long term and possibly also short term damages. Therefore, d_S has to be enlarged to a minimum of 240 mm, as recommended by Eq. (81). Then the amplitudes become lower than 0.60% of d_a as shown in Table 12.

***Tube row 1**, inlet flow region, third mode*:

To demonstrate the calculation procedures, the amplitude of the first tube row shall be determined for ***vortex shedding excitation*** of the third mode of vibration ($\tilde{A}_{w3}/d_a$ = 1.37) as shown in Fig. 32. First the Strouhal numbers are obtained from Fig. 15 and the resulting critical vortex excitation velocities according to Eq. (36) are shown in Table 13.

The Strouhal number Sr_{w2} in the 30° layouts and at τ = 1.4 is active only for Reynolds numbers <75,000 and then only in the first three tube rows [39]. The Reynolds number for the third



O2. Fig. 32. Mode shapes and related amplitudes for vortex shedding and turbulent buffeting of the first tube row at $\dot{V}_B = 0.17$ m^3/s [3].

mode is $Re_{w2} = 4.68 \cdot 0.025/1 \cdot 10^{-6} = 117{,}000$ and therefrom 70% due to Eq. (37) gives a limiting value of Re = 82,000, which is larger than 75,000. Therefore, the only critical resonance velocity in the third mode is 6.78 m/s. Such a high velocity can only be reached in the inlet flow region. To determine the velocity distribution in the inlet region, the *jet flow model* Eq. (74) is used:

Eq. (74a)	$l_{1Mo} = 298$ mm
Eq. (74b)	$A_{qs1Mo} = 0.0254$ m^2
	$u_{s1Mo} = 6.70$ m/s
Eq. (39)	$\eta = 0.988$
Eqs. (40) and (41)	$k_A(\eta) = f_{VA} = 0.946$
Eq. (55b), Table 14, and Fig. 5	$\Delta S = 0.13 \cdot 0.85 = 0.11$
Eqs. (19), (21), and (22)	$\Lambda_3 = 0.0241$
Eq. (38)	$\Delta_3 = 0.104$
Fig. 20	$c_y = 0.03$
Table 1	$\bar{\Phi} = 0.565$
Eq. (38) : resonance value	$A_{w3}/d_a = 0.0522$
Corrected value	$k_A \cdot A_{w3}/d_a = 0.0494$
Eq. (63)	$J_{w3} = 1$
Eq. (63) Weighted value	$\tilde{A}_{w3}/d_a = 1.64\%$

The so calculated amplitude is higher than the value from Fig. 32. The reason is the assumption of a constant equivalent velocity with the length of 298 mm, which was derived considering the fluid-dynamic instability. In reality, the peak velocity exists along the length of the nozzle diameter, approximately 211 mm, and starts to decrease gradually outside the nozzle cross-section. For analyzing the vortex shedding excitation caused by a variety of critical velocities, it is necessary to know the real velocity distribution and its gradients in the relevant sections, in order to have a reasonable estimate of the resonance flow velocities and their excitation levels. This can be achieved by means of the amplitude weighting factor $k_{A,i,j}$ according to the Eqs. (39) and (40).

O2. Table 13. Critical velocities for vortex shedding u_{swji}, m/s

	Sr_{wj} | Mode i	1	2	3	4
RR 1	$Sr_{w1} = 0.417$	2.14	3.13	6.78	7.80
	$Sr_{w2} = 0.604$	1.48	2.16	–	–

It is possible to reconstruct an approximate representation of the velocity distribution. For example, the inlet and outlet flow sections can be divided into five sections, and for every section a linear velocity gradient between a lower u_{szu} and an upper velocity u_{szo} is defined: these will be calculated by means of u_{sB} in the adjacent sections. So it is possible to estimate *amplitude weighting factors* (Eqs. 39 and 40), as shown in Table 14.

In the present case, the calculated approach length (l_{1Mo} = 298 mm) is divided into three parts (1,1–1,3) with $l_{1,1} = l_{1,3} = 0.2 \cdot l_{1Mo} = 60$ mm, $\Psi_{1,1} = \Psi_{1,3} = 0.88$, and $\Psi_{1,2} = 1$. Other details can be obtained from Table 14. The resulting amplitude for vortex excitation in the third mode (see column 9) is $\tilde{A}_{w3}/d_a = \sqrt{0.000177} = 0.0133$ or *1.33%*, which is in good agreement with the result of 1.37% in Fig. 32.

As an example, the calculation of the amplitude for ***turbulent buffeting*** in the third mode: $\tilde{A}_{t,RMS,3}/d_a = 0.26\%$ from Fig. 32, will be illustrated for the inlet flow section with values from columns three and eight in Table 14. The excitation in the inlet flow section is dominant, whereas the other sections contribute only a small amount of energy.

Eq. (29)	$Sr_{i1,2} = 0.4026$
Eq. (29)	$Sr_{i1,1+1,3} = 0.4572$
Eq. (30b)	$S_{F1,2} = 0.00655$
Eq. (30b)	$S_{F1,1+1,3} = 0.00346$
Eq. (32)	$(A_{t,RMS,3}/d_a)_{1,2} = 0.00770$
Eq. (32)	$(A_{t,RMS,3}/d_a)_{1,1+1,3} = 0.00463$
Table 14	$\Delta S_{1,2} = 0.076$
Table 14	$\Delta S_{1,1+1,3} = 0.034$
Eq. (63)	$\Delta S_{1,2} \{(A_{t,RMS,3}/d_a)_{1,2}\}^2 = 4.506 \cdot 10^{-6}$
Eq. (63)	$\Delta S_{1,1+1,3} \{(A_{t,RMS,3}/d_a)_{1,1+1,3}\}^2 = 0.729 \cdot 10^{-6}$
	$\sum = 5.235 \cdot 10^{-6}$
Eq. (63)	$\tilde{A}_{t,RMS,3}/d_a = 0.23\%$

The difference between this value and the value of 0.26 from Table 12 results from the flow excitation in the outlet flow region, which has not been considered in this calculation. The computation for all relevant tube rows, spans, modes and for variable design parameters is rather complex, and therefore the use of a computer program, such as [3], is recommended, which is anyway necessary for the estimation of the partial energy ratios ΔS.

O2. Table 14. Detailed calculation of the vortex-induced vibration amplitude in the third mode for tube row one at the inlet flow section, $u_{sw3} = 6.78$ m/s

7 Symbols

Symbol	Description (unit)
A	amplitude (m)
A	area (m^2)
$A_M = \left(d_2^2 - d_1^2\right) \cdot \pi/4$	cross-sectional area of shell wall (m^2)
A_q	flow cross-sectional area (m^2)
$A_R = \left(d_a^2 - d_i^2\right) \cdot \pi/4$	cross-sectional area of tube wall (m^2)
a	speed of sound (m/s)
b	tube-support width (m)
c	spring stiffness (N/m)
c_h	hydrodynamic mass coefficient (−)
c_y	dynamic lift coefficient (−)
d	diameter (m)
d_1	inner diameter of exchanger shell (m)
d_2	outer diameter of exchanger shell (m)
d_H	outer tube limit (m)
E	modulus of elasticity (N/m^2)
F	force (N)
FRR	tube row in window (−)
f	frequency, function (Hz, −)
$\bar{f}_i$	relative natural frequency (−)
H	height of a window cutout (m)
h	lowest distance between bundle and nozzle (m)
I	area moment of inertia (m^4)
J	joint-acceptance coefficient, correlation factor (−)
$K(\tau)$	stability constant (−)
K^*	stability ratio (−)
k	correction factor (−)
L	total length of tube (m)
l	partial length of tube, span length between supports (m)
l_c	correlation length (m)
l_m	length of a flow path (m)
$\bar{l}_k$	relative equivalent length of tube for buckling (−)
l_S	distance tube sheet and nozzle centre (m)
l_u	distance of baffle plates (m)
M	mass (kg)
M	number of flow paths (−)
m	mass/unit length (kg/m)
m_h	hydrodynamic added mass/unit length (kg/m)
N	number of tube spans (−)
NRR	number of tube rows (−)
N_{RR}	tube row number (−)
n	exponent (−)
n_R	number of tubes in the bundle (−)
n_R^*	number of load bearing tubes (−)
P	exponent of the mass-damping parameter (−)
p	gauge pressure (N/m^2)
R	number of partial sections in a tube span or flow path (−)
r	damping constant (N · s/m)
Re	Reynolds number (−)
RR	tube row (−)
S	energy ratio (−)
s	gap width, wall thickness, width of flow area (m)
s'	chord length of a tube row in the shell cross section (m)
S_F	normalized power spectral density of fluid force (−)
Sr	Strouhal number (−)
Sr_i	dimensionless turbulence resonance frequency (−)
ST	Stokes number (−)
t	tube spacing (m)
u_∞	upstream flow velocity in x-direction (m/s)
$u^\star$	dimensionless gap velocity = $u_s/(f \cdot d_a)$ (−)
u_s	gap velocity in x-direction (m/s)
$\hat{u}_s$	maximum value of gap velocity $u_s(z)$ (m/s)
$\tilde{u}_s$	equivalent gap velocity (m/s)
u_τ	bundle velocity = $u_\infty \cdot \tau / (\tau - 1)$ (m/s)
$\dot{V}$	volumetric flow rate (m^3/s)
v	velocity in y-direction (m/s)
w	velocity in z-direction (m/s)
X	span length at tube ends (m)
X	dimensionless plate stiffness (–)
x	co-ordinate of tube position (m)
Y	jet expansion factor under the nozzle (–)
y	co-ordinate of tube position (m)
α	tube layout angle (°)
γ	linear thermal expansion coefficient (1/K)
Δ	mass-damping parameter (–)
$\Delta d_B = d_B - d_a$	boring clearance at the tube supports (m)
$\Delta l_S = l_S - 0.5\, l_m$	eccentricity of the nozzle position (m)
ΔS	partial energy ratio (–)
ϑ	temperature (K)
$\Delta\vartheta = \vartheta - \vartheta_0$	difference in average wall temperature during operating conditions ϑ from that corresponding to stress free conditions ϑ_0 (K)
$\eta = f_w/f_i$	frequency ratio (–)
ε	volume fraction (–)
$\dot{\varepsilon}_g$	volume fraction of gas flow (–)
ζ	damping coefficient (–)
Λ	logarithmic decrement of damping (–)
ν	kinematic viscosity m^2/s
ν	Poisson's ratio (–)
ρ	density (kg/m^3)
τ	pitch ratio (–)
Φ_i	normalized ith vibration mode shape (–)
Ψ	normalized distribution function of flow velocity (–)

Indices

A	exterior tubes of the bundle, amplitude
a	outer side of tubes, acoustic
B	holes in tube support plates, operating conditions
F	window
f	fluid in shell side
g	gas phase
gl	gas/liquid (two-phase)
H	outer tube limit
i	mode i
I	interior bundle tubes
IF	inlet flow region
j	integer referring to vortex Strouhal number
K	shell compensator
k	critical value for instability
LF	leakage flow
l	liquid phase
M	material damping, shell
Mo	model
m	average, flow section number, integer
n	tube span number, integer
o	upper value
P	impingement plate
PF	partial flow
q	cross-section
R	tube
Ra	border
RMS	root mean square
RR	tube row
RS	boundary flow
r	sectional number of a flow path or a tube span, integer
S	structural damping, nozzle
s	gap between the tubes
t	turbulent buffeting
u	flow dividing baffle plate, lower value
V	viscous damping
VA	dynamic response amplification
w	vortex shedding, critical value for vortex shedding
x	co-ordinate in flow direction, normal to the tube axis
y	co-ordinate normal to the flow direction and the tube axis
z	co-ordinate along the tube axis
α	tube layout
τ	bundle
Φ	mode

Construction of Heat Exchangers

O1 Hints on the Construction of Heat Exchangers

Günther Kirchner
BASF SE, Ludwigshafen, Germany

1 Heat Exchangers

The following factors are important in selecting the most suitable heat exchanger for any of the numerous applications that may arise in chemical and process engineering:

- the operating temperature and pressure,
- differences in product temperatures,
- corrosion,
- leakage and safety aspects,
- phase conversion,
- economy,
- space requirements.

Particular attention has been devoted to these aspects in the following description of the various types of heat exchangers.

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_67,

1.1 Construction Codes and Operation

In Germany, the construction of heat exchangers is subject to the provisions of the national boiler and pressure vessel code [1]. The legal requirements for their inspection and their performance as pressure vessels are considered to be met if the corresponding specifications in the relevant design codes (in Germany: *Druckgeräterichtlinie 97/23/EG* [2], *AD 2000-Regelwerk* [3]) are satisfied. The regulations also refer to the pertinent (*DIN*) standards.

Acceptance and routine performance tests that are specified in the regulations [4] are supervised by specialized bodies [in Germany: e.g., *Technischer Überwachungsverein* (*TÜV*)]. They are analogous to the performance tests described in the *Standard Testing Procedure for Heat Exchangers* compiled by the *American Institute of Chemical Engineers* (*AIChE*).

2 Shell-and-Tube Heat Exchangers

Shell-and-tube heat exchangers are comparatively easy to construct and are very versatile. They can be used for gases and liquids over a wide range of temperatures and pressures and in phase conversion, i.e., condensation and evaporation. Consequently, they are widely accepted in many branches of industry, particularly in the chemical industry and power stations.

2.1 Nomenclature and Standards

Guides to the nomenclature used in various national codes and standards (i.e., DIN 28 183) are given in the form of drawings, an example of which is presented below (Fig. 1). This drawing lists the main components of a shell-and-tube heat exchanger with two stationary heads.

Currently available English translations of some German (*DIN*-) standards, that relate to shell-and-tube heat exchangers, are listed in the appendix. In common with other national codes, they can be supplemented by *TEMA* standards [5], although these are specifically related to *American Society of Mechanical Engineers* (*ASME*).

2.2 Types

2.2.1 Shell-and-Tube Heat Exchangers with Two Fixed Tube Sheets

In this design, the two tube sheets are welded onto the shell (Fig. 2). As a result of this inflexible connection, the stresses caused by differences between the shell-side and tube-side temperatures cannot be relaxed. If the differences are big and the stresses are thus excessively high, an expansion joint may be fitted into the shell.

Under these circumstances, the tube sheets are no longer supported by the shell and must therefore be of a more robust design. An example is shown in Fig. 3.

2.2.2 Shell-and-Tube Heat Exchangers with Floating Head

Only one tube sheet in a floating head shell-and-tube heat exchanger is fixed to the shell and the other is free to move within the shell. Thus, differential expansion between the shell and the tubes does not present any problems. The sole purpose served by the movable tube sheet and its dished head is to baffle flow on the tube side. Since the tube bundle can be withdrawn from the shell, floating-head heat exchangers are mainly used in applications where the outsides of the tubes have to be frequently cleaned. In this case, square tube pitch is an advantage. If fouling of the inner surfaces of the tubes is anticipated, the fixed dished end can be flanged instead of welded (Fig. 4).

