$$x = x_k + \frac{A}{\dot{Q}}\int_{T}^{T_k} \lambda(\Theta)\,\mathrm{d}\Theta, \tag{14}$$

for hollow cylinders

$$\ln\frac{r}{r_k} = \frac{2\pi l}{\dot{Q}}\int_{T}^{T_k} \lambda(\Theta)\,\mathrm{d}\Theta, \tag{15}$$

for hollow spheres

$$\frac{1}{r} = \frac{1}{r_k} - \frac{4\pi}{\dot{Q}}\int_{T}^{T_k} \lambda(\Theta)\,\mathrm{d}\Theta. \tag{16}$$

The value Θ in these integrals is the temperature as integral variable.

Often (for metals) the temperature dependence of the thermal conductivity is linear (Eq. (13)); then the temperature distribution in a layer for any of the three aforementioned cases is

$$T = T_k - \frac{\lambda_\kappa}{a}\left(1 - \sqrt{1 - \frac{2a}{\lambda_\kappa^2}P}\right), \tag{17}$$

with λ_k being the thermal conductivity at T_k.

The heat flow per m length for the plane wall is

$$P = \frac{\dot{Q}}{A}(x - x_k), \tag{18}$$

for the hollow cylinder

$$P = \frac{\dot{Q}}{2\pi l}\ln\frac{r}{r_k}, \tag{19}$$

for the hollow sphere

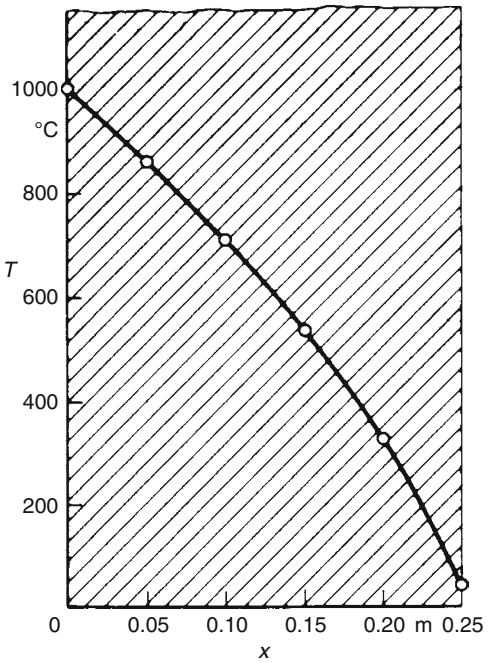
$$P = \frac{\dot{Q}}{4\pi}\left(\frac{1}{r_k} - \frac{1}{r}\right). \tag{20}$$

In case that the thermal conductivity depends on location e.g., due to different moisture contents, it is often useful to integrate Eq. (1) numerically or divide the insulating layer into separate layers.

3.1 Example

Example 3

On the boundaries of a plane insulating layer, 250 mm thick, temperatures of $T_1 = 1000°C$ and $T_2 = 40°C$ were measured. The thermal conductivity of the material (kieselguhr) is $\lambda = (0.08 + 1.5 \cdot 10^{-4}/°C)$ W/m K (Fig. 5).



E1. Fig. 5. Temperature distribution in a plane insulating layer with variable thermal conductivity (example 3).

Calculate the heat flux (heat flow density) and the temperature distribution.

According to Eq. (13),

$$\lambda_{1000,40} = \left(0.08 + 1.5\frac{1000 + 40}{2}10^{-4}\right)\text{W/m K} = 0.158\,\text{W/m K}.$$

The heat flux according to Eq. (2) is

$$\frac{\dot{Q}}{A} = \frac{(1000 - 40)}{(0.25/0.158)}\,\text{W/m}^2 = 607\,\text{W/m}^2.$$

With Eq. (18) at $x_1 = 0$, we receive

$$P = 607 \times \text{W/m}^2$$

and with Eq. (17) and $\lambda_1 = (0.08 + 1.5 \cdot 10^{-4} \cdot 1000)$ W/m K $= 0.230$ W/m K

$$T = \left(1000 - \frac{0.230}{1.5 \cdot 10^{-4}}\left(1 - \sqrt{1 - \frac{2 \cdot 1.5 \cdot 10^{-4}}{0.230^2}607\,x}\right)\right)°\text{C},$$

$$T = \left(1000 - 1533\left(1 - \sqrt{1 - 3.44\,x}\right)\right)°\text{C}$$

x in m	0	0.05	0.10	0.15	0.20	0.25
T in °C	1000	862	709	535	324	40

This temperature distribution is shown in Fig. 5.

4 Two-Dimensional Heat Conduction [1, 2]

4.1 Introduction

The heat flow from an isothermal plane A_1 to another isothermal plane A_2 in arbitrary geometric configuration can be calculated from

$$\dot{Q} = -\lambda\int\int_{A_1}(\partial T/\partial n)_1\,\mathrm{d}A = \lambda\int\int_{A_2}(\partial T/\partial n)_2\,\mathrm{d}A_2. \tag{21}$$

Using the conduction *shape coefficient* S (given in a length m)

$$S = \frac{\iint\limits_{A_1} (\partial T/\partial n)_1 \, \mathrm{d}A_1}{T_2 - T_1} = \frac{\iint\limits_{A_2} (\partial T/\partial n)_2 \mathrm{d}A_2}{T_2 - T_1}, \qquad (22)$$

it follows

$$\dot{Q} = \lambda S(T_1 - T_2). \qquad (23)$$

If the shape coefficient is related to a characteristic length l or r, a *dimensionless shape factor* is obtained

$$S/l = S_l \text{ or } S/r = S_r.$$

And the heat flow per length is

$$\dot{Q}/l = \dot{Q}_l = \lambda S_l (T_1 - T_2). \qquad (24)$$

Shape factors for a variety of configurations are presented in Tables 1–4.

In all the figures, the heat is conducted from one isotherm to another through the hatched area only. Other boundaries are considered adiabatic. The two-dimensional configurations are assumed to be very long in depth (except the hollow spheres), so that three-dimensional end effects do not disturb.

4.2 Examples

Example 4

An airplane runway, $\delta = 20$ m wide, shall be heated to a constant temperature of $T_2 = 5°C$ when the surrounding ground surface is at $T_2 = 0°C$.

How big are conduction heat losses across the ground with $\lambda = 1$ W/m K, when on both sides along the runway the ground is covered by insulating material either (a) $b = 1$ m wide or (b) 5 m wide.

Assuming that heat losses through the insulating material and transient processes are negligible, an approximate calculation can be based on the configuration 4 in Table 1 and Fig. 6.

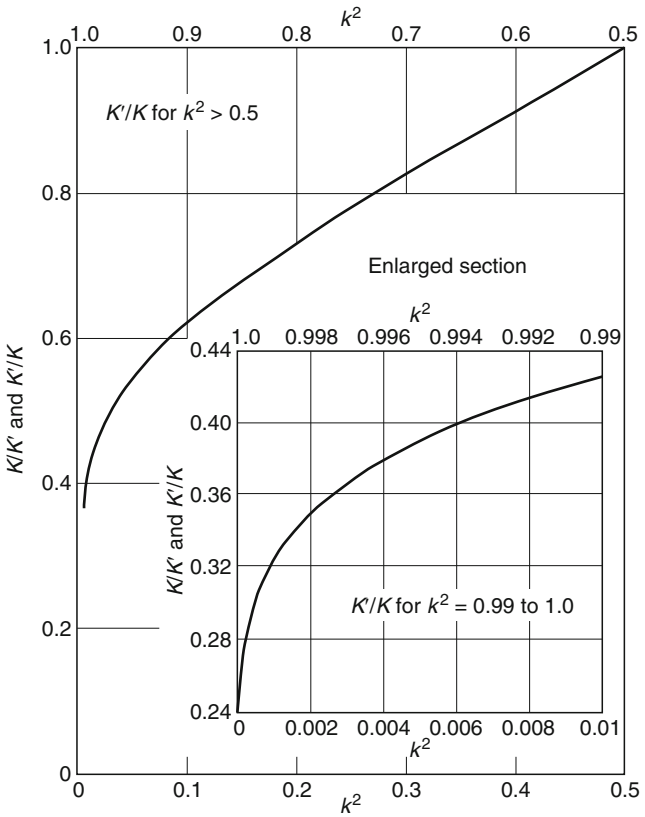
(a) For $b = 1$ m, we read from configuration 4 the value k and obtain for

$k^2 = [20/(2 + 20)]^2 = 0.83$ and from Fig. 6 $K'/K = 0.70$.

From configuration 4, Table 1 $S_l = 2/0.70 = 2.857$ and $\dot{Q}_l = 1 \cdot 2.857 \cdot 5$ W/m $= 14.29$ W/m.

(b) For $b = 5$ m, $k^2 = [20/(10 + 20)]^2 = 0.44$; $K/K' = 0.955$.

$S_l = 2 \cdot 0.955 = 1.910$; $\dot{Q}_l = 1 \cdot 1.910 \cdot 5 = 9.55$ W/m.



E1. Fig. 6. Relation K/K' or K'/K vs. k^2 for band-type configurations.