2.2.3 U-Tube Shell-and-Tube Heat Exchangers

As can be seen from Fig. 5, the U-tube heat exchanger has only one tube sheet, into which both ends of the tubes are inserted. The only means available for cleaning the inner surfaces of the tubes is by chemicals. The outer surfaces,

O1. Fig. 4. Shell-and-tube heat exchanger with floating head.

however, can be cleaned mechanically, because the tube bundle can be removed from the exchanger. The tubes with the smallest bending radius are those closest to the center line of the heat exchanger. If this radius is less than a given minimum, the first row of tubes must be arranged cross-wise (cf. Fig. 6). The smallest bending radius is determined by wall thickness, diameter, and material of the tube. Table 1 gives minimal bending radii for various tube diameters for carbon steel and for

30	–	62	42	38	35
38	–	–	52	47	42

CrNi-steel. Examples of specifications for steel U-tubes are those given in DIN 28 178.

Tube bundles with floating head or U-tubes can be fitted in vessels or large tanks of any given design, as is illustrated in Fig. 7. They can be used to heat or evaporate the liquid within the vessel.

2.3 Design Considerations

2.3.1 Flow Patterns in Shell-and-Tube Heat Exchangers

The first step in designing a shell-and-tube heat exchanger is to decide which fluid is to flow inside the tubes and which outside, i.e., on the shell side. The flow pattern depends primarily on thermodynamic and fluid dynamic aspects and on the permissible pressure drop. The choice is also affected by design criteria. Thus, the fluid selected for tube-side flow would be that at the higher pressure, tends towards higher fouling, or necessitates an expensive material of construction because of its very corrosive effect. Fluids whose physical properties entail low heat transfer coefficients should flow on the shell side.

2.3.2 Geometric Considerations

The geometry of a shell-and-tube heat exchanger should be designed to permit optimum flow velocities on both the tube and shell side. This aim is usually realized by computer programs. The input data and the data to be optimized include the properties of the fluids, the length and other dimensions of the tubes, the tube spacing, the maximum allowable pressure drop, and the most economic flow rate.

2.3.3 Flow Velocities

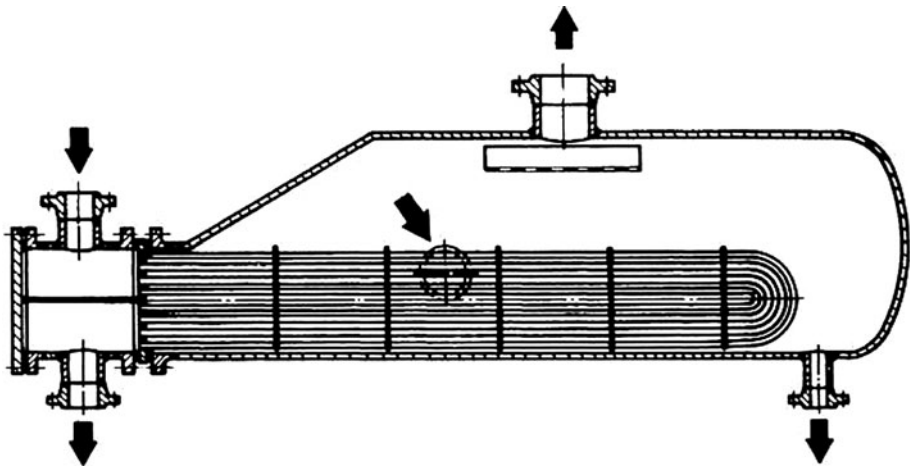
Heat transfer coefficients can generally be enhanced by raising the flow velocity, but this necessarily entails a higher pressure drop. An improvement in heat transfer and the associated reduction in transfer area, i.e., low equipment costs, are obtained at the expense of higher pump or compressor outputs. Consequently, costs optimization is required to determine the economic optimum flow velocity.

Another consideration is the reduction of fouling by ensuring that the flow velocity is not less than a given minimum, which depends on the specific properties of the fluid. Thus, if river water flows on the tube side, the velocity should not be <1 m/s, and values of 1.5–2.5 m/s should be aimed at. The average velocities on the shell side should be about 0.8 m/s for liquid fluids. An upper limit is imposed on the flow velocity by vibration, cavitation, and erosion.

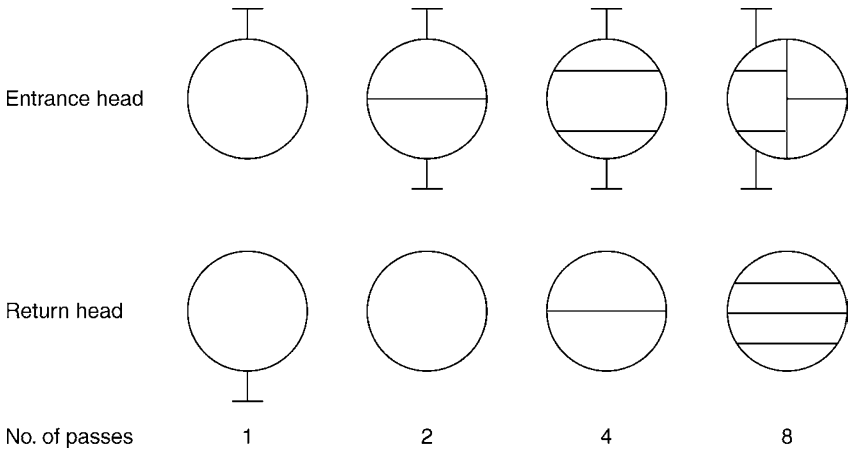
The maximum velocity in gas streams should not exceed 20 m/s at atmospheric pressure and 70 m/s in vacuo. In the case of wet steam, lower velocities are recommended. In these cases, the tubes should be protected against direct impingement of the vapor flow. Dependent on the pressure in the condenser, steam velocities in the vapor channels should be between 30 and 70 m/s [6].

2.3.4 Multiple-Pass Operation

The velocity can be increased and/or the flow path can be lengthened if the tube bundle is divided into two or more groups by



O1. Fig. 7. Shell-and-tube heat exchanger, kettle-type reboiler.



O1. Fig. 8. Typical pass layouts in multiple-pass heat exchangers.

inserting pass partitions in the dished head and thus diverting the stream of fluid on the tube side. The number of passes in standard designs is one, two, four, or eight.

Figure 8 shows the pass layouts of the partitions in the dished heads of multiple-pass shell-and-tube heat exchangers. The partitions should be arranged so that the number of tubes is roughly the same in each pass.

2.3.5 Inner Tubes, Length, and Wall Thickness of Tubes

The outer diameters specified in the German standard on seamless alloy and carbon steel tubes for use in shell-and-tube heat exchangers (DIN 28180) are 16, 20, 25, 30, and 38 mm.

The chemical industry favors the tubes of 25 mm outer diameter, which have a wall thickness of 2 mm.

Tubes of smaller diameter are mainly used in mechanical engineering for coolers and radiators.

The wall thickness depends on the design value (obtained from engineering codes, e.g., *AD Merkblätter*), the material to be used (i.e., on costs considerations), and the operating conditions (erosion, corrosion, and vibration). It usually lies between 1.2 and 3.2 mm. Reference values for the number of tubes, the heat transfer area, and the outer tube limit (OTL) are listed against the shell diameter in Tables 2–4.

2.3.6 Tube Pitch

The tube spacing largely influences the fluid velocity on the shell side and thus the pressure drop and heat transfer. The figures specified in German standards (DIN 28182) are listed in Table 5. It can be seen that they depend on the tube outer diameter d_o and the means adopted for expanding the tubes into the tube sheets. The minimum feasible pitch depends on the method of tube end attachment, the material of construction or the tube/tube sheet pairing, the tube wall thickness, and the tolerances for machining.

2.3.7 Estimation of the OTL and the Tube Spacing Plan

The tubes in shell-and-tube heat exchangers with fixed tube sheets are mostly spaced in a triangular pattern. The number that can thus be accommodated within a given circumscribed circle (OTL) is greater than that achieved with a square pitch. The tube pitch patterns that can be obtained are shown, together with the relevant pitch angle, in Fig. 9. Both triangular and square patterns can be arranged either through or around the center point of shell-and-tube heat exchangers that are completely filled with tubes and without cleaning lanes. Each case must be considered on its own merits in deciding to which arrangement preference should be given, i.e., how the space within the shell can be best utilized.

The OTL for a given tube count z and pitch t in the geometry shown in Fig. 10 can be obtained from the following relationship:

$$\mathrm{OTL} = \sqrt{f_1 z t^2 + f_2 z^{1/2} t + d_o}. \quad (1)$$

The numerical value for the constant f_1 is 1.1 for triangular and 1.3 for square tube pattern and that for f_2 can be obtained from Table 6. Equation (1) is valid for shells completely filled with tubes. The number of tubes corresponding to empty sections of the shell must be added to the given number z. The constant f_2 applies to lanes for pass partitions with seals of uniform width, viz. 10 mm, but not for U-tube heat exchangers. Equation (1) is sufficiently accurate if $z/t > 10\ \mathrm{mm}^{-1}$.

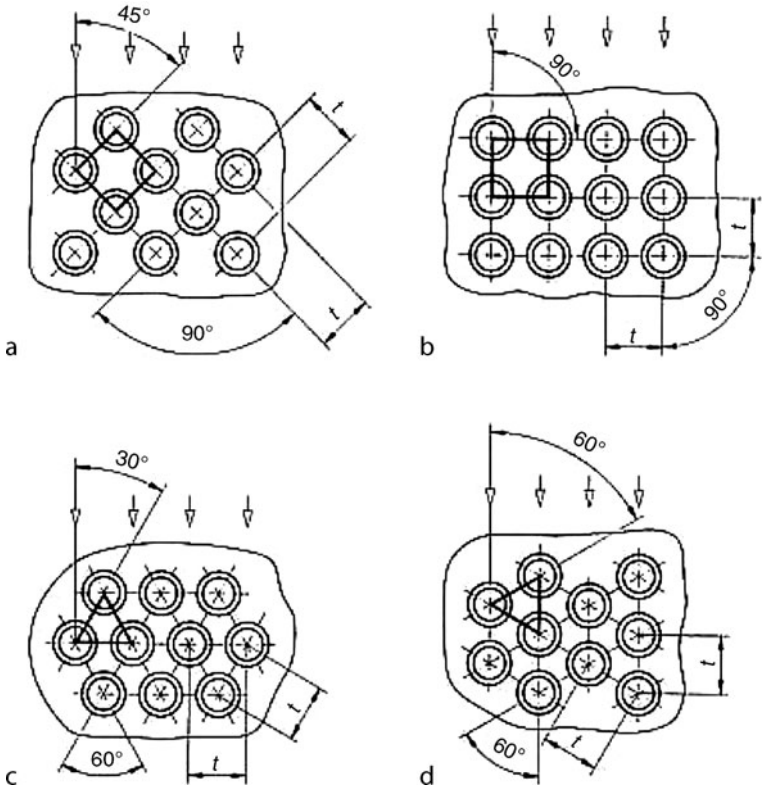
2.3.8 Baffles on Shell side

Segmental baffles are usually fitted within the shell to guide the stream of fluid. Designs of baffles for shells completely filled with tubes are shown in Figs. 11 and 14. The streams flow alternately in the axial and transverse directions over the outer surfaces of the tubes.

The value selected for the average velocity between the cross-current segmental baffles should be roughly the same as that in the window for the axial stream.

Figures 12 and 13 show segmental baffles in shells incompletely filled with tubes ("no tubes in window" design). The doughnut and disc baffles illustrated in Fig. 14 allow a tubeless central and peripheral zone, with the result that axial flow over the outer surfaces of the tubes can be avoided, as is evident from Fig. 15. Oblique flow over the tubes can be reduced if baffle plates are arranged between the segmental baffles, as is illustrated in Fig. 13.

In order to minimize leakage flows, the baffle pitch e between segment baffles in Figs. 12 and 14 should not be <20%, and the baffle cut (window opening segment height) f not <15% of the



O1. Fig. 9. Square (**a**, **b**) and triangular (**c**, **d**) tube pitch patterns. The inflow angle is shown in each case.

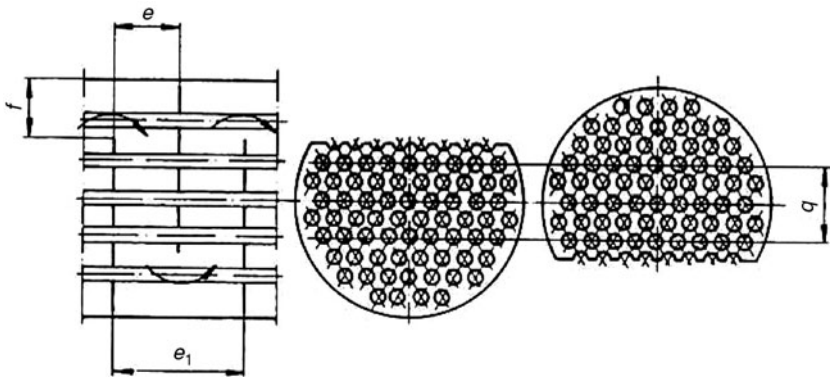
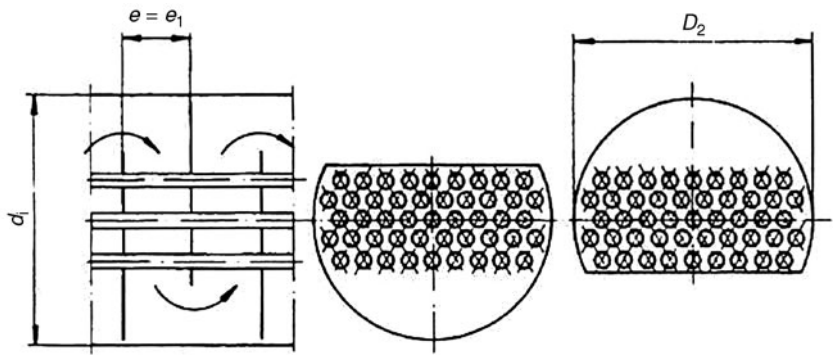
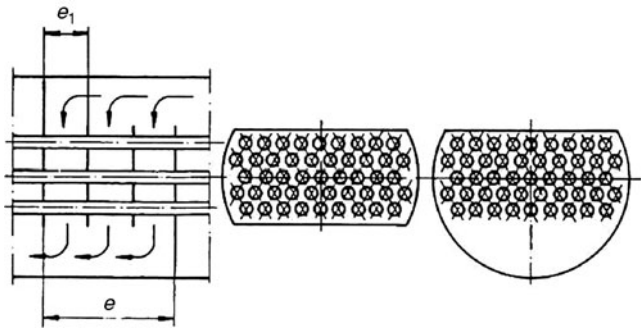
No. of passes	1	2	4	8
f_2 in mm	0	22	70	105



O1. Fig. 11. Segmental baffle in heat exchanger completely filled with tubes.



O1. Fig. 12. Segmental baffle in heat exchanger partly filled with tubes.



O1. Fig. 13. Segmental baffle with sheet-metal deflector.