Example 5

A steam conduit ($r = 100$ mm) has 45 mm high fins on both sides in order to prevent the 150 mm thick insulation from sliding down. What is the shape factor of this configuration (Table 2, Nr. 7) compared to that without fins (Table 3, Nr. 1) or to the configuration Nr. 2, Table 3, when the insulating material has subsided by $e = 45$ mm? The insulation is shrouded by an isothermal metal sheet.

From Table 2, Nr. 7, we calculate $h/\delta = \frac{\ln 145/100}{\ln 250/100} = 0.45$; $2b/\delta = \frac{\pi}{\ln 50/100} = 3.429$.

From Fig. 7, we obtain $S_R = 0.1375$ (S_R is considered constant for $2b/\delta > 2.0$); for the configuration with fins we obtain $S_l = 2\,(3.429 + 0.2750) = 7.408$ (configuration 7); without fins $S_l = 2\pi/\ln(250/100) = 6.857$ (Table 3, Nr. 1); for eccentric pipes $S_l = 2\pi/\operatorname{arcosh} 1.4095 = 7.17$ (Table 3, Nr. 2).

5 Heat Losses from Walls and Pipes

5.1 Rough Estimate for Insulated Walls in Inside Rooms

An exact calculation of heat losses can be obtained from equations given in Chap. C2 together with equations for heat transfer coefficients from Part F. For the appropriate insulation thickness e.g., for containers or for an approximate determination of heat losses for hot room walls, an estimate can be obtained with Fig. 9. Here, it is assumed that the heat transfer in the container and the heat conduction through the container wall are high enough so that the respective temperature difference can be neglected. For the outside heat transfer coefficient, a mean value for natural convection (Eq. (25)) can be used:

$$\alpha_a = 1.6 \frac{\mathrm{W}}{\mathrm{m^2 K}} \sqrt[4]{\frac{T_w - T_u}{K}}, \qquad (25)$$

with T_w the outside wall temperature of the insulation, T_a the ambient temperature. The heat transfer by radiation is taken into account with the radiation number $C = 4.7$ W/(m^2 K^4), the ambient temperature with $T_a = 20°C$. Technical data of the thermal conductivity are given in Fig. 9 in parenthesis for the

E1. Table 1. Shape factors for plane walls and band-type configurations (length l; $S/l = S_l$; K/K' and K'/K according to Fig. 6)

Configuration (Nr)	Shape factor	Remarks
1 	Plane wall: $S_l = b/\delta$	
2 	Aligned bands in a semi-infinite solid medium: $S_l = \frac{1}{2}K'/K$	$k = \delta/(2b + \delta)$
3 	Band perpendicular to an isothermal boundary: $S_l = K'/K$	$k = \delta/(2b + \delta)$
4 	Band aligned between isothermal boundaries: $S_l = 2K/K'$	$k = \delta/(2b + \delta)$
5 	Band aligned to an isothermal boundary: $S_l = K/K'$	$k = \delta/(2b + \delta)$
6 	Band perpendicular between isothermal boundaries: $S_l = 2K/K'$	$k = \frac{1}{\sqrt{1 + (\delta/2b)^2}}$
7 	Band parallel to an isothermal boundary: $S_l = 2K'/K$	$k = \frac{1}{\cosh\left(\frac{\pi b}{4\delta}\right)}$

E1. Table 1. (continued)

Configuration (Nr)	Shape factor	Remarks
8 	Band between perpendicular isothermal boundaries: $S_I = 2K'/K$	$k = \cos\left(\frac{\pi b}{2\delta}\right)$
9 	Band on a semicircular boundary: $S_I = 2K'/K$	$k = \frac{1-(b/r)^2}{1+(b/r)^2}$
10 	Band confocal in an elliptic tube: $S_I = \frac{2\pi}{\ln\frac{a+c}{b}}$	$b = \sqrt{a^2 - c^2}$

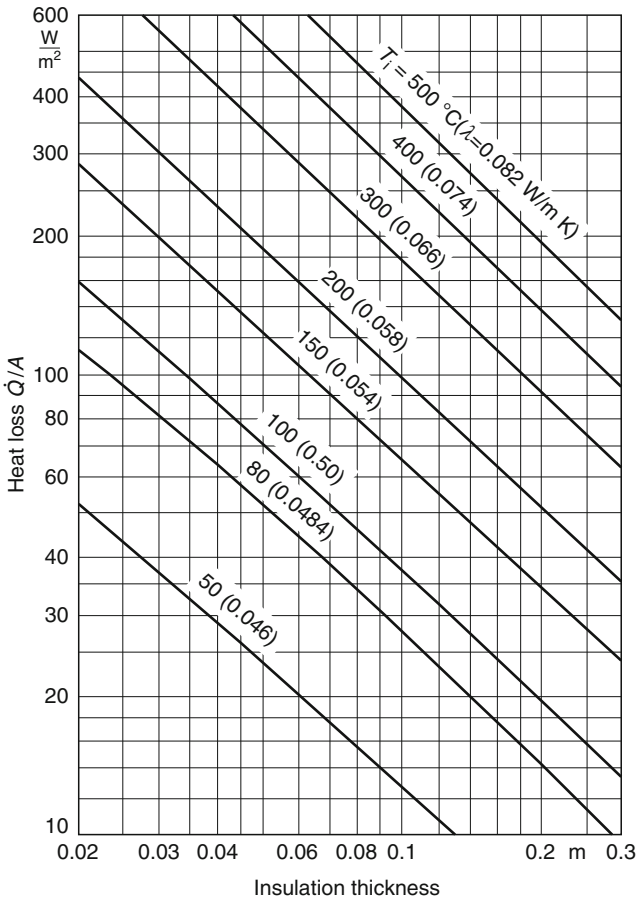
10 	In semi-infinite medium with adiabatic top: Sphere $S_r = \frac{4\pi}{1 + r/2d}$ circular disc $S_r = \frac{4\pi}{\frac{\pi}{2} + \arctan\frac{r}{2d}}$	$d/r > 2$ T_2 very far away



E1. Fig. 9. Heat loss of insulated outside walls vs. insulation thickness.

respective temperature region. The arithmetic mean of the surface temperatures is taken as reference temperature. Data of Fig. 9 are quite precise for thick insulations, for thin insulations larger deviations can occur due to inaccuracies of Eq. (25).

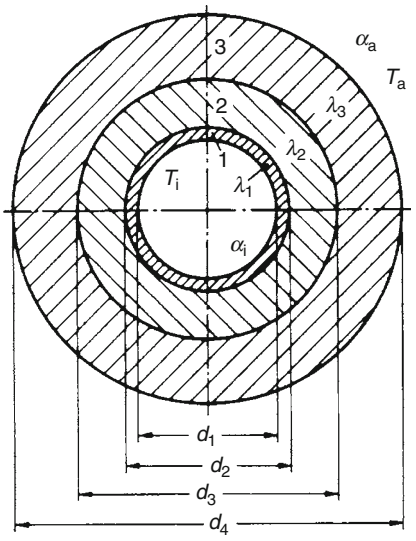
5.2 Heat Losses from Insulated Pipes

The exact calculation of such heat losses is performed with the equation for concentric multilayered pipes (Chaps. C2 and E1 in Sect. 2.2).

For a pipe 1 with two insulating layers, 2 and 3, as shown in Fig. 10, this equation is

$$\frac{\dot{Q}}{l} = \frac{\pi(T_\mathrm{i} - T_\mathrm{a})}{\frac{1}{\alpha_1 d_1} + \frac{1}{2\lambda_1}\ln\frac{d_2}{d_1} + \frac{1}{2\lambda_2}\ln\frac{d_3}{d_2} + \frac{1}{2\lambda_3}\ln\frac{d_4}{d_3} + \frac{1}{\alpha_3 d_4}}. \qquad (26)$$

The heat transfer coefficient α_i is calculated according to Chap. G1, the heat transfer coefficient α_a in stagnant air according to Part F and in moving air by Chap. G2. If relevant, radiation can be accounted for according to Chap. K1. Data for thermal conductivity are taken for a mean state of each insulating layer, e.g., the arithmetic mean of the bordering temperatures and the mean moisture content. For an anticipated strong temperature- or moisture drop/increase, it is recommended to subdivide the insulating layers and use graded thermal conductivities.



E1. Fig. 10. Cross section of a pipe (1) with two insulation layers (2,3) according to equ. (26).

5.3 Graphical Determination of Heat- and Cold-Losses in Stagnant Surrounding Air

The nomogram Fig. 11 can be used for a fast determination of such losses. The heat transfer coefficient on the outside layer can be obtained from the approximation

$$\alpha_\mathrm{a} = 8\frac{\mathrm{W}}{\mathrm{m^2K}} + 0.04\frac{\mathrm{W}}{\mathrm{m^2K^2}}\Delta T, \qquad (27)$$

with ΔT being the (positive) difference between wall and surrounding temperatures; Eq. (27) includes radiation and natural convection. It gives satisfactory results within $5\ \mathrm{K} \le \Delta T \le 100\ \mathrm{K}$ and $0.05\ \mathrm{m} \le d_{n+1} \le 1\ \mathrm{m}$ with d_{n+1} as outer diameter of the insulation. This equation provides a mean value of the theoretically calculated heat transfer coefficients for the given range [7]. An auxiliary value D is introduced in the nomogram that allows for all heat flow resistances except the outside heat transfer

$$D = d_{n+1}\left(\frac{1}{\alpha_1 d_1} + \frac{1}{2\lambda_2}\ln\frac{d_2}{d_1} + \frac{1}{2\lambda_2}\ln\frac{d_3}{d_2} + \cdots + \frac{1}{2\lambda_n}\ln\frac{d_{n+1}}{d_n}\right). \qquad (28)$$

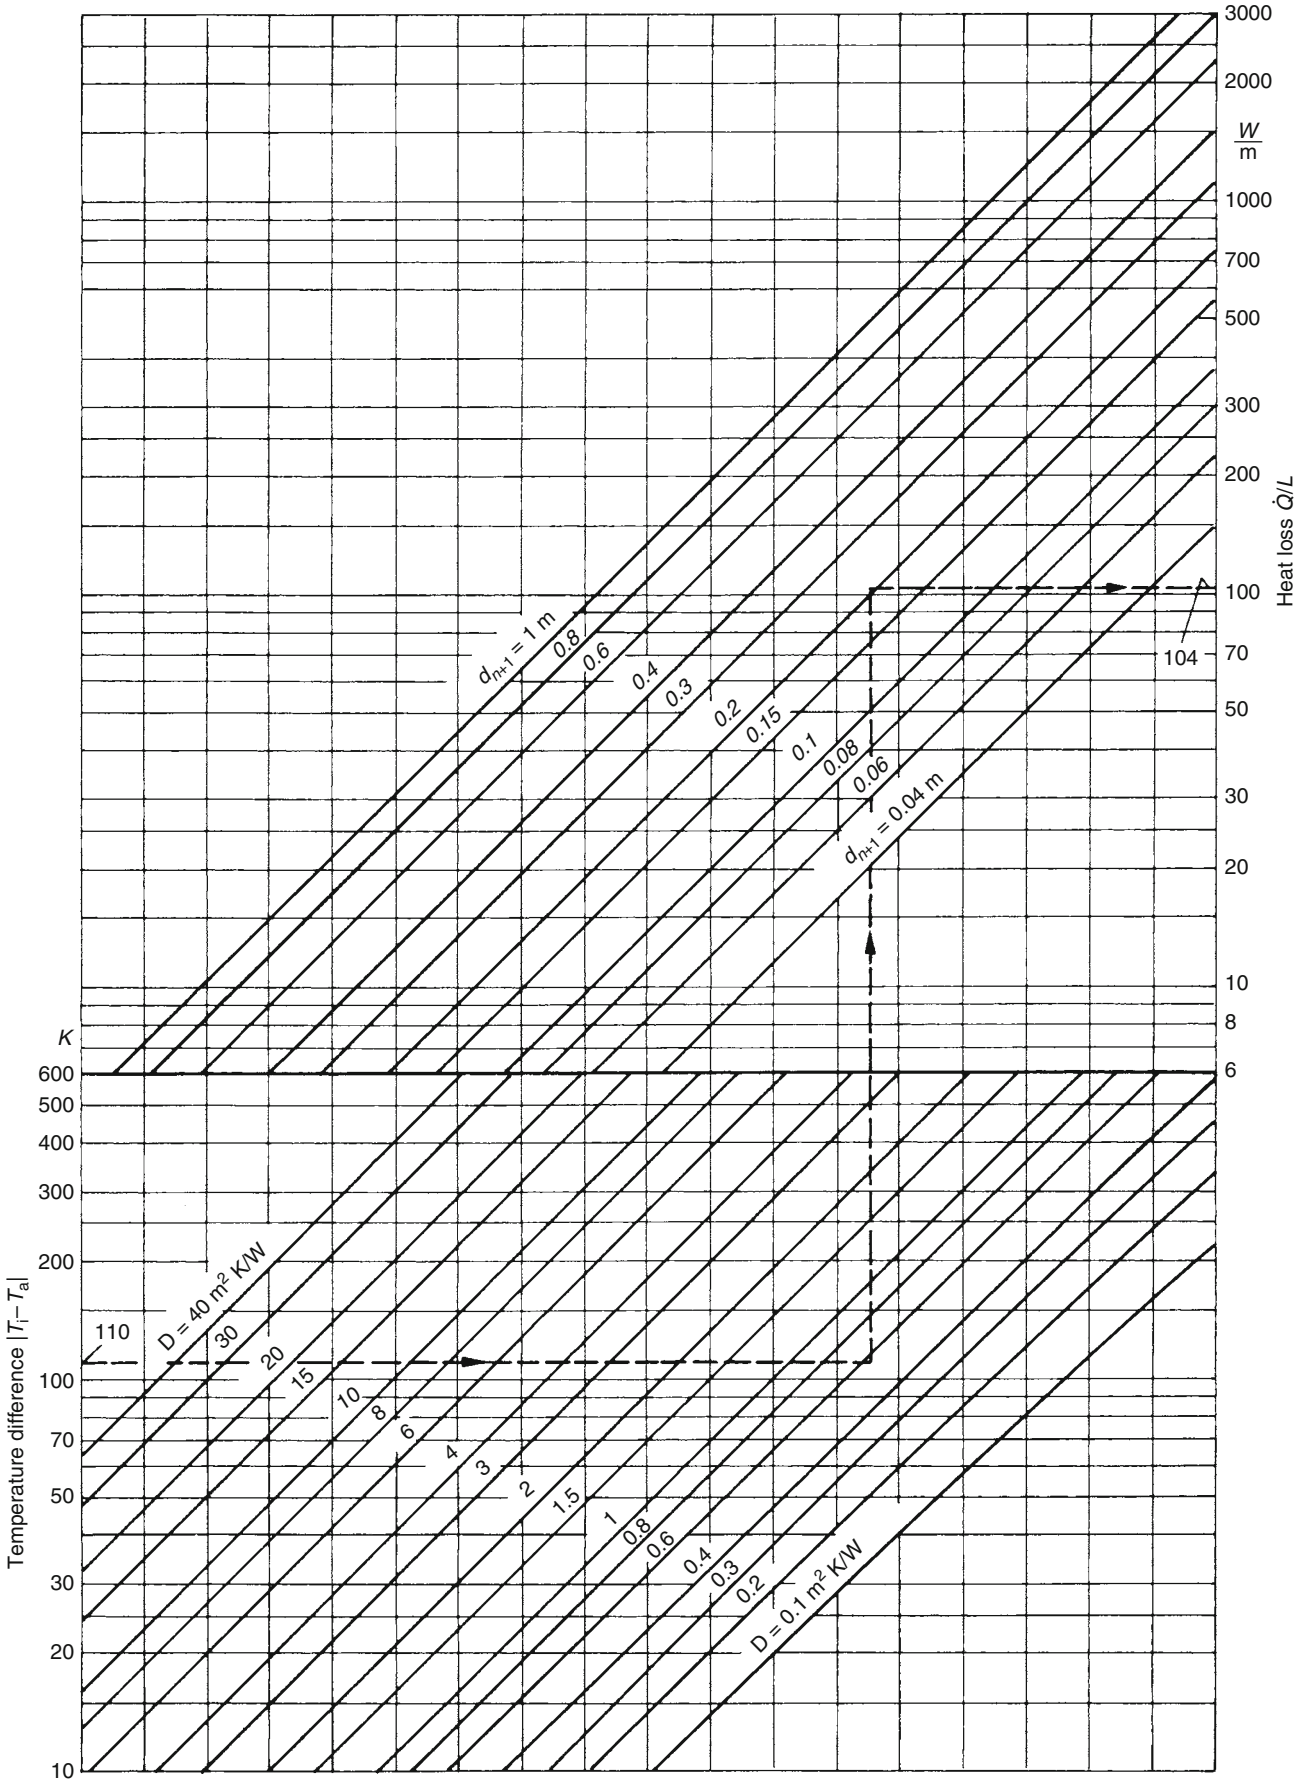
As temperature difference, the positive difference between the inner temperature T_i and the ambient temperature T_a has to be taken.

5.3.1 Examples

Example 6

How big is the heat loss for a pipe 10 m long, inner/outer diameter 100/108 mm, insulation thickness 50 mm, with thermal conductivity 0.12 W/m K, ambient temperature 10°C; the pipe carries saturated steam of 120°C.

Neglecting the thermal resistance within the pipe and the wall, one obtains from Eq. (28)



E1. Fig. 11. Nomogram for approximate determination of heat- and cold-losses of insulated pipes.

$$D = 0.208\left(\frac{1}{2 \cdot 0.12}\ln\frac{0.208}{0.108}\right)\frac{\mathrm{m^2K}}{\mathrm{W}} = 0.57\ \frac{\mathrm{m^2K}}{\mathrm{W}}.$$

As shown in the nomogram (Fig. 11, along the sketched line) starting at $T_i - T_a = 110$ K to $D = 0.57$ and $d_{n+1} = 0.208$ m gives $\dot{Q}/l = 104$ W/m heat loss per m and in total $\dot{Q} = 104$ W/m · 10 m = 1040 W.