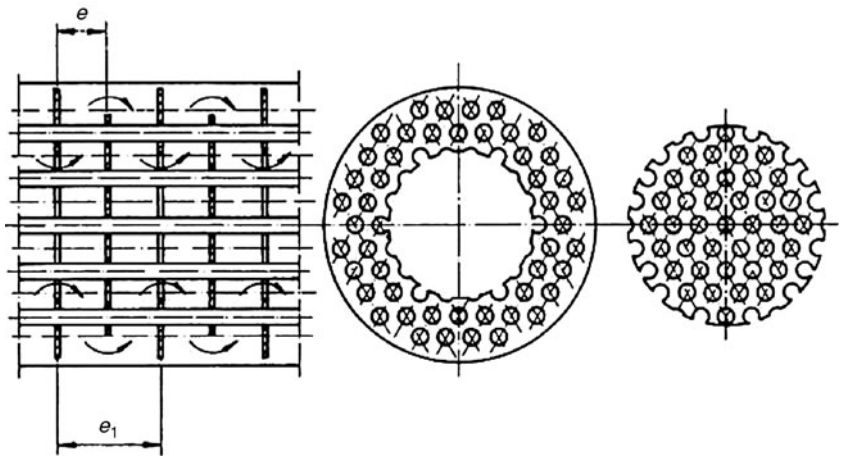
shell inner diameter d_i. The baffle cut f should not exceed 45% of the shell inner diameter.

The openings in the doughnut baffle shown in Fig. 14 should account for at least 20% of the cross-sectional area of the shell.

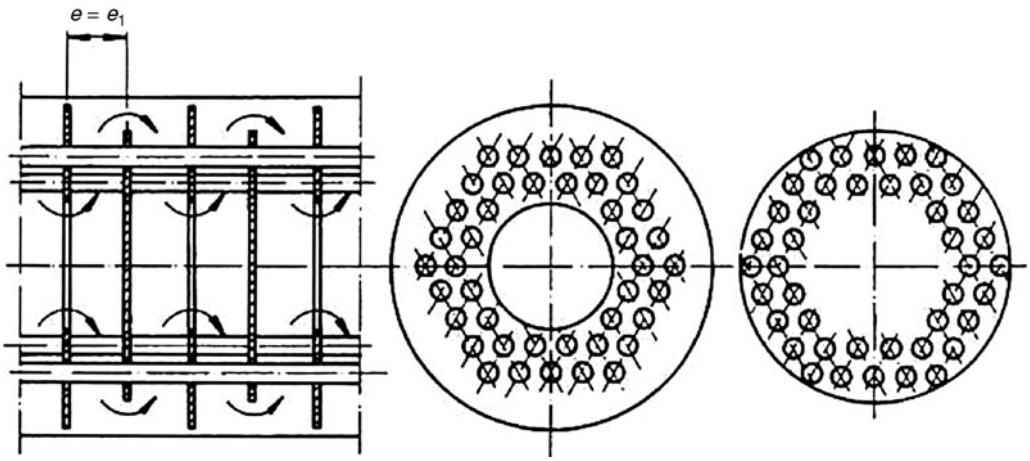
In certain cases, the flow cross-section in the shell has to be split in the axial direction in order to – for example – induce a countercurrent in a U-tube heat exchanger. Under these circumstances, the shell is divided by a longitudinal baffle.

2.3.9 Support Plates

At very high volume flow rates, crossflow is no longer feasible, because cross-flow velocities become too high and vibration and/or erosion occurs. Shell-side flow in heat exchangers will then be in the axial direction, and the shell-side fluid will flow parallel to the tubes. In this case, the tubes are supported in grids built up of flat sections.



O1. Fig. 14. Disc and doughnut baffles in heat exchanger completely filled with tubes.



O1. Fig. 15. Disc and doughnut baffles in heat exchangers with no tubes in window.

2.3.10 Sealing Strips and Dummy Tubes

Dummy tubes, sealing strips, spacers, and segmental baffles can be seen in Fig. 16, which shows the arrangement of tubes in an eight-pass shell-and-tube heat exchanger. A measure that is generally adopted to reduce bypass streams is to insert dummy tubes in the pass partition lanes that lie in the direction of flow; and to insert a pair of sealing strips behind every fifth tube bank in the cross-flow zones. The design of floating head shell-and-tube heat exchangers entails that an annular zone of up to 40 mm width may be free of tubes within the shell. In this case, special attention should be given to the fact that maldistribution can be avoided by sealing strips.

2.3.11 Clearances Between the Inner Diameter of the Shell and the Outer Diameter of Segmental Baffles

Dimensions and tolerances for shell-and-tube heat exchangers are laid down in DIN 28008. Figures for the diametric clearance between the shell inner diameter d_i and the outer diameter D_2 of segmental baffles are listed in Table 7. Owing to the conditions of manufacture, these clearances are inevitable, and the only means of reducing them is to machine the inner surfaces of the shell.

2.4 Design Details

2.4.1 Tube-to-Tube Sheet Joint

Figure 17a–c, e, and f are examples of standardized tube end weldings in tube sheets, as given in DIN 8558 part 2, tag C 10.1–10.4. Other feasible means of attaching the tubes to the tube sheet are rolling (Fig. 17d and g), and hydraulic or explosive expansion. Welding and roller expansion can also be combined, see DIN 28 187. Crevice-free welding (Fig. 17f) is preferred, if there is the risk of crevice corrosion on the shell side due to the presence of chlorine.

Roller-expanded connections are suitable only for low temperatures and pressures or for slight fluctuations in temperature and pressure. Consequently, preference is usually given to welded joints in the chemical industry and in boiler construction.

≤400	3
450–1000	4
>1000	6

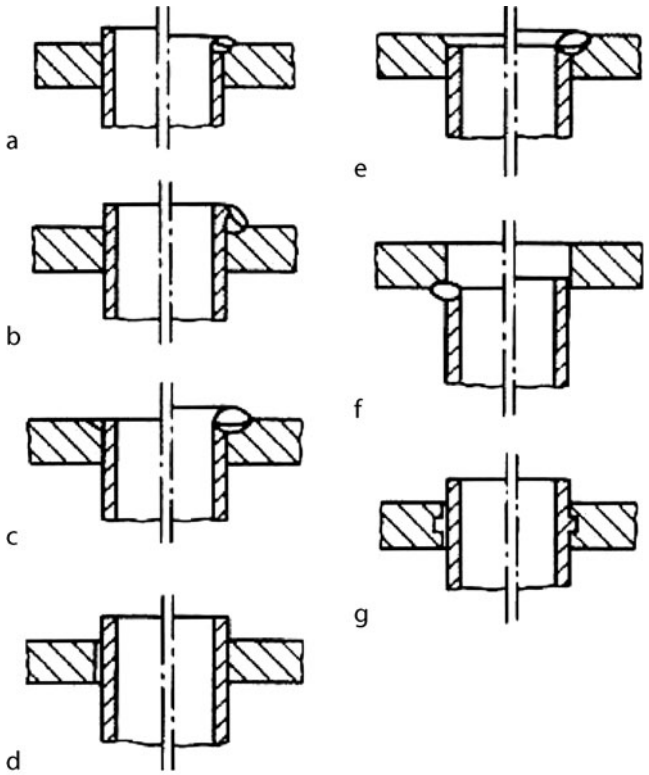
The tubes are usually welded in two staggered layers. In all cases, the thickness of the stressed welded should be at least the same as that of the tube wall.

If the inner tubes are to be coated, resort is mostly taken to the connections illustrated in Fig. 17a, c, and e.

2.4.2 Tube Sheet

Design calculations, e.g., that recommended in *AD-Merkblatt B5* [3], for shell-and-tube heat exchangers completely filled with tubes and without an expansion joint in the shell usually reveal that the tube sheet need be very thick. For manufacturing reasons, the choice generally falls on tube sheets of 12–20 mm thickness, the actual value depending on the diameter of the heat exchanger. The design of a "thin" tube sheet welded to the shell flange is illustrated in Fig. 18. "Thick" plates (Fig. 19) may be necessitated by strength considerations, e.g., if the shell not completely filled by the tubes or if an expansion joint has been fitted. In this case, the tube sheet may also be designed as a flange.

Differential thermal expansion between the shell and the tubes may impose additional stresses in heat exchangers with fixed tube sheets, i.e., without expansion joints. Instructions on how allowance can be made for the additional forces thus induced in the walls of pressure vessels are given in the *S*3 series of *AD-Merkblätter* [3]. However, these instructions do not apply to other additional forces, e.g., those induced by increases in weight or irregular temperature distribution. Under these circumstances, the stresses can be determined by the method

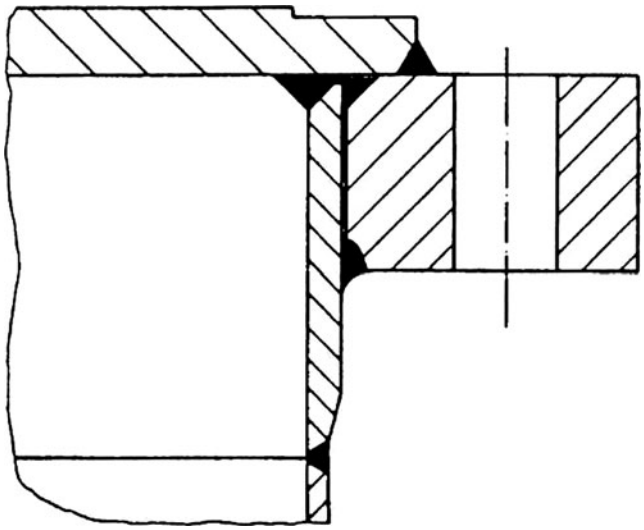


O1. Fig. 17. Means of securing tubes in the tube sheet (Methods **a**–**d** are described in DIN 8558, methods **e**–**g** are described in Sect. 2.4.1).

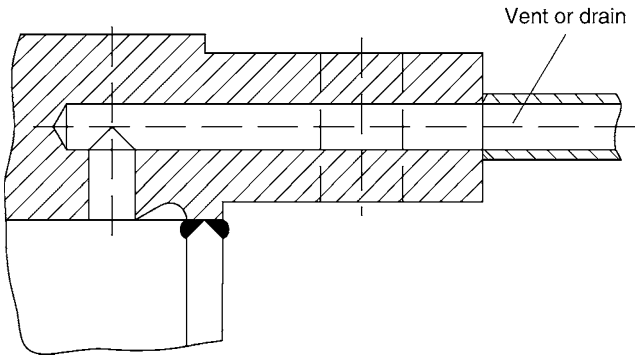
suggested by Sterr [7], in which case the relationships to temperature and pressure must be known at startup, during taking on stream, during operation, and at breakdowns.

2.4.3 Impingement Protection

As a result of the high inflow velocities, the innermost bank of tubes immediately below the shell inlet may suffer damage by



O1. Fig. 18. Thin tube sheet.



O1. Fig. 19. Thick tube sheet.

erosion or cavitation. It should thus be protected by an impingement plate or louver under the following circumstances.

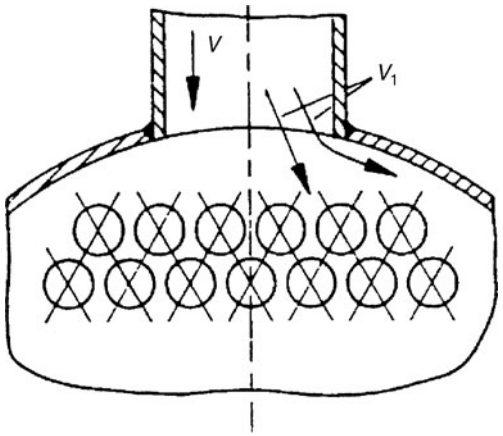
- If the inner tubes are exposed to condensing vapor.
- If ρv^2 for single-phase flow of noncorrosive or non-erosive liquids exceeds 2300 kg/ms^2.
- If ρv^2 for all other liquids up to the boiling point exceeds 750 kg/ms^2.

Another condition that must apply is that $\rho {v_1}^2 < 6000$ kg/ms^2 [7], where v is the average flow velocity at the inlet and ρ is the effective flow velocity between the tubes in the first row, as is illustrated in Fig. 20.

In shell-and-tube heat exchangers with fixed tube sheets, the impingement baffles are secured in the form of plates or louvers and are secured to the shell as is shown in Figs. 21 and 22. According to Fig. 22, the impingement plate should be designed somewhat wider than the cross-section of the incoming flow [8].

2.4.4 Design of Segmental Baffles and Support Plates

Apart from directing flow, segmental baffles serve to protect the tubes from damage by vibration and to prevent them



O1. Fig. 20. Flow velocities v_1 and v_2 at shell-side inlet and between the tubes.

from buckling. The requisite thicknesses of segmental baffles and support plates are listed as functions of the rated shell diameter and the distance between supports e_1 (Figs. 11–15) in Table 8.

Thicker segmental baffles are required if pulsating flow is anticipated (An example of a heavy-duty design is given in DIN 28185). If the volume flow rate is high, segmental baffles must be more widely spaced. In this case, the conditions for the prevention of buckling and damage by vibration no longer apply, and additional support plates must therefore also be installed (Fig. 23).

Very often, the design entails a large spacing between the first or last segmental baffle and the tube sheet. The ensuing dead spot can be made smaller by installing a baffle under the shell nozzle, as is shown in Fig. 24.

2.4.5 Nozzles

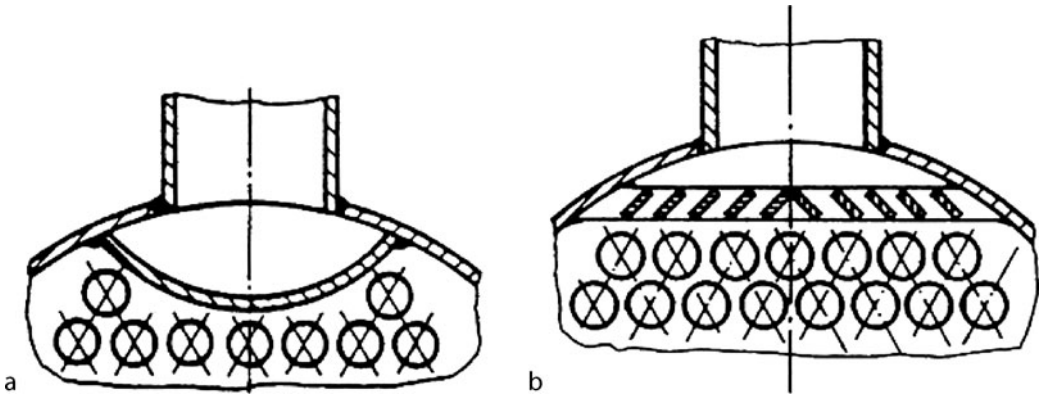
The head and shell nozzles must be designed to avoid the formation of gas or vapor cushions that could impede heat transfer or promote the concentration of contaminants at the vapor/liquid phase boundary and thus lead to corrosion of the inner tubes, shell, or dished ends.

Provision must also be made for vents and drains in the event that the shell-side and tube-side spaces cannot be completely drained or vented. They may assume the form of separate connections or holes drilled in the tube sheets (cf. Fig. 19). Vents and drains should also be drilled in the pass partitions (Fig. 25).