Example 7

A pipe 200/216 mm inner/outer diameter is insulated with two layers, each 50 mm thick. The thermal conductivity of the inner layer is 0.14 W/m K, of the outer 0.07 W/m K. Gas of 500°C flows inside the pipe, the inside heat transfer coefficient is 60 W/m^2 K. The ambient air temperature is 20°C.

What is the heat loss per m length?

$$D = 0.416\left(\frac{1}{60 \cdot 0.216} + \frac{1}{2 \cdot 0.14}\ln\frac{0.316}{0.216} + \frac{1}{2 \cdot 0.07}\ln\frac{0.416}{0.316}\right)$$
$$= 1.41\ \frac{\mathrm{m^2K}}{\mathrm{W}}.$$

From the nomogram (Fig. 11), we obtain with $T_i - T_a = 480$ K and $d_{n+1} = 0.416$ the heat loss $Q/l = 405$ W/m.

5.4 Heat Losses with Wind

For moving air, the heat resistance on the outside is $1/\alpha_a$. This is given in Fig. 12 for various wind speeds and various outside diameters of the insulation, d_{n+1}. This figure also presents the wind forces according to the *Beaufort*-scale for the various ranges of wind speed. The heat transfer coefficient α_a can be calculated from relations for pipes in cross-flow [8], considering a mean heat transfer coefficient for radiation of 5 W/m^2 K.

The heat loss can be obtained from Eq. (26).

If the defined value D (Eq. (28)) is already known, it is easier to obtain the loss from

$$\frac{\dot{Q}}{l} = \frac{d_{n+1}\pi(T_i - T_a)}{D + 1/\alpha_a}. \tag{29}$$

5.4.1 Example

Example 8

The pipe of Example 6 is exposed to wind (w = 10 m/s). From Fig. 12, we obtain for w = 10 m/s and d_{n+1} = 0.208 m, $1/\alpha_a = 0.021$ m^{2}K/W and from Eq. (29)

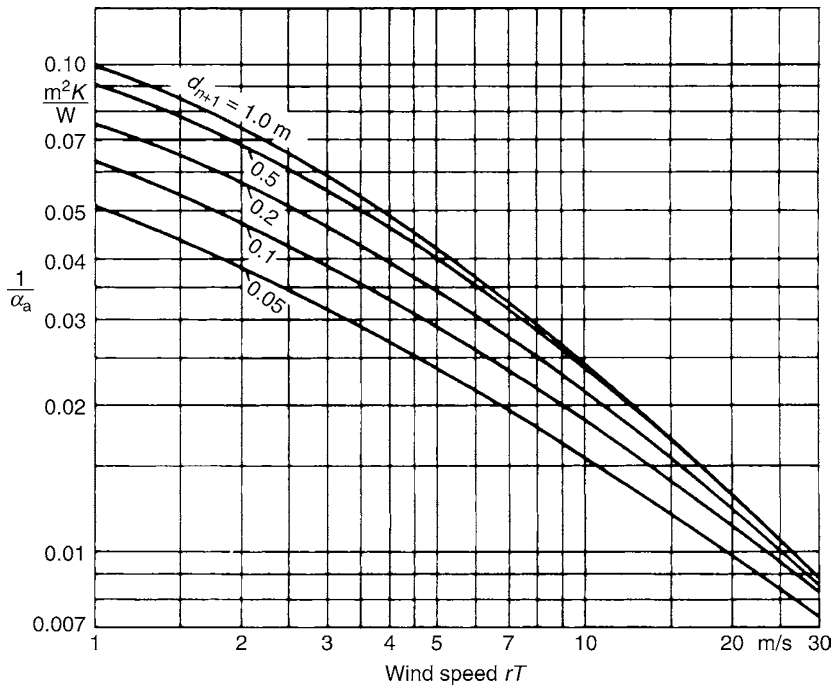
$$\frac{\dot{Q}}{l} = \frac{0.208\pi 110}{0.57 + 0.021}\ \mathrm{W/m} = 122\ \mathrm{W/m},$$

$$\dot{Q} = 122\ \mathrm{W/m} \cdot 10\ \mathrm{m} = 1220\ \mathrm{W}.$$

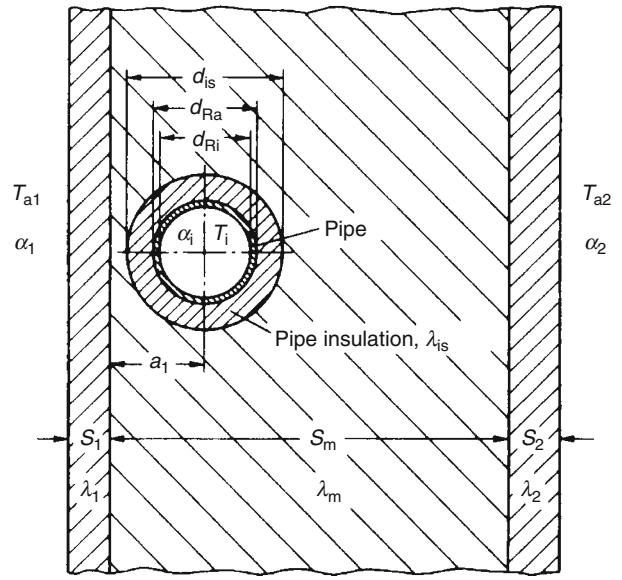
5.5 Heat Losses of Pipes Inside Walls

A picture and symbols of such an arrangement are given in Fig. 13.With these data (according to [9]) Fig. 14 can be used to determine the losses (note that Fig. 13 assumes an isothermal wall, T_{a1}).The temperature difference ΔT accounts for possible different temperatures, T_{a1} and T_{a2} on either side of the wall:

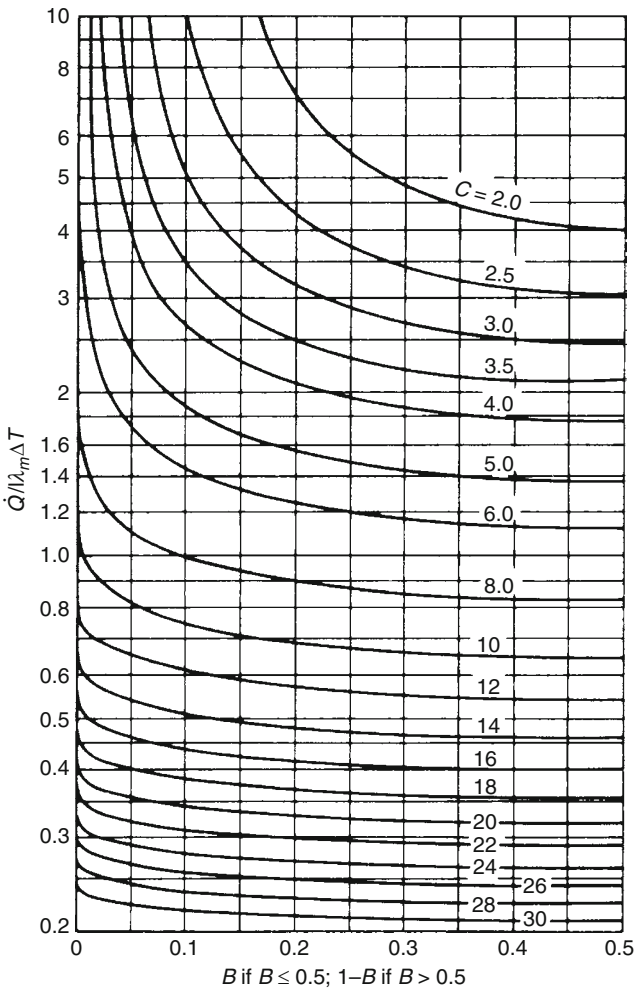
$$\Delta T = T_i - T_{a1} + B(T_{a1} - T_{a2}). \tag{30}$$



E1. Fig. 12. Determination of heat losses with wind: heat resistence vs. wind speed.



E1. Fig. 13. Pipe in a wall.



E1. Fig. 14. Determination of heat-and cold-losses for pipes in walls according to [9].

The auxiliary values B and C have to be calculated from

$$B = \frac{\frac{1}{\alpha_1} + \frac{s_1}{\lambda_1} + \frac{a_1}{\lambda_m}}{\frac{1}{\alpha_1} + \frac{s_1}{\lambda_1} + \frac{s_m}{\lambda_m} + \frac{s_2}{\lambda_2} + \frac{1}{\alpha_2}} \tag{31}$$

and

$$C = \frac{2\lambda_m}{\alpha_1 d_{Ri}} + \frac{\lambda_m}{\lambda_{ik}} \ln \frac{d_{is}}{d_{Ra}} + \ln\left[\frac{2\lambda_m}{d_{is}}\left(\frac{1}{\alpha_1} + \frac{s_1}{\lambda_1} + \frac{s_m}{\lambda_m} + \frac{s_2}{\lambda_2} + \frac{1}{\alpha_2}\right)\right]. \tag{32}$$

A temperature drop within the metallic pipe wall is neglected.