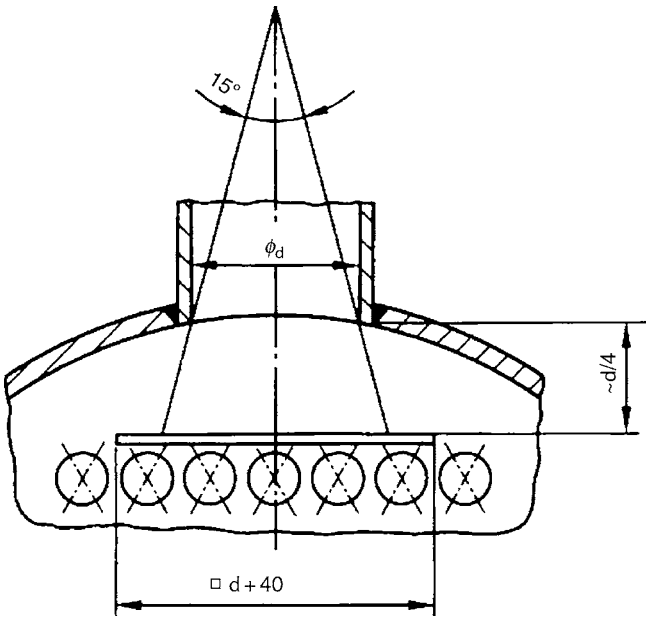
2.4.6 Pass Partition Seals

A type of seal that is frequently used for a dished-end partition is shown in Fig. 25a. Its breadth b is usually 8–10 mm. A flexible partition seal is illustrated in Fig. 25b. Partitions upon which a seal has been mounted, as is demonstrated in Fig. 25c, are often encountered in coolers that operate at low temperatures and pressures ($p = 6$ bar and $t < 150$°C).

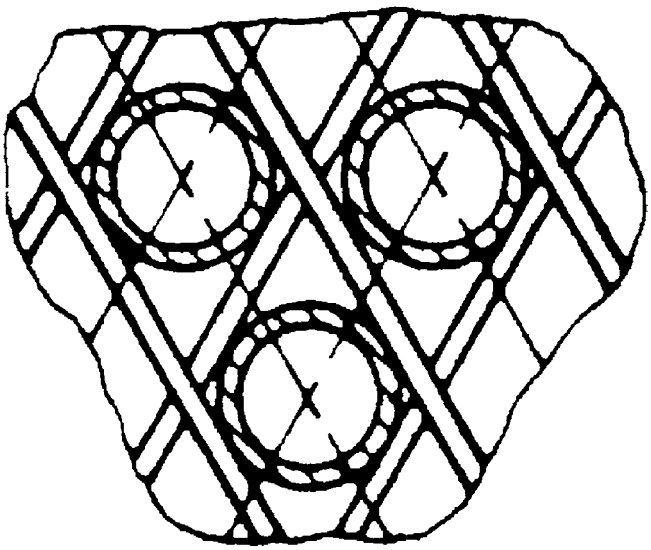
The pass partitions must be reinforced or supported if pressure surges are likely, the difference in pressure between the baffles is high, or the vessel is cleaned by flushing under pressure.



O1. Fig. 21. Designs of impingement protection: **a**) plate **b**) louver.



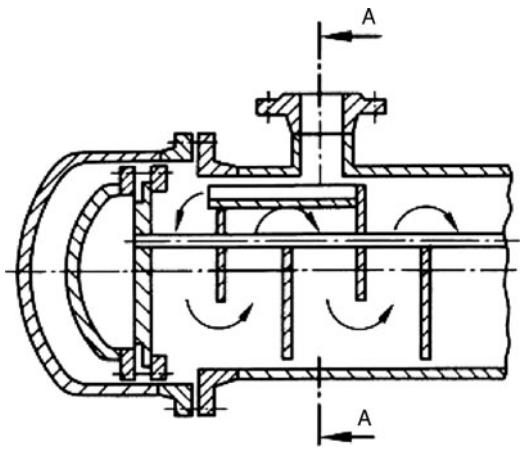
O1. Fig. 22. Arrangement of impingement plates.



O1. Fig. 23. Supporting grid.

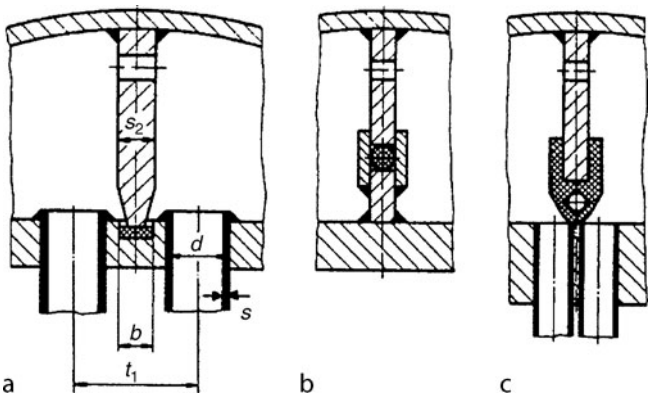
O1. Table 8. Thickness of segmental baffles and support plates in relation to the pitch e_1 (DIN 18 185) (dimensions in mm).

Nominal diameter	Pitch e_1					
	≤150	151–300	301–450	451–600	601–750	>750
	Thickness s					
150–350	4	4	4	4	5	6
400–700	4	4	5	5	6	8
800–1000	–	6	6	8	8	10
1100–2000	–	6	8	8	10	10



O1. Fig. 24. Baffle to reduce dead space.

If the partition is thicker than the width of the seal, it must be chamfered at the surface of contact to ensure a snug fit. Whenever the inner surfaces of the dished heads and tubes have to be coated with a baking finish, the partition should be beveled to a width of about 5 mm. Otherwise, the coating may be damaged at the edges of the groove that forms the seal in the tube sheet (cf. Fig. 25a) when the dished head is assembled or the partition vibrated during operation. Figures for the minimum thickness of pass partitions are submitted in Table 9.



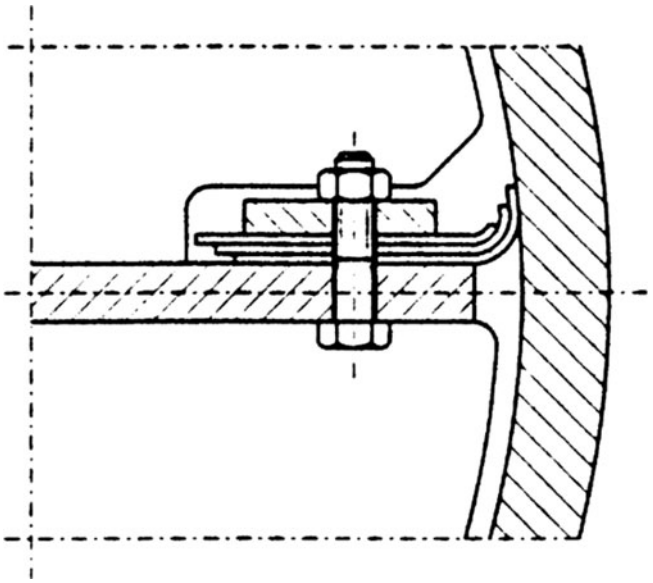
O1. Fig. 25. Seals for pass partition plates in dished head (Methods **a**–**c** are described in Sect. 2.4.6).

O1. Table 9. Thickness of partitions (dimensions in mm)

Dished head diameter	Carbon steel	Alloy steel
≤600	8	6
>600	12	10
>1400	16	14

2.4.7 Seals on Longitudinal Baffles

Figure 26 shows how a longitudinal baffle is sealed against the shell wall in a shell-and-tube heat exchanger with removable tube bundles and two shell-side passes. The thickness of the sheet-metal partition is about 8 mm for shells of up to 700-mm diameter; and about 12 mm, for larger exchangers. The leaf springs on the assembly should be designed so that the seal is pressed against the shell wall under the excess pressure that acts on the inlet side during operation.

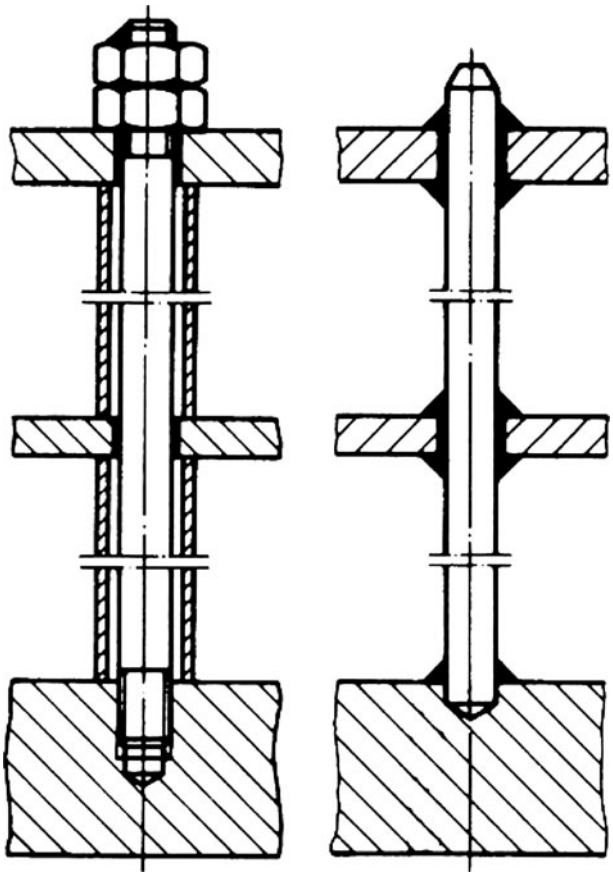


O1. Fig. 26. Seal on longitudinal partition plate.

2.4.8 Tie Rods

Two designs of tie rods are shown in Fig. 27. Their purpose is to secure the baffles in their intended position. Since the baffles (whether segments, discs or doughnuts) may not vibrate during operation, the tie rods should mainly be fitted close to the edges of the baffles. The tie rod arrangement described in DIN 28184 Parts 1–3, DIN 28190, and DIN 28191 apply only to certain sections between segmental baffles.

Sealing strips and dummy tubes can also serve as tie rods. The number and diameter of tie rods required in shells of various diameters can be obtained from Table 10.



O1. Fig. 27. Tie rods for segmental or support baffles.

2.4.9 Surface Coatings

Parts of shell-and-tube heat exchangers can be coated with a baking finish if the medium, e.g., river water, is likely to cause encrustation or corrosion.

Some coatings are impermeable to water vapor, and others are not. They ought to be impermeable if the aqueous medium with which they are in contact is at a temperature higher than that at the opposite side, as otherwise the coating will peel off when the water diffuses through it and condenses on its underside at the metal interface. Dished heads are always coated with impermeable finishes, because the outside temperature is often

O1. Table 10. Number and diameter of tie rods (dimensions in mm)

Rated shell diameter	Tie rod diameter	Minimum number
150–200	10	4
250–500	12	6
600–1200	12	8
1400–2000	16	12

lower than that on the inside. (The maximum sustained temperature that a baking finish can with stand is about 150°C.)

The thickness of the coating required depends on the surface of the tubes. It should be approximately 200 µm to ensure the absence of pores. Allowance must be made for the associated reduction in the surface heat transfer coefficient. The thermal conductivity of the coatings is about 0.7 W/mK. Instructions on substrate preparation are given in DIN 28051.

2.5 Evaporators

2.5.1 Vertical Evaporators with Tube-side Evaporation

These evaporators are usually of the natural-circulation type (thermosyphon reboiler, Fig. 28). The pressure drop in the circulating product must be kept low, because flow is caused solely by differences in density between the liquid and the two-phase stream formed by evaporation. The cross-sectional area of the vapor tube should be at least equal to the sum of the cross-sectional areas of the evaporation tubes, and the cross-sectional area of the lower inlet tube should be at least one-half of that of the vapor tube. Only one tube-side pass is feasible, and there are usually two fixed tube sheets.

If the tubes are short and the shell side is heated by condensing steam, baffles can be dispensed with. The number of passes is defined by the ratio of the mass flow Tate of inlet liquid to that of the outlet vapor and normally lies between 6 and 14.

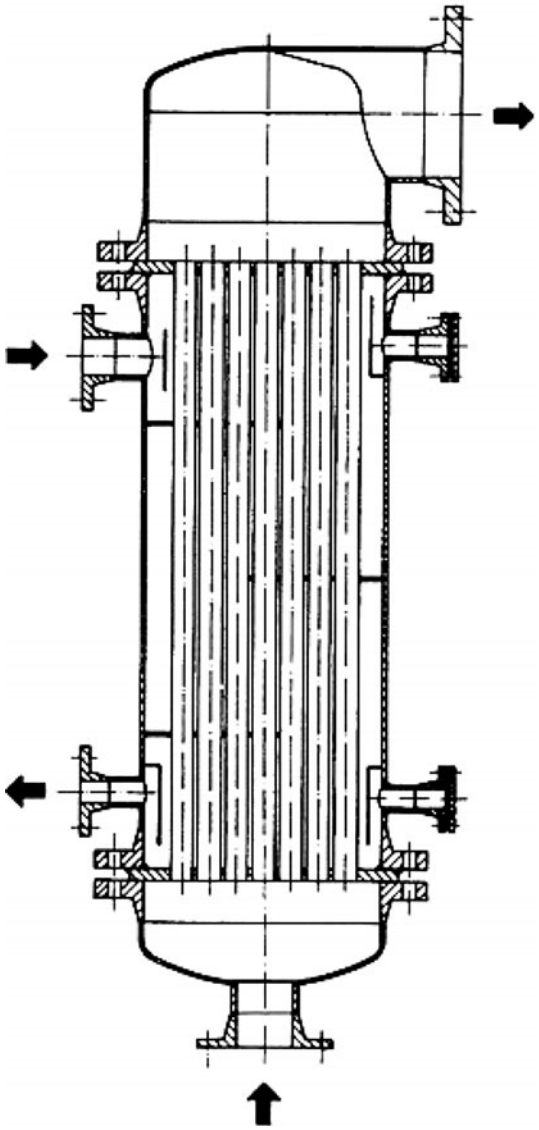
Natural-circulation evaporators are useful for concentrating liquids and as reboilers in columns. Forced circulation is necessary if the pressure drop becomes too high for natural circulation. In this case, a pump must be installed in the inlet pipe, and an attempt should be made to attain as many as 40 circulation passes.

A special design of the natural-circulation type is the Robert evaporator, which is integrated at the bottom of the column and extends over the entire column cross-section (Fig. 29). The circulating fluid flows upward through the heat exchanger tubes and is returned through the central downcomer.

The tubes are usually very short. For large Robert evaporators, at least one of the two tube sheets must be thick enough to bear the load exerted by the correspondingly heavier tube bundle without appreciably sagging.

2.5.2 Falling-Film Evaporators

Falling-film evaporators (Fig. 30a, b) are vertical shell-and-tube heat exchangers that are usually steam-heated on the shell side.



O1. Fig. 28. Thermosyphon Reboiler.