The data in Fig. 14 are based on the following equations [9]

$$\frac{\dot{Q}}{l\lambda_m \Delta T} = \frac{2\pi}{\ln(K + \sqrt{K^2 - 1})} \tag{33}$$

with

$$K = \frac{1}{\pi} e^C \left(1 + \frac{\pi^2}{4} e^{-2C}\right) \sin(\pi B). \tag{34}$$

For very thick walls or a pipe in the ground, the value B greatly reduces and the value C greatly increases. Then Eq. (34) becomes according to [10]

$$K = \frac{2\lambda_m}{d_{is}}\left(\frac{1}{\alpha_1} + \frac{s_1}{\lambda_1} + \frac{a_1}{\lambda_m}\right)\left(\frac{d_{is}}{d_{Ra}}\right)^{\lambda_m/\lambda_{is}} \exp\left(\frac{2\lambda_m}{\alpha_i d_{Ri}}\right). \tag{35}$$

5.5.1 Example

Example 9 (According to [11])
A heating pipe, outer diameter 21.3 mm, inside a ceiling, is surrounded by a 6 mm insulating layer. The ceiling is 160 mm thick, including a floor cover of 5 mm. The pipe axis is 35 mm distant from the lower side of the ceiling. Water of 80°C flows inside the pipe. The various conductivities are pipe insulation 0.04 W/m K, ceiling 2.0 W/m K, and floor cover 0.20 W/m K. The heat transfer coefficient from the ceiling top side is 12 W/m^{2}K, from the lower side 8 W/m^{2}K. The respective room temperatures are 18°C in the upper room and 22°C in the lower. How big is the heat loss per m pipe length?

According to Eq. (31)

$$B = \frac{\frac{1}{8} + 0 + \frac{0.035}{2.0}}{\frac{1}{8} + 0 + \frac{0.155}{2.0} + \frac{0.005}{0.20} + \frac{1}{12}} = 0.460$$

and Eq. (30)

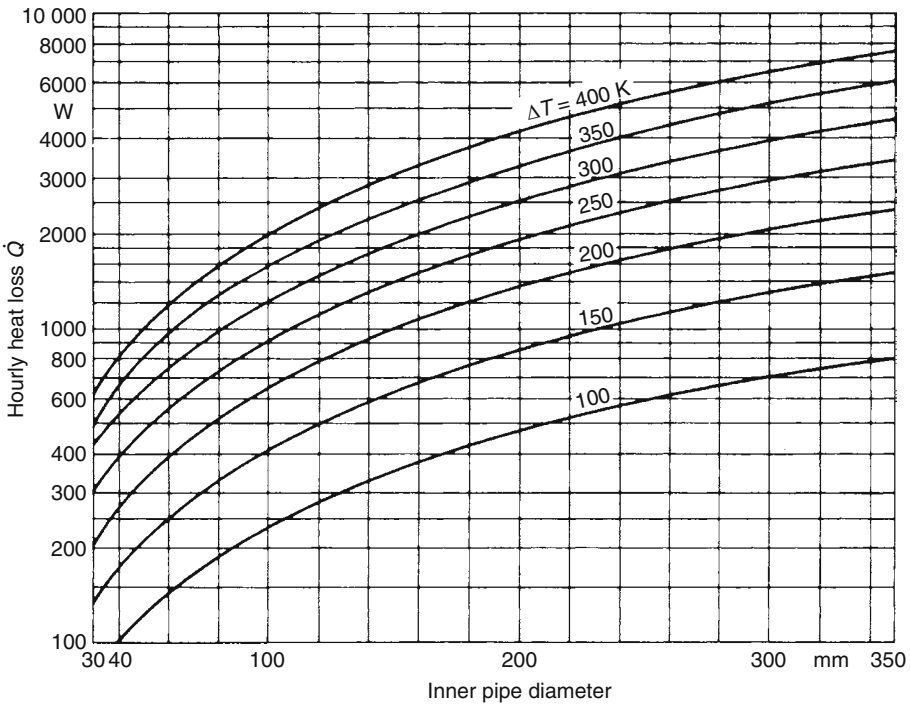
$$\Delta T = 80\ \text{K} - 22\ \text{K} + 0.460(22 - 18)\ \text{K} = 59.8\ \text{K}.$$

According to Eq. (32) when the heat transfer resistances of the flowing water and the pipe wall are neglected,

$$C = 0 + \frac{2.0}{0.040} \ln \frac{33.3}{21.6} + \ln\left[\frac{2 \cdot 2.0}{0.0333}\left(\frac{1}{8} + 0 + \frac{0.155}{2.0} + \frac{0.005}{0.20} + \frac{1}{12}\right)\right] = 25.3.$$

E1. Table 5. Additions for valves and slide valves

kind of insulation		Inner diameter of pipe (mm)	Eqivalent length of the uninsulated pipe in m. at a pipe temperature of	
			100°C	400°C
inside rooms	stripped	100	6	16
		500	9	26
	1/4 stripped	100	2.5	5
	3/4 insulated	500	3	7.5
	1/3 stripped	100	3	6
	2/3 insulated	500	4	10
outside rooms	stripped	100	15	22
		500	19	32
	1/4 stripped	100	4.5	6
	3/4 insulated	500	6	8.5
	1/3 stripped	100	6	8
	2/3 insulated	500	7	11



E1. Fig. 15. Determination of hourly heat losses of stripped flanges according to [12].

With B and C we obtain from Fig. 14 or from Eqs. (33) and (34)

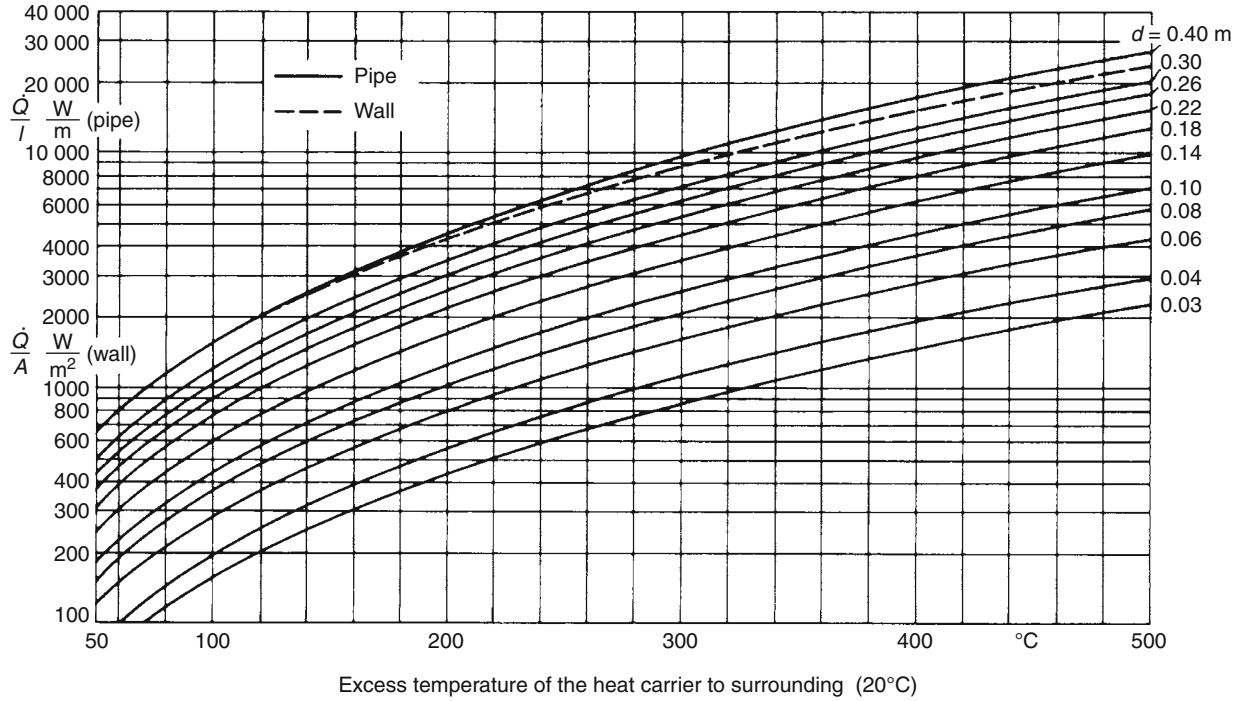
$$\frac{\dot{Q}}{l\lambda_m \Delta T} = 0.25.$$

The heat loss per length is

$$\frac{\dot{Q}}{l} = 0.25 \cdot 2.0 \cdot 59.8 \text{ W/m} = 30 \text{ W/m}.$$

5.6 Additional Heat Losses of Insulated Pipes

Additional heat losses originate from flanges, valves, pipe suspensions, manifolds, and other auxiliary devices. A determination of such losses is inexact; the following data should only be considered estimates.



E1. Fig. 16. Determination of heat losses for uninsulated pipes and containers inside rooms.

Pipe suspensions: for chains and thin iron strips 10–15% should be added to the total pipe length; for heavy sleeve bearings, 20%.

Stripped flanges: data from Fig. 15 may be used for inside rooms [12] when fluids or saturated steam flows in the pipe with a high heat transfer coefficient. For gas flow with low heat transfer coefficients, the data from Fig. 15 should be reduced by 20%. For stripped flanges outside rooms, it is assumed that heat losses are equal to that of a stripped pipe of the same area.

Insulated flanges: for a continuous insulation with constant diameter, no additions are made. When flange caps are involved, 0.5–1 m insulated pipe length is added.