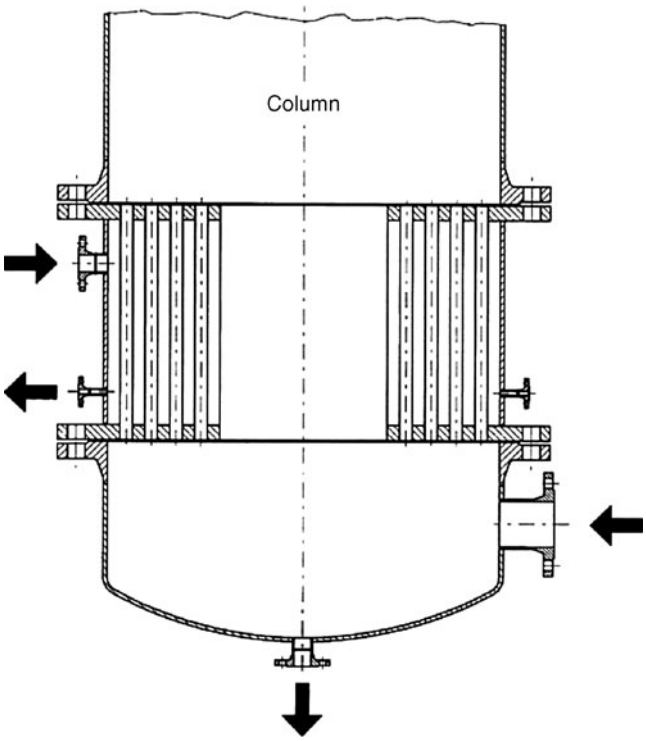
The liquid flows downwards along the inner walls of the tubes and is thus partially evaporated.

Ideal operation entails that all the tubes are uniformly wetted by a continuous film of liquid. As a consequence, the liquid flow rate should not be less than 1 m^3/h/m of circumference of all the tubes.

The liquid distributors in large evaporators are mostly plates, in which the perforations (Fig. 31) have been designed such, that the liquid jets impinge on the interstices between the evaporator tubes and then flow towards the next bank.

It must be ensured that the liquid flows uniformly into the distributor. If, for instance, it were introduced at the center of the evaporator, a cone located underneath the inlet pipe would allow it to spread evenly outwards. Maldistribution caused by departures from the horizontal or currents within the distributor can be avoided if the bead of liquid on the perforated plate is not allowed to fall below 50 mm, even under minimum load. An annular gap must be located between the distributor and the dished end in order to permit pressure equalization between the space above and the space below the perforated plate.

If some of the liquid evaporates on entering the distributor, tubes of larger diameter should be selected to ensure that the flow of vapor does not disturb the falling film on the tube walls.



O1. Fig. 29. Robert evaporator.

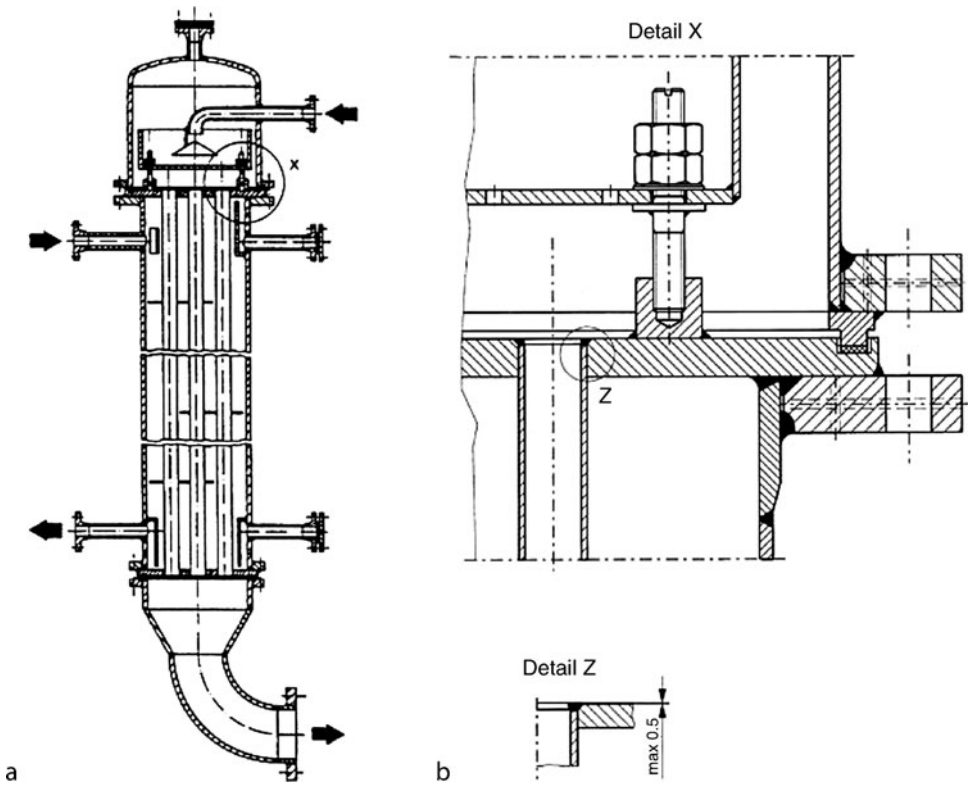
The design shown in Fig. 32 can be adopted in special cases in which the face-milled vertical tubes project above the upper tube sheet. The projections may be expanded into a tulip shape or be tangentially slotted or perforated. Another possibility is to insert shaped inserts into the tubes. If expansion into a tulip shape is selected, the tube spacing must be wider than that recommended in DIN 28182. In this case, the liquid should be introduced through an annular distributor or over a cowl.

In order to ensure that the liquid is uniformly distributed, the overflow or inlet edges of all the tubes must be smooth and even, i.e., without beads or burrs. The upper tube sheet in evaporators with tulip shaped tube inlets must be resistant to bending.

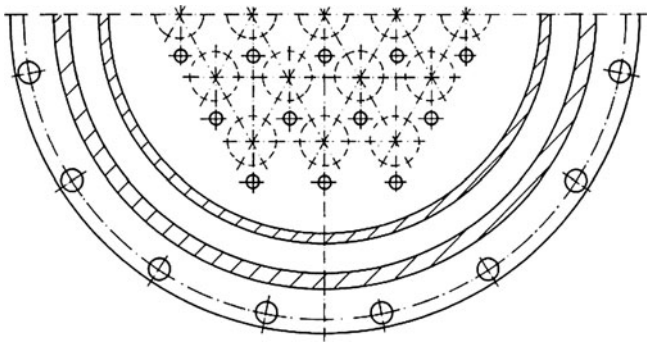
2.5.3 Vertical Evaporators with Shell-side Evaporation

This design is mainly encountered in steam generation, and the heating medium (within the tubes) may be a contaminated product.

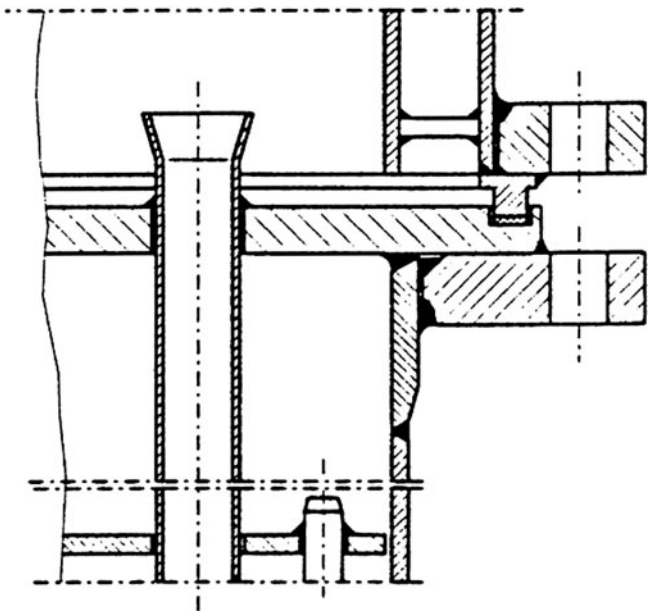
The water enters underneath the shell, and the vapor–liquid mixture is withdrawn at the top. Problems arising from thermally induced stresses in the shell and the upper support plate can be avoided by ensuring that the tube-side heating medium is not admitted at the upper end, as otherwise it will be at its maximum temperature when it comes into contact with the hottest part of the shell. The ensuing superheating of the steam may then give rise to impermissibly high thermally induced stresses. Particular care must be devoted to ensuring that the steam is completely and uniformly withdrawn and does not



O1. Fig. 30. (**a**) Falling-film evaporator and (**b**) detailed sections through a falling-film evaporator.



O1. Fig. 31. Perforated-plate distributor.



O1. Fig. 32. Tulip-shaped evaporator tube inlet.

accumulate to form a stationary cushion. Several outlets distributed over the circumference or internal siphons are generally required for this purpose. Another point to ensure is effective and complete venting underneath the upper support plate.

The shell side is frequently designed as a recirculating evaporator, and a steam dryer is required to separate the liquid from the vapor.

A multiple-effect design may also be adopted for the tube side. The installation of a floating head or V-tube bundle gives rise to a variant that is frequently resorted to in high-pressure techniques. In this design, the fixed support plate is underneath. The shell extends well above the tubes and is used as a vapor space, in which case an external steam dryer is not required.

2.5.4 Horizontal Evaporator with Shell-side Evaporation

Pool boiling occurs in this type of evaporator, i.e., there is no defined flow pattern. The design is therefore recommended whenever the product need not or cannot be circulated or only retardation of boiling is aimed at. As a rule, the tubes should be flooded on the shell side. Consequently, if the evaporator is completely filled with tubes, an external vapor space (steam dryer) is required, usually together with several outlets. If the evaporator is not completely filled with tubes, the free space above the tube bundle can be utilized as the vapor space.

Some of the many variants that this permits are described below.

If the first tube bank in a bundle lies within a large shell-side vapor space formed above the bundle in an evaporator only partially filled with tubes, it will serve as a mist extractor and steam superheater.

A second variant consists of a U-tube or floating head bundle inserted on the shell side. Its best-known representative is a kettle reboiler (cf. Fig. 7). The tubes are expanded mechanically into full-bore support plates, which are spaced in accordance with the heat flux in the bundle. For instance, the spacing in kettle reboilers is between 500 and 700 mm.

2.6 Condensers

This section concerns surface condensers for total and partial condensation with a liquid, e.g., water, as the cooling medium. Since the vapor has a higher volume flow rate than that of the liquid – or at least at the commencement of condensation – it is usually designed to pass through the shell.

If inert, i.e., incondensable, gases are contained in the vapor, they must be allowed to escape through a separate outlet, the location of which depends on the gas/vapor density ratio (Fig. 33). Thus it must be fitted on the downside of the condenser if the density of the inert gas is higher than that of the vapor; and on the upper side, if the density is less. The flow of cooling liquid through the tubes should be arranged so that the inert gases pass over the coldest tube before they are removed.

The tube wall on the condensation side should be as "dry" as possible. In other words, the condensate should run off the surface of the tube by the shortest possible path in order to improve heat transfer. It is for this reason that horizontal condensers are generally superior to vertical.

2.6.1 Vertical Condensers with Shell-side Condensation

The design can be recommended for moderate condensation rates at pressures above atmospheric. It is most frequently adopted for heating recirculation and falling-film evaporators, in which case the shell-side condensation of steam or vapor causes the product to evaporate within the tubes.

At high condensation rates, the condensate film that flows along the tubes becomes thicker and thus impairs heat transfer. The design gives rise to difficulties if the vapor contains inert gases with a density lower than its own. In this case, the two outlets for the inlet and the inert gas would be located at the upper end of the evaporator. Hence design measures must be

adopted to ensure that the vapor is not short-circuited through the inert gas outlet.

2.6.2 Vertical Condensers with Tube-side Condensation

The point to observe in this design is that the vapor should flow downwards through the tubes and thus not hinder the descending condensate film. If this is not feasible or cannot be realized in all the tubes, e.g., in multiple tube-side passes, the cross-section of the tube must be large enough to ensure that the rising vapor does not hold up or even break down the descending condensate film.

2.6.3 Horizontal Condensers with Tube-side Condensation

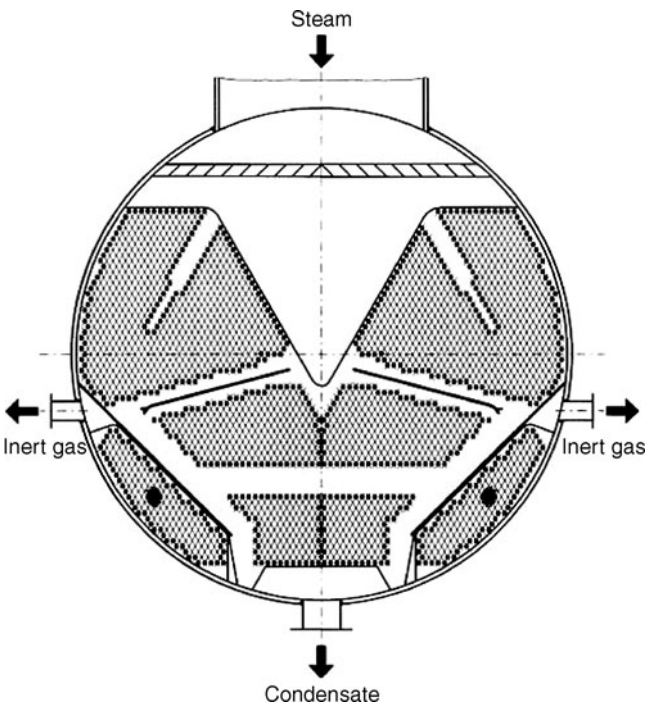
Heat transfer is favored somewhat more by this design than it is in vertical condensers, because the upper part of the tubes always remains unwetted. If the condenser has been designed with only one tube-side pass, it should be slightly inclined at a slope of at least of 1% so that the condensate can flow more rapidly out of the tubes.

2.6.4 Horizontal Condensers with Shell-side Condensation

This is the most common and most effective design of condenser. If the pressure is above atmospheric or if only partial condensation occurs, the condenser may be almost completely filled with tubes provided that the maximum vapor inlet velocity is not exceeded. If vapors are condensed at subatmospheric pressures, their initial volume will be so great that the flow velocities between the first tube banks will be very high. In this case, some unfilled, i.e., tubeless, space must be left in the inlet zone. In vacuum condensation, additional wedge-shaped tubeless vapor channels frequently have to be formed and/or the spacing in the first few tube banks has to be increased (cf. Fig. 33).

At any rate, positive condensate removal must be ascertained, as otherwise the lower tubes may be flooded. This aim is generally achieved by cutouts or slots on the lower side of the support plate or segment baffles. A single crossflow pass of vapor over the tube bundle is standard practice in vacuum condensation with the consequence that the condensers are fitted with full-bore support plates and not with baffles.

If the inlet vapor is wet, it is absolutely essential to protect the first tubes from erosion by means of impingement baffles.



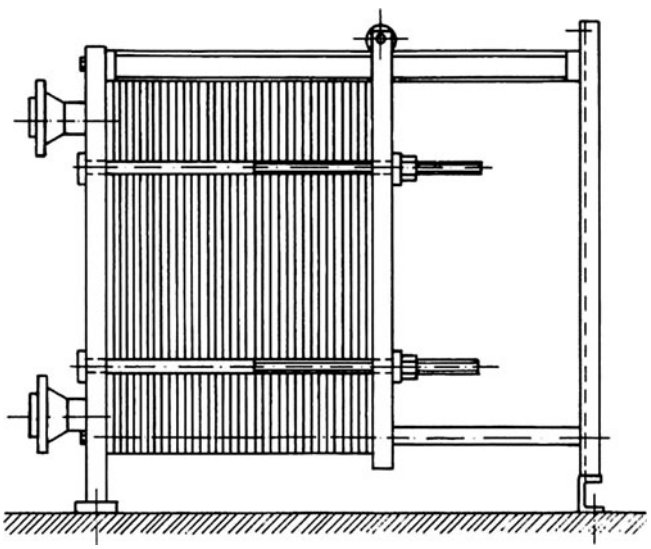
O1. Fig. 33. Pattern of tubes in a vacuum condenser.

3 Compact Heat Exchangers

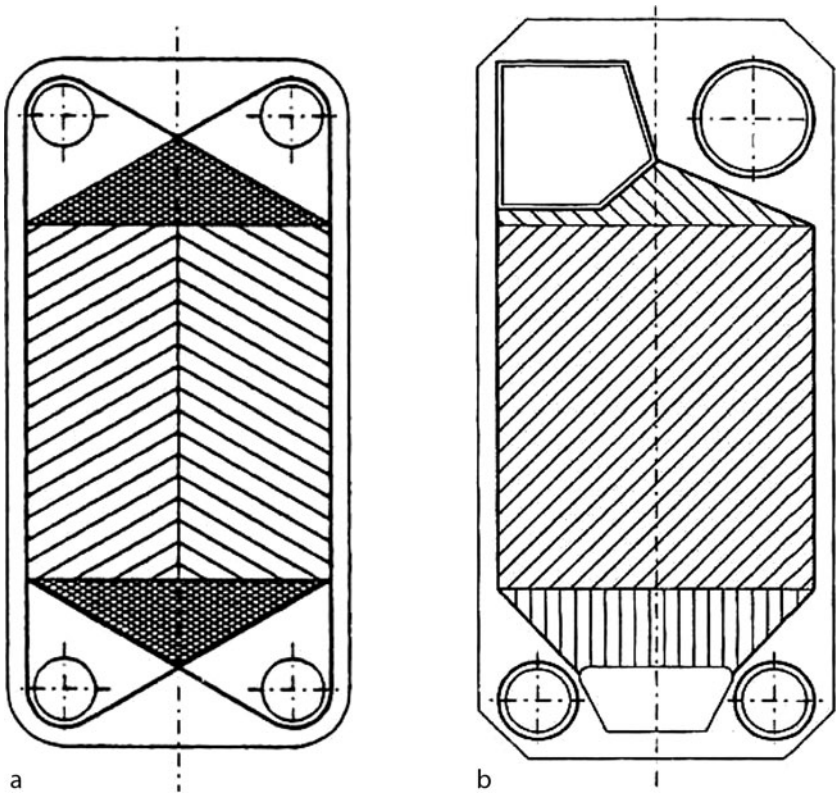
3.1 Plate Heat Exchangers

Plate heat exchangers consist of an assembly of several profiled sheet-metal panels (Fig. 34), each of 0.4–0.8 mm thickness (Fig. 35). The assemblies are mounted in frames and bolted together. The compressive forces thus induced are absorbed by spacers, which are often very thick and are also bolted in the frame together with the assembly.

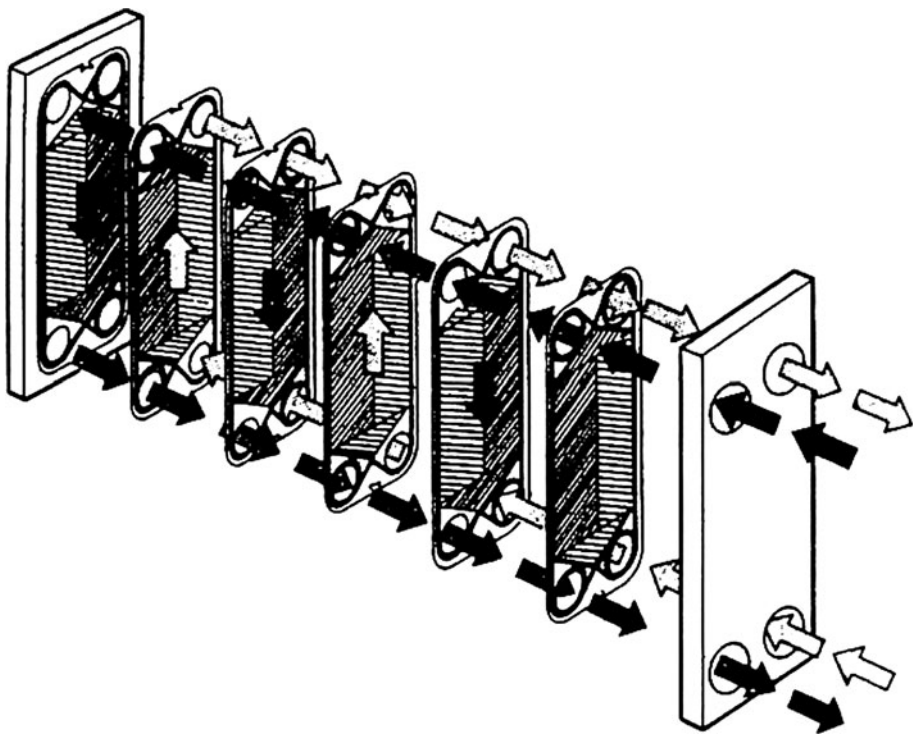
The heat transfer media are fed through four openings, one at each corner of a panel. Two openings at a time are alternately shut off from the remainder of the flow compartment so that the two media flow alternately in the spaces between the panels. Individual openings can be closed to allow all the panels or certain assemblies to be connected *in tandem* and a multiple-pass arrangement can thus be achieved (Fig. 36).



O1. Fig. 34. Assembled plate heat exchanger.



O1. Fig. 35. Individual plates for (**a**) heater and (**b**) evaporator.



O1. Fig. 36. Flow pattern in plate heat exchanger.

The operational limits of plate heat exchangers are primarily set by the compressive strength of the plates and the heat resistance of the seals. As a general rule, operation is feasible at pressures of up to 25 bar and maximum temperatures of 170°C. The materials of construction are predominantly chromium–nickel steels; but titanium, nickel alloys, and other specialties are also encountered.

The profiles on the individual panels can be varied to allow optimum operation under given conditions. For instance, they permit allowance to be made for solids fractions, high viscosities, or a permissible pressure drop. They can also ensure that flow is always turbulent, with the consequence that extremely high heat transfer coefficients can be achieved. Thus if the panels are tightly packed, high heat transfer rates can be attained within a small space.

Great turbulence is responsible for comparatively high pressure drops but reduces fouling. In fact, the tendency to fouling in plate heat exchangers is four times less than that in shell-and-tube types.

The individual panels are separated from one another by elastomer seals that are of complicated shape and are often assembled by adhesives, which serve no other function, i.e., do not act as seals. There is a growing trend towards panels that allow seals to be secured mechanically. The great advantage of this is that the seals can be easily removed for cleaning.

Heat exchangers in which the plates are welded full-face together, see Fig. 37, are becoming widely accepted and allow a wide variety of designs. The advantage over conventional plate heat exchangers is that no sealing problems arise. A disadvantage is encountered in cleaning welded versions, because the individual plates can no longer be dismantled.

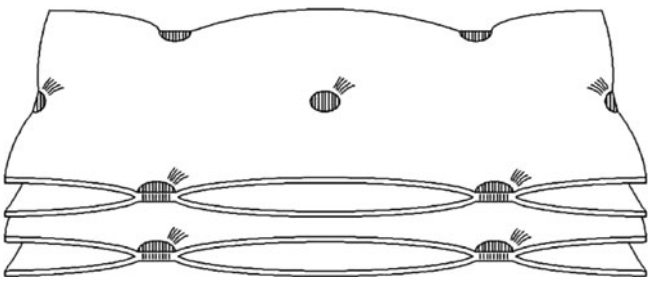
3.2 Spiral Heat Exchangers

Spiral heat exchangers consist of two steel strips of the same width that are wound in the form of equi-spaced spirals around a central body. Usually, a number of steel pegs are welded to the strips in order to ensure that the spacing remains constant. The widened ends of the spirals accommodate the inlet and the outlet and also serve as distributors for the respective flow compartments. The channels thus formed are alternately caulk-welded. After it has been faced, the entire structure is sealed at the one end and covered with a flat lid at the other (Fig. 38). An advantage that is thus obtained is that both flow paths can be mechanically cleaned. Two different methods apply for operating spiral heat exchangers.

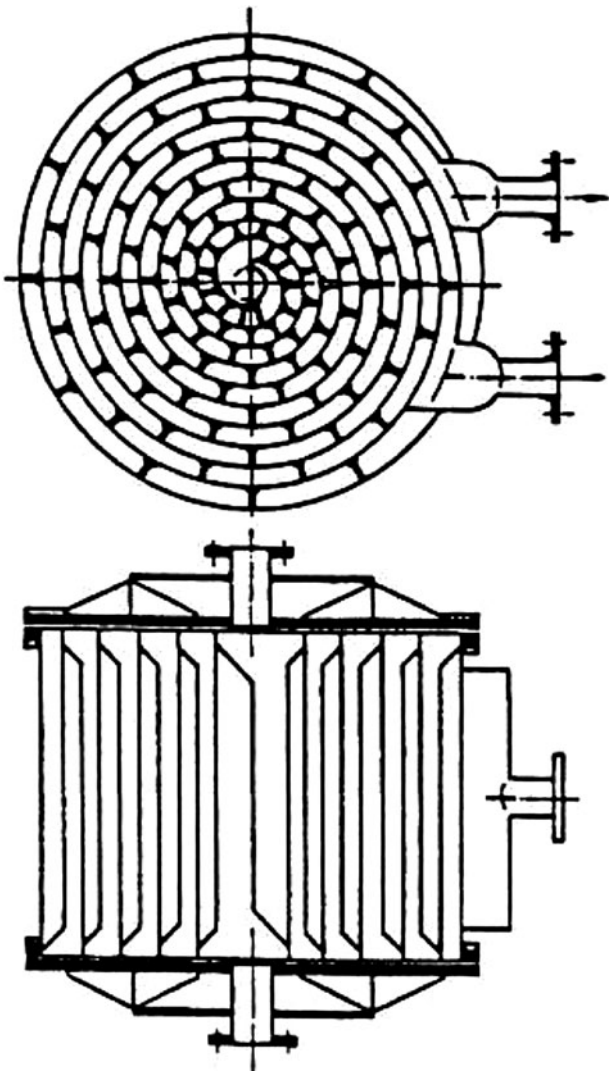
(1) *Countercurrent*: In this case, the one product flows spirally inwards towards an axial outlet, and the other product flows outwards.
(2) *Crossflow*: Here, the one product is led through a spiral flow channel caulk-welded at both sides. The other product flows axially through the other cross-section, which is open at both sides.

A special design is the reflux condenser shown in Fig. 39. The vapors rise upwards through a central pipe and condense on the spiral windings. The condensate is trapped in an annular vessel, from which it is run off.

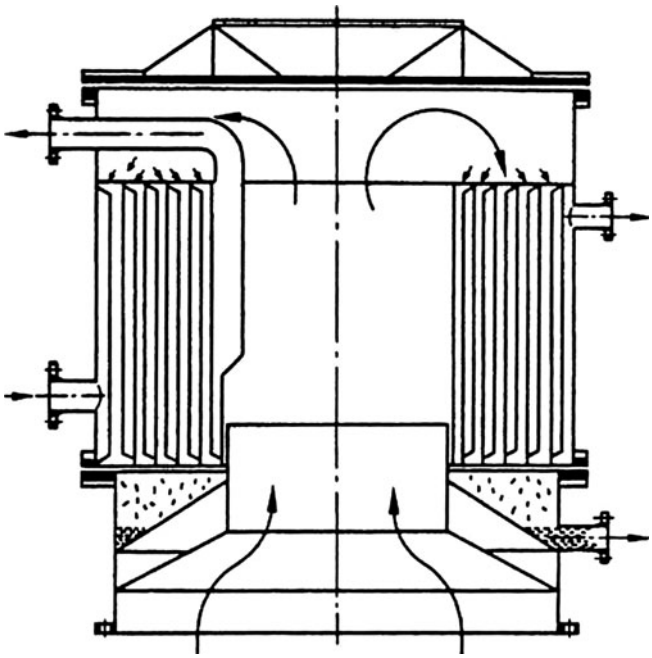
Spiral-plate heat exchangers have diameters of up to 2 m and are constructed from strips of 2 m maximum width. Any material that can be welded and cold-worked may be used for the construction. As a rule, the operating pressure is restricted to 20 bar. The maximum operating temperature is governed by the heat resistance of the lid seal. The width of the flow channels can be varied within wide limits, with the result that the spiral



O1. Fig. 37. Profile of welded plates.



O1. Fig. 38. Spiral heat exchanger.



O1. Fig. 39. Spiral-plate heat exchanger used as condenser.

heat exchanger can be readily adapted to allow optimum conditions for a given process.

4 Other Designs

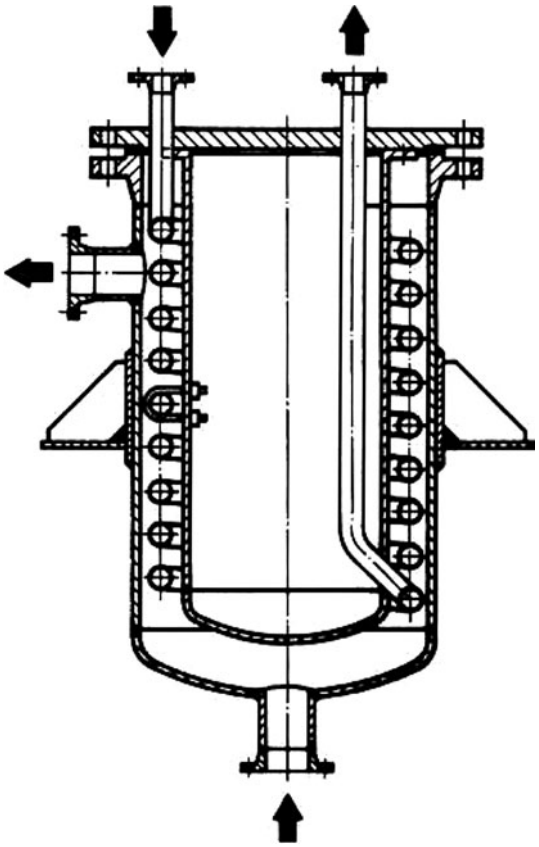
4.1 Helical Coil Heat Exchanger

A helical coil heat exchanger is particularly easy to construct: a tube is spirally wound around a cylinder and inserted in a cylindrical vessel provided with an inlet and an outlet for the heating or cooling medium. The capacity of the vessel can be fully exploited by inserting several coils, the one within the other, and connecting them in parallel. The coil inlets and outlets may be located at the top or bottom, depending on requirements and the means for installation (Fig. 40).