Valves and slide valves: additions according to Table 5 may be used.

5.7 Heat Losses of Noninsulated Pipes and Containers Inside Rooms

The exact calculation of heat losses for stripped surfaces in stagnant air can be obtained from Part F. The diagram Fig. 16 allows for a quick approximate determination of heat losses on stripped pipes. This is of interest when the economical advantage of an insulation is desired. This diagram is valid for inner rooms with 20°C air temperature and a radiation number of $C = 4.7\ \mathrm{W/m^2K^4}$ for the surface. The inner heat transfer is neglected as long as $\alpha_i \geq 1000\ \mathrm{W/m^2K}$. For other air temperatures, the following multiplication factor should be applied.

Air temperature in °C	−10	0	+10	+20	+30	+40
Factor *f*	0.88	0.91	0.96	1.00	1.05	1.10

E2 Transient Conduction in Stagnant Media

Holger Martin
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Basic Equations

Time-dependent temperature fields $T(r, t)$ play a crucial role in many technical applications. Their mathematical modeling enables us to predict the duration of a heating or cooling process, the heat taken up or released during the process, or the exact position inside a body where a maximum or a minimum temperature occurs at a certain time. The fundamentals needed for a calculation of such temperature fields are the first law of thermodynamics (applied as an energy balance of the system in question) and Fourier's law of heat conduction (as a rate equation, or an equation describing the "kinetics" of heat transfer). For the volume element of a stagnant incompressible medium, the (thermal) energy balance is

$$\rho c_p \frac{\partial T}{\partial t} = -\nabla \dot{q}. \tag{1}$$

Equation (1) states that the internal energy of the volume element is increased if the net heat flux out of the system is less than the heat flux entering the system. An additional increase of internal energy by adding power (work/time) (such as electric power) or an internal release of thermal energy from the dissipation of other energy forms has to be taken into account by an added term on the right-hand side of Eq. (1).

The kinetics of heat conduction (i.e., Fourier's law) relates the so far unknown heat flux to the gradient of the temperature field:

$$\dot{q} = -\lambda \nabla T. \tag{2}$$

Following Eq. (2), the direction of heat flux coincides with the direction of the negative temperature gradient. This is only true if the thermal conductivity λ does not depend on direction. Coupling the balance, Eq. (1), with the kinetics, Eq. (2), results in an equation to calculate the temperature field (Fourier's equation):

$$\rho c_p \frac{\partial T}{\partial t} = \nabla \lambda \nabla T. \tag{3}$$

For constant conductivity λ Eq. (3), with the thermal diffusivity $\kappa = \lambda/(\rho c_p)$, simplifies to

$$\frac{\partial T}{\partial t} = \kappa \nabla^2 T. \tag{3a}$$

Table 1 contains a comprehensive collection of the differential operations symbolized by the nabla operator, ∇, in Eqs. (1–3a) in the three main coordinate systems.

2 Initial and Boundary Conditions

Time-dependent temperature fields are caused by perturbations of a steady-state initial condition. Such a perturbation, in general, consists in a change of state of the surroundings at a moment $t = t_I$ [Conveniently, the time at the beginning of the heating or cooling process is set to $t_I = 0$, i.e., the time is counted at the moment, when the temperature of the surroundings is (suddenly) changed]. The temperatures $T(r, t)$ at any time later, $t > 0$, are then determined unambiguously, if the temperature field is known at $t = 0$

$$T(r, 0) = \varphi(r) \text{ initial condition} \tag{4}$$

and when the state of the surroundings is given for all times $t > 0$ (boundary conditions).

The boundary conditions in general form are

$$-\lambda \left(\frac{\partial T}{\partial n}\right)_0 = \dot{q}_0 \text{ boundary condition,} \tag{5}$$

where $\partial/\partial n$ means a differentiation in the direction outward, normal to the surface. Equation (5) relates the temperature gradient at the surface of the body to the heat flux through the surface, which in turn might be calculated via Eq. (2) from the temperature field of the surroundings. Strictly spoken, a coupled system of differential equations (3) for the temperature fields inside and outside the body in consideration had to be

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_17,

solved. To avoid this difficulty, usually the heat flux at the surface $\dot{q}_0$ has to be specified somehow, for example, by Newton's "law of cooling"

$$\dot{q}_0 = \alpha_a (T_0 - T_\infty). \tag{6}$$

This form of the boundary condition with a constant outer heat transfer coefficient α_a and a given temperature of the surroundings $T_\infty = T_\infty (r_S, t)$ becomes very simple, if the outer heat transfer resistance $(1/\alpha_a)$ vanishes. In this case, as to be seen from Eq. (6), the surface temperature T_0 itself becomes a given quantity $(T_0 = T_\infty)$

$$T_0 = T_\infty (r, t). \tag{7}$$

Equation (7) is called a boundary condition "of the first kind." If the heat flux, however, is specified at the surface

$$-\lambda \left(\frac{\partial T}{\partial n} \right)_0 = \dot{q}_0 (r, t) \tag{8}$$

one speaks of a boundary condition of the second kind. The more general case, as given by Eqs. (5) and (6),

$$\left(\frac{\lambda}{\alpha_a} \frac{\partial T}{\partial n} + T \right)_0 = T_\infty (r, t) \tag{9}$$

is called a boundary condition of the third kind. From Eqs. (3–5) (in one of the forms corresponding to Eqs. (7–9) the time-dependent temperature field inside a stagnant incompressible medium (without internal energy dissipation) is determined unequivocally.

3 Analytical Solutions

For simply shaped bodies a great number of analytical solutions for transient temperature fields are known [1–4]. Some of the practically most important and simplest of these solutions are described in the following.

3.1 Step Change of State of the Surroundings

3.1.1 One-dimensional Heat Flux

The direction of the heat flux vector always coincides, in these cases, with a single direction of the coordinate system, as for example with the x-direction in a Cartesian system – the planes $x =$ const. are then isothermal faces, or with the r-direction in cylindrical or in spherical coordinates – in these cases the isothermal faces are cylindrical or spherical shells with $r =$ const. The temperature field equation (3a) simplifies accordingly (see also Table 1):

For the plane temperature field $T(x, t)$:

$$\frac{\partial T}{\partial t} = \kappa \frac{\partial^2 T}{\partial x^2} \tag{3b}$$

for the cylindrically symmetrical temperature field $T(r, t)$:

$$\frac{\partial T}{\partial t} = \frac{\kappa}{r} \frac{\partial}{\partial r} \left(r \frac{\partial T}{\partial r} \right) \tag{3c}$$

for the spherically symmetrical temperature field $T(r, t)$:

$$\frac{\partial T}{\partial t} = \frac{\kappa}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial T}{\partial r} \right). \tag{3d}$$

The three equations (3b–d) can be written comprehensively in the form

$$\frac{\partial T}{\partial t} = \frac{\kappa}{r^n} \frac{\partial}{\partial r} \left(r^n \frac{\partial T}{\partial r} \right) \tag{3e}$$

with $n = 0$, 1, or 2 for plane, cylindrically or spherically symmetric temperature fields.

The simple shapes corresponding to the three aforementioned one-dimensional temperature fields are the following:

(a) $-X \le x \le X; -\infty < y, z < \infty;$

slab of thickness $2X$, infinitely extended in the y- and z-directions, in the following referred to as "the slab" for shortness:

(b) $0 \le r \le R; 0 \le \varphi \le 2\pi; -\infty < z < \infty;$

circular cylinder of diameter $2R$, infinitely extended in the z-direction, in the following referred to as "the cylinder" for shortness:

(c) $0 \le r \le R; 0 \le \varphi \le 2\pi; 0 \le \psi \le \pi;$

sphere of diameter $2R$.

As an initial condition, Eq. (4), the most simple case,

$$T(r, 0) = T_I = \text{const.} \tag{4a}$$

E2. Table 1. Vector operations in the three main coordinate systems

	Cartesian coordinates (x, y, z)	Cylinder coordinates (r, φ, z)	Spherical coordinates (r, φ, ψ)
Gradient ∇T	$e_x \frac{\partial T}{\partial x} + e_y \frac{\partial T}{\partial y} + e_z \frac{\partial T}{\partial z}$	$e_r \frac{\partial T}{\partial r} + e_\varphi \frac{1}{r} \frac{\partial T}{\partial \varphi} + e_z \frac{\partial T}{\partial z}$	$e_r \frac{\partial T}{\partial r} + e_\varphi \frac{1}{r \sin\psi} \frac{\partial T}{\partial \varphi} + e_\psi \frac{1}{r} \frac{\partial T}{\partial \psi}$
Divergence $\nabla \dot{q}$	$\frac{\partial \dot{q}_x}{\partial x} + \frac{\partial \dot{q}_y}{\partial y} + \frac{\partial \dot{q}_z}{\partial z}$	$\frac{1}{r^2} \frac{\partial}{\partial r} (r \dot{q}_r) + \frac{1}{r} \frac{\partial \dot{q}_\varphi}{\partial \varphi} + \frac{\partial \dot{q}_z}{\partial z}$	$\frac{1}{r^2} \frac{\partial}{\partial r} (r \dot{q}_r) + \frac{1}{r \sin\psi} \frac{\partial \dot{q}_\varphi}{\partial \varphi} + \frac{1}{r \sin\psi} \frac{\partial}{\partial \psi} (\dot{q}_\psi \sin\psi)$
Laplacian $\nabla^2 T$	$\frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2} + \frac{\partial^2 T}{\partial z^2}$	$\frac{1}{r^2} \frac{\partial}{\partial r} \left(r \frac{\partial T}{\partial r} \right) + \frac{1}{r^2} \frac{\partial^2 T}{\partial \varphi^2} + \frac{\partial^2 T}{\partial z^2}$	$\frac{1}{r^2} \frac{\partial}{\partial r} \left(r^2 \frac{\partial T}{\partial r} \right) + \frac{1}{r^2 \sin^2\psi} \frac{\partial^2 T}{\partial \varphi^2} + \frac{1}{r^2 \sin\psi} \frac{\partial}{\partial \psi} \left(\sin\psi \frac{\partial T}{\partial \psi} \right)$
	Relations to the Cartesian coordinates	$x = r \cos\varphi$	$x = r \cos\varphi \sin\psi$ **e** unit vector
		$y = r \sin\varphi$	$y = r \sin\varphi \sin\psi$
		$z = z$	$z = r \cos\psi$