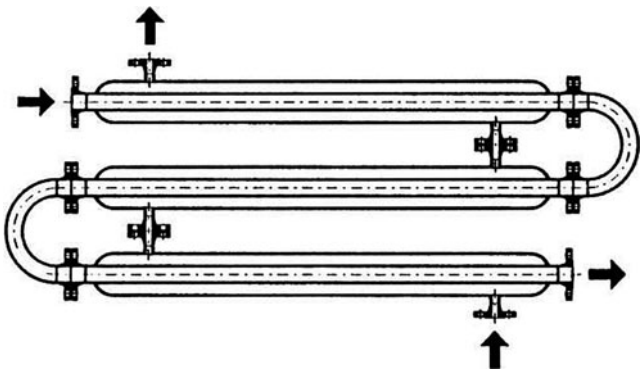
A disadvantage of this design is that it can be mechanically cleaned on the outside but not on the inside. The flow velocity of the medium on the outside is low, and the specific heat transfer is thus poor.

4.2 Double-Tube Heat Exchangers

This heat exchanger consists of an outer tube and a concentric inner tube. It is generally in the form of straight sections connected by 180° bends (Fig. 41). The mass flow rates and thus the flow velocities are usually low. Consequently, heat transfer is poor, and very long tube lengths are therefore required. Double-tube heat exchangers are mainly used in high pressure techniques, because the thick tubes allow very high temperatures and pressures to be controlled. If the straight lengths are connected by large bends (of at least 3D), the inner tube may be cleaned by a go-devil. However, the only means of cleaning the outer tube is by chemicals.



O1. Fig. 40. Helical-tube heat exchanger.

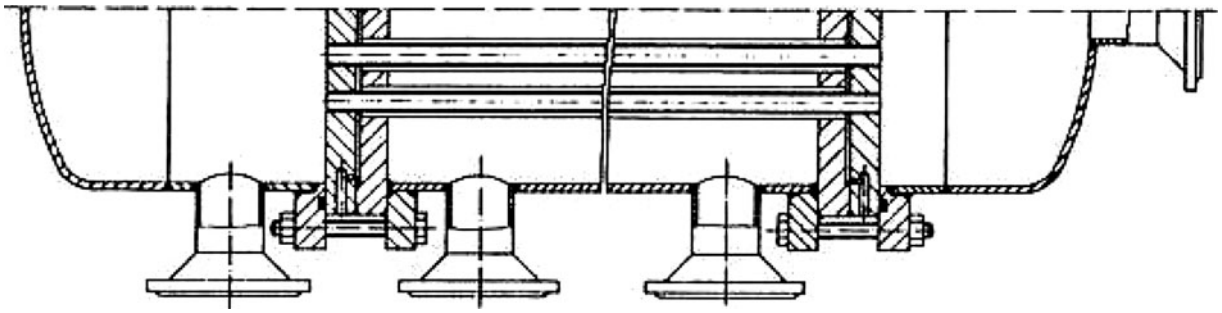


O1. Fig. 41. Double-tube heat exchanger.

4.3 Safety Heat Exchangers

This term is generally applied to heat exchangers that are designed to prevent the product streams from mixing in the event of leakage. In most cases, they are shell-and-tube heat exchangers with concentric double tubes instead of single tubes. If any leakage occurs, the product enters the annulus and is led outside. A monitor allows any leaks to be immediately detected, and there is no likelihood that the product streams will mix (Fig. 42).

Heat transfer between the double tubes can be improved by two fundamentally different designs.



O1. Fig. 42. Safety heat exchanger.

(1) The annulus between the concentric tubes is filled with a medium that is compatible with both products and has a comparatively high thermal conductivity.
(2) One of the two tubes has spiral fins – either the outer tube with internal fins or the inner tube with internal fins. The inner tube is then widened to form a metallic contact with the outer.

An advantage of the first variant is that the pressure of the intervening medium can be set to a value that allows rapid detection when it is reduced by leakage. However, problems may arise in finding a medium that is compatible with both products.

The same effect can be achieved in plate heat exchangers by means of double plates. If a leak occurs, the product concerned passes outside through the gap between the double plates.

4.4 Graphite Heat Exchangers

By virtue of its resistance to heat and chemicals, graphite is attracting increasing attention in the design of heat exchangers. It possesses the good thermal conductivity of metals and the very good corrosion resistance of nonmetals. Since it is porous in the original state, it is impregnated with phenol-formaldehyde or furan resins. Under these circumstances, its range of service temperatures is –60°C to 200°C. Impregnation increases its strength by a factor of about 2–3.

Graphite heat exchangers can be operated at pressures ranging from 1 bar to about 15 bar. Pressure surges, e.g., water hammer or the rapid opening and closing of valves, may damage graphite and must therefore be avoided. The physical properties of graphite that affect the design of heat exchangers are listed in Table 11.

Graphite is resistant to the large majority of all known chemicals with the exception of free bromine and chlorine, free fluoride ions, sulfuric acid/potassium dichromate, and concentrated nitric acid.

Graphite heat exchangers can be used in almost all heat transfer processes, e.g., cooling or heating of corrosive media and condensation or evaporation in natural-circulation or falling-film evaporators. Different designs exist to cope with the various operating conditions and applications. Shell-and-tube and block heat exchangers are the most common.

O1. Table 11. Physical properties of graphite [9]

Property	Unit	Graphite impregnated with synthetic resin[a]
Tensile strength	N/mm^2	28 bis 33
Flexural strength (axial)	N/mm^2	50 bis 60
Compressive strength	N/mm^2	75 bis 85
Modulus of elasticity	N/mm^2	$(20 \text{ bis } 30) \cdot 10^3$
Poisson ratio	–	0.2 bis 0.25
Elongation at break	%	0.15 bis 0.3
Density	kg/m^3	2.0 bis 2.1

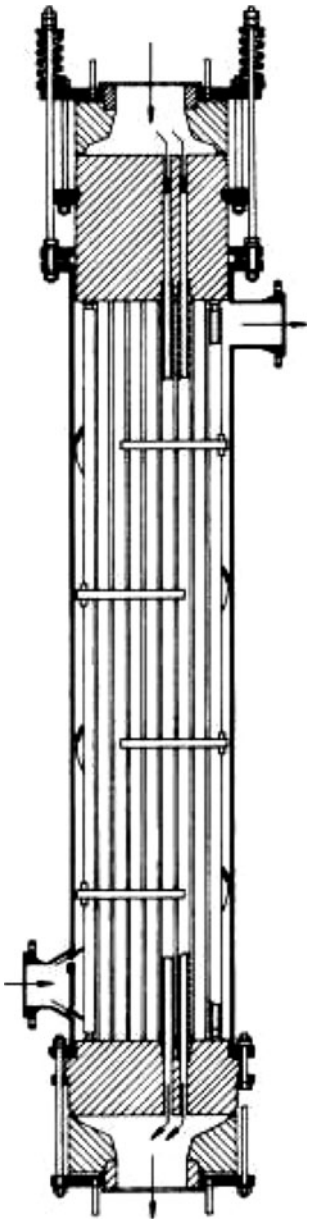
Specific heat capacity	kJ/kg K	1.0
Thermal coefficient of linear expansion	1/K	$3.5 \cdot 10^{-6}$
Temperature limit	°C	200

[a]Measured in the axial direction of tubes
[b]Measured in the radial direction of tubes

The shell-and-tube types, see Fig. 43, consist of a graphite tube bundle and a steel shell that may be clad, enamelled or coated if corrosion protection is required on both sides. The design of the heat exchanger is governed by the properties of graphite that are similar to those of ceramics. Features are the thick support plate and the adjustable spring bolts for tensioning. The only means of securing the tubes in the support plates are those applicable to all other unbreakable graphite joints, viz. bonding with adhesives. The capacities of graphite heat exchangers normally range up to 1000 m^2 and a pressure of 6 bar.

Block heat exchangers consist of cylindrical blocks through which lateral holes have been drilled at several levels. A standard layout is illustrated in Fig. 44. The stack of graphite blocks is housed in a steel shell. The dished ends are frequently constructed from graphite or PTFE-coated steel and are tensioned together with the blocks by means of adjustable spring bolts. The diameter of the drilled holes can be brought into line with the processing conditions and lies between 8 and 16 mm. The codes for the design, construction, and testing of pressure vessels, e.g., *AD-Merkblätter* [3], also apply to graphite shell-and-tube heat exchangers.

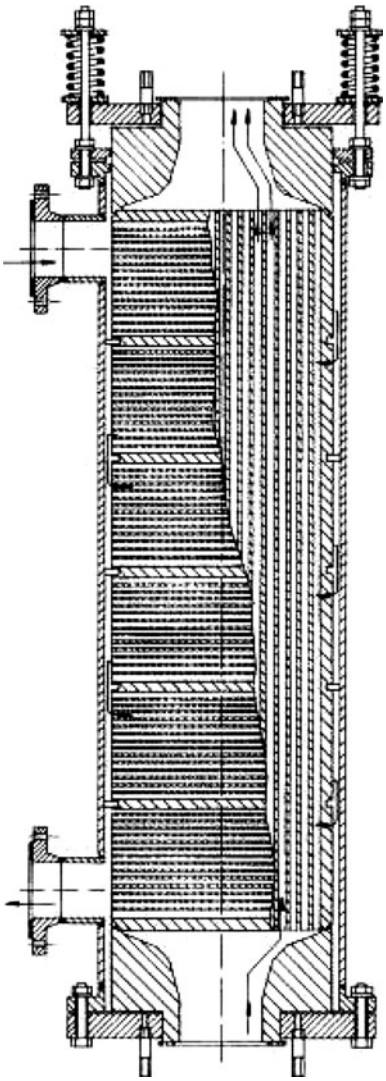


O1. Fig. 43. Graphite shell-and-tube heat exchanger.

Special graphite designs are annular and plate heat exchangers. The flow pattern in an annular type is comparable to that in a spiral heat exchanger. A system of circular channels is milled into graphite discs of 40–110 mm thickness and about 400–600 mm diameter. The number and size of the channels can be engineered to ensure effective heat transfer for given media under given process conditions. Annular heat exchangers are eminently suitable as reflux and vacuum condensers.

With the exception of the sealing system, graphite plate heat exchangers correspond to their metal counterparts. Since graphite can be shaped, the edges of the heat transfer plates can be formed to effect a seal. The sealant is an elastomer. The maximum design temperatures and pressures for graphite plate heat exchangers are 140°C and 6 bar.

Points to observe in graphite heat exchangers are that no forces or moments must be allowed to act at the graphite supports and that preference should be given to expansion joints in individual cases.



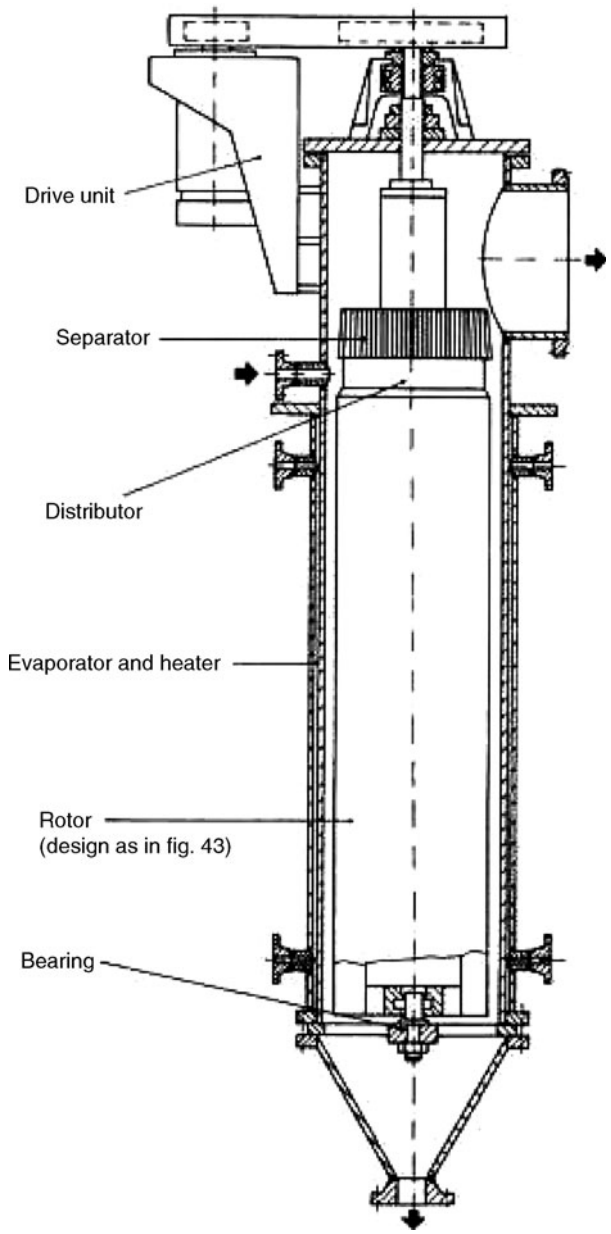
O1. Fig. 44. Graphite block heat exchanger.

4.5 Thin-Film Heat Exchangers

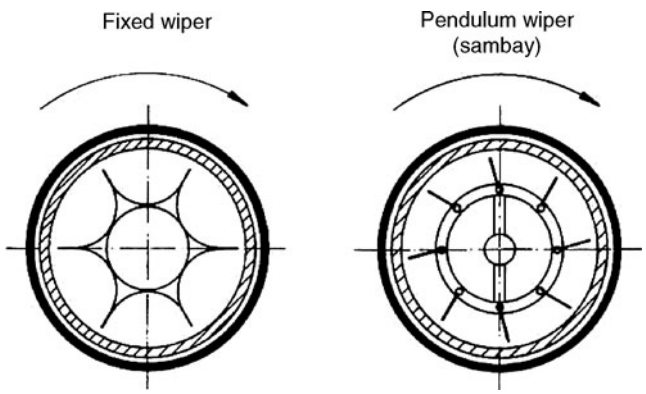
Thin-film heat exchangers are resorted to far highly viscous and heat-sensitive products. They feature high heat transfer coefficients, good part-load performance, and short residence times and are most frequently designed as evaporators.

A thin-film evaporator consists of a heated cylindrical or conical section fitted with a rotor (Fig. 45) and an upper dome for the removal of the entrained droplets. The product is fed above the jacket heater, spread over the circumference by a distributor ring, and whirled by the rotor blades against the heated wall in the form of a thin film, which descends in a spiral path. The vapor formed rises upwards in countercurrent flow and passes through the separator. The unevaporated fraction reaches the lower end and is removed from the evaporator.

Depending on the demands imposed, the rotor is fitted with fixed or movable wiper blades (Fig. 46).



O1. Fig. 45. Thin-film heat exchanger.



O1. Fig. 46. Rotors in thin-film heat exchanger.

Thin-film evaporators are designed in lengths of up to 15 m and outer diameters of up to 2 m.

4.6 Air-Cooled Heat Exchangers

Air-cooled heat exchangers are frequently used in chemical production plant, refineries, steelworks, foundries, and power stations. The basic requirement is an adequate difference throughout the whole year between the temperature of the ambient air and that of the product to be cooled.

From the physical aspect, air is a poor coolant, but it has many properties that render it superior to water for cooling purposes. Examples are that

- it is available in unlimited amounts;
- it is cleaner;
- it presents less corrosion and cleaning problems.