is chosen here, and as a boundary condition, following Eq. (9):

$$\left(\frac{\lambda}{\alpha_a}\frac{\partial T}{\partial r}+T\right)_{r=R}=\begin{cases}T_I & \text{for } t\le 0\\ T_\infty & \text{for } t>0\end{cases} \tag{9a}$$

that is, a single step change of the temperature of the surroundings from T_I to T_∞ at $t = 0$.

The field equation (3e) together with the initial and boundary condition equations (4a) and (9a) can be written in dimensionless form using the following definitions.

The normalized temperature:

$$\Theta\equiv\frac{T-T_\infty}{T_I-T_\infty}; \tag{10}$$

the normalized distance from the center of symmetry:

$$\xi\equiv\frac{r}{R}\ \text{or}\ \frac{x}{X}; \tag{11}$$

the dimensionless time (or Fourier number):

$$\tau\equiv\frac{\kappa t}{R^2}\quad\text{or}\quad\frac{\kappa t}{X^2}; \tag{12}$$

and the ratio of the internal conductive resistance (R/λ) to the outer heat transfer resistance $(1/\alpha_a)$, or the Biot number:

$$\mathrm{Bi}=\frac{\alpha_a R}{\lambda}\quad\text{or}\quad\frac{\alpha_a X}{\lambda}. \tag{13}$$

With Eqs. (10–13) one obtains

$$\frac{\partial\Theta}{\partial\tau}=\frac{\kappa}{\xi^n}\frac{\partial}{\partial\xi}\left(\xi^n\frac{\partial\Theta}{\partial\xi}\right) \tag{14}$$

with $n = 0$ for the slab, $n = 1$ for the cylinder, and $n = 2$ for the sphere.

Initial condition:

$$\Theta(\xi,0)=1; \tag{15}$$

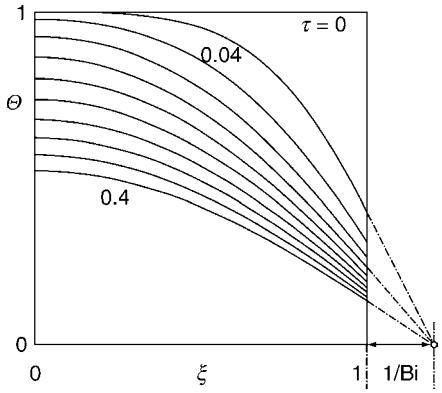
boundary condition:

$$\left(\frac{1}{\mathrm{Bi}}\frac{\partial\Theta}{\partial\xi}+\Theta\right)_{|\xi|=1}=\begin{cases}1 \text{ for } \tau\le 0,\\ 0 \text{ for } \tau>0.\end{cases} \tag{16}$$

In this normalized form, it makes no difference whether a heating or a cooling problem is treated. The normalized temperature given in Eq. (10) decreases from 1 at the beginning $(\tau = 0)$ to 0 for sufficiently high values of time $(\tau\to\infty)$.

Figure 1 shows an example for such a transient temperature field. The fact that all the tangents at the instantaneous temperature curves at the surface $(\xi = 1)$ have a common intersection at a point outside the body is remarkable and very helpful for plotting these curves. It follows immediately from the boundary condition equation (16). The coordinates of this point of intersection ("pole") are $(\Theta = 0,\ \xi = 1 + 1/\mathrm{Bi})$.

If the outer heat transfer resistance tends toward zero (that means $1/\mathrm{Bi}\to 0$), the pole comes immediately to the surface and the boundary condition of the first kind is reached, that is $\Theta\ (\xi = 1;\ \tau > 0) = 0$. In this case, the temperature differences inside the body are the greatest possible. This is asymptotically reached in heating or cooling of big bodies made of poorly conducting material (stone, sand, plastics, or the like) with a high outside heat transfer coefficient (well-mixed water, evaporation, or condensation).



E2. Fig. 1. Temperature field $\Theta(\xi, \tau, \mathrm{Bi})$ for a slab with a boundary condition of the third kind.

If the outer resistance, however, compared to the inner conductive resistance, becomes more important, the pole moves outward from the surface. The wall tangents and therefore the whole temperature curves become increasingly flatter. From a simple geometric consideration the maximum inside temperature difference max $\Theta\ (\xi = 0) - \Theta(\xi = 1) \equiv \Delta\Theta_{\max}$ can be estimated. One finds

$$\Delta\Theta_{\max}<\frac{\mathrm{Bi}}{1+\mathrm{Bi}}. \tag{17}$$

For Biot numbers $\mathrm{Bi} < 0.1$, the central and surface temperatures differ by <9% of the initial difference $(\Theta_I - \Theta_\infty)$ to the surroundings. An example for such a case is the cooling or heating of small well-conducting bodies (metals) in stagnant gas (small outer heat transfer coefficient).

Further from Fig. 1 it can be seen that the temperature field for short times τ shows significant changes only in a narrow zone under the surface of the body. It has a typical boundary layer behavior. The thickness ($2X$ or $2R$) has no influence on the field; the body may be regarded as half-infinitely extended in this time-range. It is more convenient then to have the origin of the length coordinate at the surface. The new coordinate becomes $y = X - x$, or $R - r$. The dimensionless numbers, τ, and Bi, no longer contain X, or R, since these dimensions have no influence on the temperatures. A more reasonable length-scale in the short-time range is the term $\sqrt{\kappa t}$, which enters the dimensionless numbers:

$$\eta\equiv\frac{y}{2\sqrt{\kappa t}}\quad\left(=\frac{1-\xi}{2\sqrt{\tau}}\right), \tag{18}$$

$$\mathrm{Bi}^*\equiv\frac{\alpha_a\sqrt{\kappa t}}{\lambda}\quad\left(=\mathrm{Bi}\sqrt{\tau}\right). \tag{19}$$

The solution for the temperature field $\Theta\ (\eta, \mathrm{Bi}^*)$ in this case is found to be [1]

$$\Theta=\mathrm{erf}\ \eta+\mathrm{e}^{-\eta^2}\mathrm{e}^{(\eta+\mathrm{Bi}^*)^2}\{1-\mathrm{erf}\,(\eta+\mathrm{Bi}^*)\}. \tag{20}$$

The error function erf (z) is defined as

$$\mathrm{erf}\,(z)=\frac{2}{\sqrt{\pi}}\int_0^z\mathrm{e}^{-\zeta^2}\mathrm{d}\zeta. \tag{21}$$

The graph of this function is shown in Fig. 2. For bodies of finite thickness, Eq. (20) is to be seen as an asymptotic solution for short times τ.

The surface temperature $\Theta_0 = \Theta(\eta = 0)$ follows from Eq. (20) as

$$\Theta_0 = e^{Bi^{*2}}\{1 - \text{erf}\,(Bi^*)\}. \tag{22}$$

For large values of Bi^*, Eq. (22) can be written as

$$\Theta_0 = \frac{1}{\sqrt{\pi}\,Bi^*}\,(\text{error} < 1\%\ \text{for}\ Bi^* > 3). \tag{23}$$

For $Bi^* \to \infty$, $\Theta_0 = 0$, that is, to a boundary condition of the first kind, and Eq. (20) reduces to the first term:

$$\Theta = \text{erf}\ \eta\ (Bi^* \to \infty). \tag{24}$$

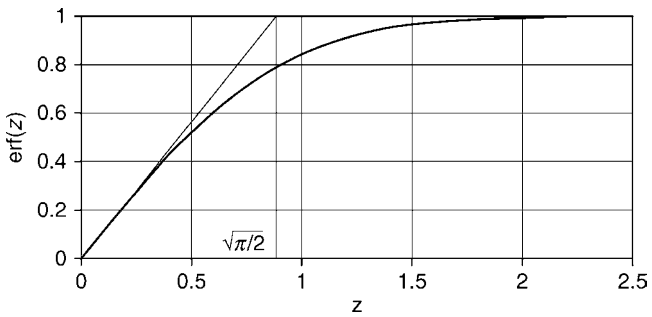
From Eq. (24), one can calculate the instantaneous heat flux through the surface with Eq. (2):

$$\dot{q}_{0,t} = \frac{\sqrt{\lambda\rho c_p}}{\sqrt{\pi\, t}}\,(T_I - T_0). \tag{25}$$

The heat flux is therefore inversely proportional to the square root of time, t. It is proportional to the square root of the product $\lambda\rho c$.