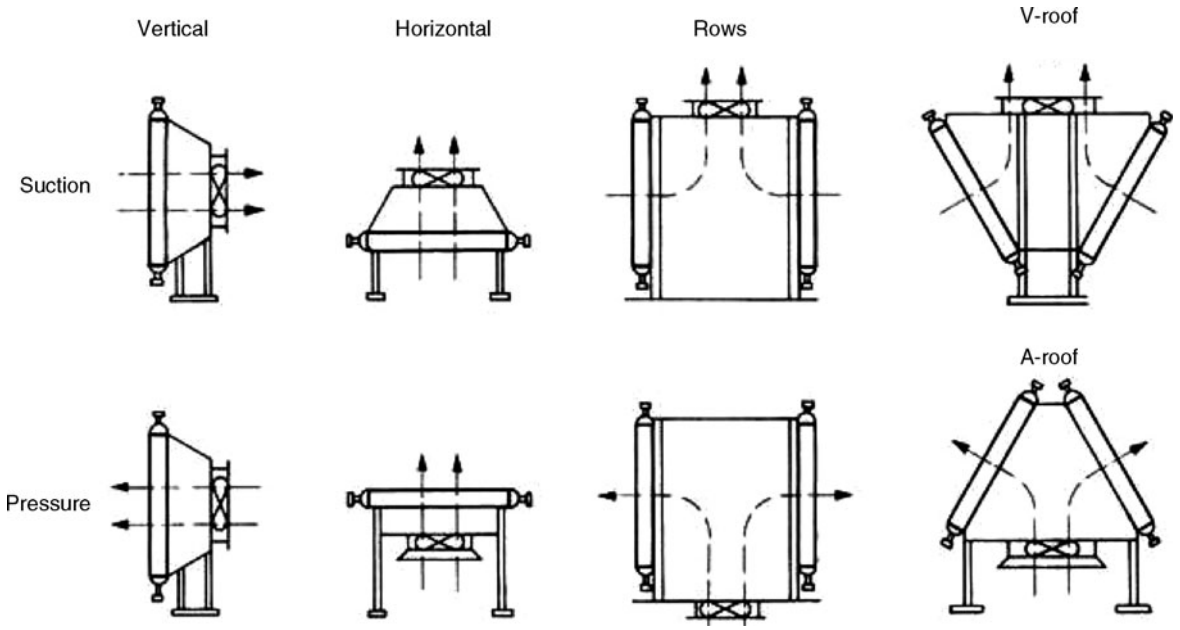
Various designs of air-cooled heat exchangers are described in DIN 45635 (Fig. 44).

The position of the tube bundle in relation to that of the fan decides whether an induced-draught or other forced-draught system is adopted. In induced-draught systems (Fig. 47, upper row), the fan is located in the current of hot air, and the greater volume of heated cooling air necessitates higher power requirements.

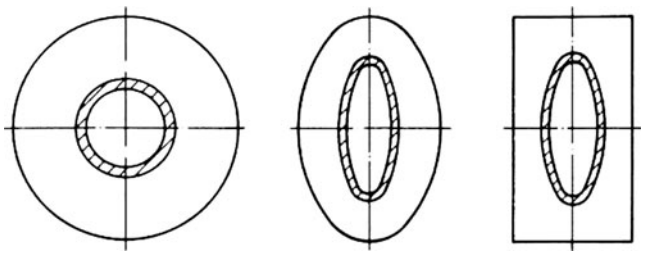
The position of the tube bundle is another factor to observe in the design of air-cooled heat exchangers. Those with horizontal bundles occupy the most floor space, but are the most frequently encountered, because they incur the lowest capital investment costs. As a rule, air-cooled heat exchangers in the form of a roof require two-thirds of the floor space occupied by the corresponding horizontal version. The inclined cooling elements may present technical advantages in condensation processes. Preference is given to the V-roof in countercurrent condensation, because of the simplicity that it allows in intake and discharge. Cooling elements may be arranged vertically if the floor space is very restricted, but the static loads imposed limit their application to small heat exchangers.

The tubes are generally finned, and the heat transfer area can thus be increased by a factor of 5–30, depending on the application. The geometry of the core tube and the fin and the means of attachment can be varied, and the entire design must be optimized from the economic, material, and manufacturing aspects. The main types of tubes are as follows.

- The oval or circular tubes shown in Fig. 48 are usually of unalloyed or stainless steel. The fins are rectangular sheet-metal strips that are forced mechanically onto the tube or steel tapes that are helically wound around the tubes. A metallic bond between the tube and the fins, as illustrated in Fig. 49a, is effected by dip-galvanizing.
- The G-type finned tube shown in Fig. 49b consists of a circular tube with a helical groove into which aluminum tape has been wound under tension and compressed. The strength of the tube wall is reduced to an extent that depends on the depth of the groove.



O1. Fig. 47. Air-cooled heat exchangers.

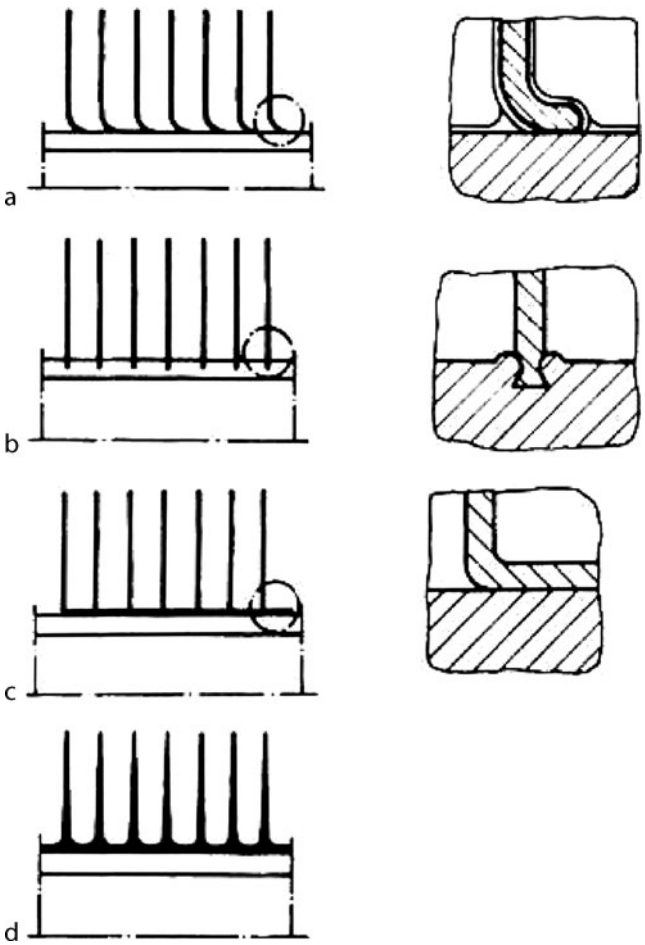


O1. Fig. 48. Circular and oval finned tubes.

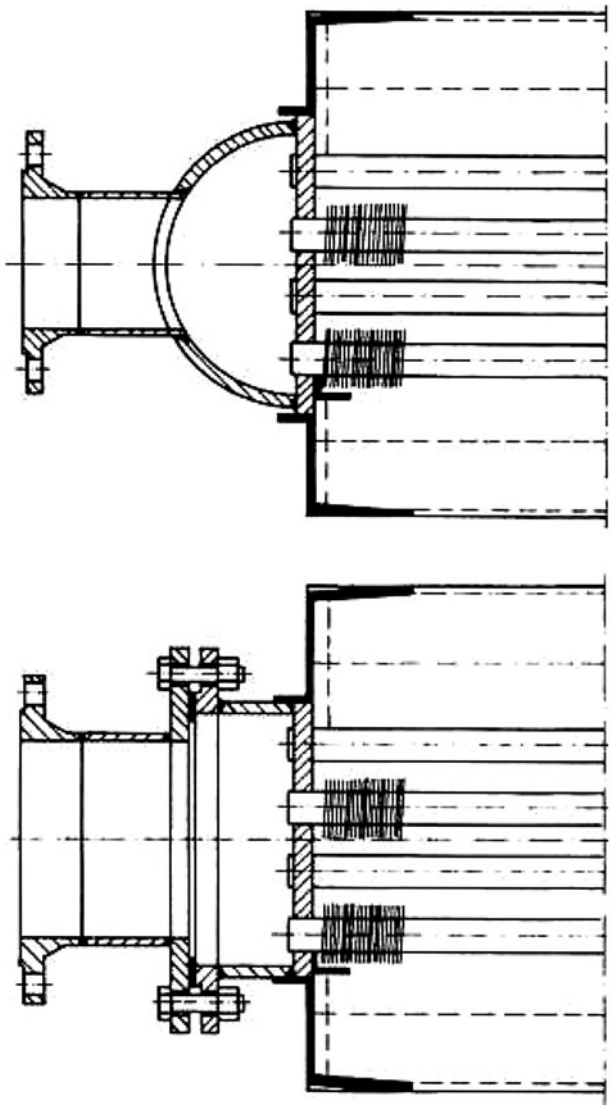
- The L-type finned tube illustrated in Fig. 49c is produced by spirally winding an aluminum L-tape under tension around a circular tube so that the bases of the fins, which are of about 3 mm width, lie close together.
- The bimetal tube with cold-impact press-formed fins shown in Fig. 49d is obtained by inserting a circular core tube in an aluminum tube. The fins are then formed mechanically, and the outer tube is pressed onto the core tube.

The choice of the material selected for the tube primarily depends on the properties of the product to be cooled or condensed. Allowance must be made for its physical properties, including the resistance to corrosion by the ambient air, the processing characteristics, the compatibility with the core tube, and the means of securing the base of the fins to the tube. The most common pairings are steel tubes and fins formed into a block by galvanizing and copper tubes with aluminum fins.

The finned tube assemblies may be up to 15 m in length and 3 m in width and usually consist of 3–7 staggered or in-line banks. They are stiffened by side walls and tube supports and are self-supporting. In-line tubes give rise to a lower pressure drop but to poorer heat transfer than staggered tubes.



O1. Fig. 49. Various types of fins (Methods **a**–**d** are described in Sect. 4.6).



O1. Fig. 50. Designs for dished ends on air-cooled heat exchangers.

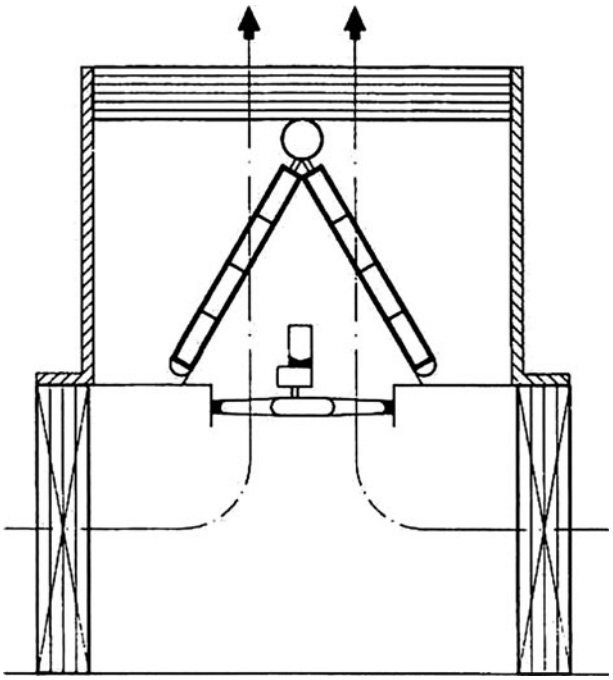
The ends of rectangular bundles of straight tubes are welded or milled into the support plates. The product is distributed and collected by means of the support plate and the dished end, which may be welded or – if the inner surfaces of the tubes have to be cleaned – flanged to the support plate (Fig. 50).

The current of cooling air is set in motion by axial flow fans with glass-reinforced-plastic or aluminum rotors that are installed in ducts connected to the tube bundles. The air velocity in the heat exchanger is about 2–3 m/s. If it is low, screens may have to be installed in order to ensure smooth and continuous operation.

The fans are usually driven by V-belts or, if the air flow rate is high, by gear transmission systems. In certain cases, power may be supplied by directly coupled, low-speed multipole motors.

The air flow rate in the heat exchanger can be controlled if necessary, e.g., if the temperature of the medium is to be kept constant or if the installation has to be protected from frost.

Fluctuations in outdoor temperature can be compensated by varying the flow rate of cooling air continuously or in stages. The following means are thus adopted:



O1. Fig. 51. Air-cooled heat exchanger with silencer.

- switching individual fans on or off,
- electric motors with pole-changing switches,
- fan blades that can be adjusted while the fan is running,
- regulating the fan motors by frequency converters,
- louvres e.g., heat transfer by free convection in winter with the fans switched off.

The operation of fans and their motors is the subject of legislation on noise suppression, and permissible values in decibels are laid down for sound pressure levels. Guidelines also exist on the measurement of sound emission from air-cooled installations, e.g., DIN 45635. Recently, more recourse is being taken to silencers, as illustrated in Fig. 48, to restrict the sound pressure level to below the permissible limit.

5 Appendix

Selection of DIN standards (English translations) in the construction of heat exchangers. Currently available from Beuth Verlag GmbH, Berlin

DIN

2391 Part 1 Seamless precision steel tubes; dimensions

2391 Part 2 Seamless precision steel tubes; technical delivery conditions

2393 Part 1 Welded precision steel tubes; dimensions

2393 Part 2 Welded precision steel tubes; technical conditions of delivery

2401 Part 1 Components subject to internal or external pressure; pressure and temperature data; terminology; nominal pressure ratings

2448 Seamless steel pipes and tubes; dimensions, conventional masses per unit length

2458 Welded steel pipes and tubes; dimensions, conventional masses per unit length
2462 Part 1 Seamless.stainless steel tubes; masses per unit length
2463 Part 1 Welded austenitic stainless steel; pipes and tubes; dimensions, conventional masses per unit length
8558 Part 2 Design and workmanship of welded joints; steel vessels and apparatus used in the chemical industry
17173 Seamless circular tubes made from steels with low temperature toughness; technical delivery conditions
17174 Welded circular tubes made from steels with low temperature toughness; technical delivery conditions
17175 Seamless tubes of heat-resistant steels; technical conditions of delivery
17177 Electric pressure-welded steel tubes for elevated temperatures; technical conditions of delivery
17455 General purpose welded circular stainless steel tubes; technical delivery conditions
17456 General purpose seamless circular stainless steel tubes; technical delivery conditions
17457 Welded circular austenitic stainless tubes subject to special requirements; technical delivery conditions
17458 Seamless circular austenitic stainless steel tubes subject to special requirements; technical delivery conditions
28180 Seamless steel tubes for tubular heat exchangers; dimensions, dimensional deviations and materials
28181 Welded steel tubes for tubular heat exchangers; dimensions, dimensional deviations and materials
28182 Tubular heat exchangers – tube pitches, diameter of bores in tube sheets, baffles and support plates
28 184 – tubular heat exchangers with two fixed heads
28 185 – components for tubular heat exchangers
28 190 – floating head heat exchanger with welded floating head – examples of design
28 191 – floating head heat exchanger with flanged floating head – examples of design
28 008 – tolerances for construction of tubular heat exchangers
EN 10220 Seamless and welded steel tubes – general tables of dimensions and masses per unit length