The mean integral value of the heat flux from $t = 0$ to t, $\dot{q}_0 = (1/t)\int_0^t \dot{q}_{0,t}\,dt$, turns out to be just twice the instantaneous flux at t:

$$\dot{q}_0 = 2\frac{\sqrt{\lambda\rho c_p}}{\sqrt{\pi\, t}}\,(T_I - T_0). \tag{25a}$$



E2. Fig. 2. Graph of the error function.

For sufficiently longer times τ, the temperature profiles inside the body of finite thickness tend to become similar to each other (see Fig. 1). They now can all be described by a single function of position $f(\xi)$ that is scaled down with increasing time:

$$\Theta = g(\tau)\, f(\xi). \tag{26}$$

Introducing this multiplicative ansatz into the differential equation (14) yields the same time-function, $g(\tau)$, irrespective of the shape of the body (or the value of n):

$$g(\tau) = \exp(-m^2\tau). \tag{27}$$

Here, m is a constant that is to be determined from the boundary conditions. The function of position, $f(\xi)$, however, depends on the shape, or the value of n (see Table 2, last column). These functions alone are not sufficient to describe the temperature field for short times, especially not the initial temperature distribution. This requires the use of an infinite series of these functions:

$$\sum_{i=1}^{I} C_i(m_i)\, f(m_i\xi).$$

The coefficients C_i of this series are calculated in order to make each finite series fit the initial temperature distribution, $\Theta(\xi, 0) = 1$, with a minimum of the sum of the squares of errors, and to converge, with increasing number, I, of the summands, against the initial temperature distribution.

The eigenvalues m_i are the roots of the transcendental equations given in the second column of Table 2. These equations can easily be solved graphically or with a numerical solver. In Table 3 the first four eigenvalues m_1–m_4, for a slab, a cylinder, and a sphere are given as functions of the Biot number. For the given problem, all these roots m_i are equal or greater than zero and tend to $\pi + m_{i-1}$ for large numbers i. The fourth eigenvalue is therefore always greater than or equal to 3π, the fourth term of the series equation (28) contains a time-scale factor $\exp(-m_4^2\tau)$, which, even for relatively short times τ, becomes very small. For example, it is <0.00014 for $\tau = 0.1$. For $\tau > 0.1$, a calculation of the first three terms of the series equation (28) will suffice. For $\tau > 0.5$, the first term alone is often exact enough.

E2. Table 2. Temperature field for one-dimensional transient heat flow in a slab, a cylinder, and a sphere after a step change of the temperature of the surroundings from the constant initial temperature of the body, T_I, to a fixed value, T_∞, at a prescribed constant value of the outer heat transfer coefficient, α_a (boundary condition of the third kind)

	m_i to be determined from	$C_i\,(m_i)$	$D_i\,(m_i)$	$f(m_i\,\xi)$
Slab	$m_i = \frac{\alpha_a X}{\lambda}\frac{\cos(m_i)}{\sin(m_i)}$	$2\frac{\sin(m_i)}{m_i + \sin(m_i)\cos(m_i)}$	$1\frac{\sin(m_i)}{m_i}$	$\cos\left(m_i\frac{x}{X}\right)$
Cylinder	$m_i = \frac{\alpha_a R}{\lambda}\frac{J_0(m_i)}{J_1(m_i)}$	$2\frac{J_1(m_i)}{m_i(J_0^2(m_i) + J_1^2(m_i))}$	$2\frac{J_1(m_i)}{m_i}$	$J_0\left(m_i\frac{r}{R}\right)$
Sphere	$m_i = \left(1 - \frac{\alpha_a R}{\lambda}\right)\frac{\sin(m_i)}{\cos(m_i)}$	$2\frac{\sin(m_i) - m_i\,cos(m_i)}{m_i - \sin(m_i)\cos(m_i)}$	$3\frac{\sin(m_i) - m_i\cos(m_i)}{m_i^3}$	$\frac{\sin\left(m_i\frac{r}{R}\right)}{m_i\frac{r}{R}}$

The Fourier series are

$$\Theta = \sum_{i=1}^{\infty} C_i(m_i)\, f(m_i\xi)\, \exp(-m_i^2\tau), \tag{28}$$

$$\overline{\Theta} = \sum_{i=1}^{\infty} C_i(m_i)\, D_i(m_i)\, \exp(-m_i^2\tau). \tag{29}$$

Figures 3–11 show the normalized center- and surface temperatures Θ_m and Θ_0 according to Eq. (28) with $\xi = 0$ and $\xi = 1$, respectively, and the normalized caloric mean temperature $\overline{\Theta}$ according to Eq. (29). These diagrams have been calculated by Soininen and Heikkilä [5] using the first 20 eigenvalues of the series solutions. The term $(1 - \overline{\Theta})$ corresponds to the heat released or taken up in relation to the initial enthalpy difference $\rho c_p\, V(T_I - T_\infty)$:

$$Q(t) = \rho c_p V(T_I - T_\infty) \cdot (1 - \overline{\Theta}). \tag{30}$$

The average temperature $\overline{T}$ is defined as an integral caloric mean value:

$$\overline{T} \equiv \int_V (\rho c_p T) dV \Big/ \int_V (\rho c_p) dV. \tag{31}$$

For constant properties ρc for a slab, a cylinder, and a sphere ($n = 0, 1, 2$) one obtains

$$\overline{\Theta} = (n+1) \int_0^1 \Theta(\xi)\xi^n d\xi. \tag{32}$$

The values $D_i(m_i)$ in Table 2 are calculated from Eq. (32). For sufficiently large values of time τ, the first of these values tends to

$$D_1(m_1) = \overline{\Theta}/\Theta_c. \tag{33}$$

In the limiting case $1/\mathrm{Bi} \to 0$ (the boundary condition of the first kind) the eigenvalues m_i can be found directly, and the first terms of the series in Eqs. (28) and (29) as a long-time asymptotic solution (practically for $\tau > 0.5$) reads

Slab:

$$\Theta(x,t) = \frac{4}{\pi}\cos\left(\frac{\pi}{2}\frac{x}{X}\right)\exp\left(-\left(\frac{\pi}{2}\right)^2\frac{\kappa t}{X^2}\right), \tag{34}$$

$$\overline{\Theta}(t) = \frac{2}{(\pi/2)^2}\exp\left(-\left(\frac{\pi}{2}\right)^2\frac{\kappa t}{X^2}\right). \tag{35}$$

Cylinder:

$$\Theta = 1.613 J_0\left(2.405\frac{r}{R}\right)\exp\left(-(2.405)^2\frac{\kappa t}{R^2}\right), \tag{36}$$

$$\overline{\Theta} = \frac{4}{(2.405)^2}\exp\left(-(2.405)^2\frac{\kappa t}{R^2}\right). \tag{37}$$

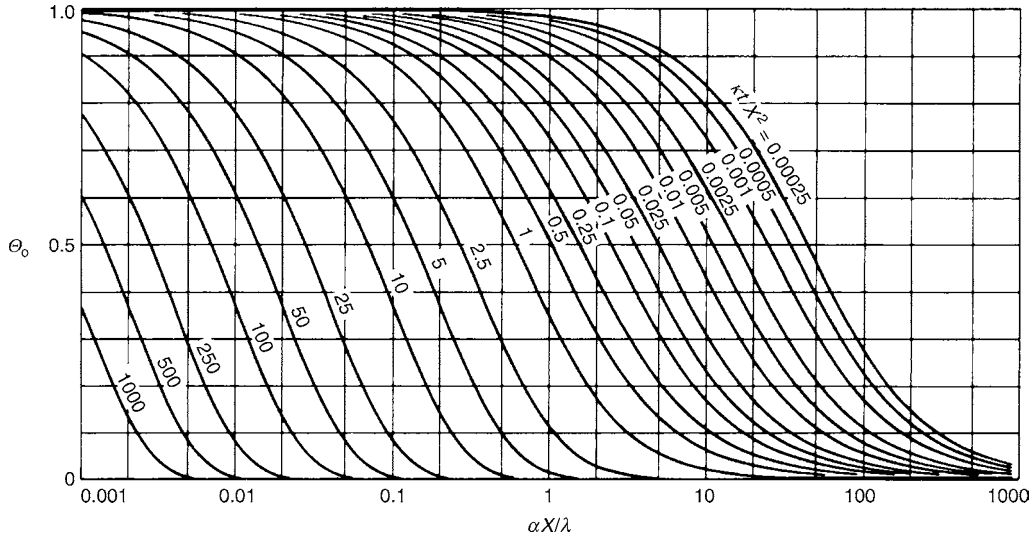
Sphere:

$$\Theta = 2\frac{\sin(\pi r/R)}{(\pi r/R)}\exp\left(-(\pi)^2\frac{\kappa t}{R^2}\right), \tag{38}$$

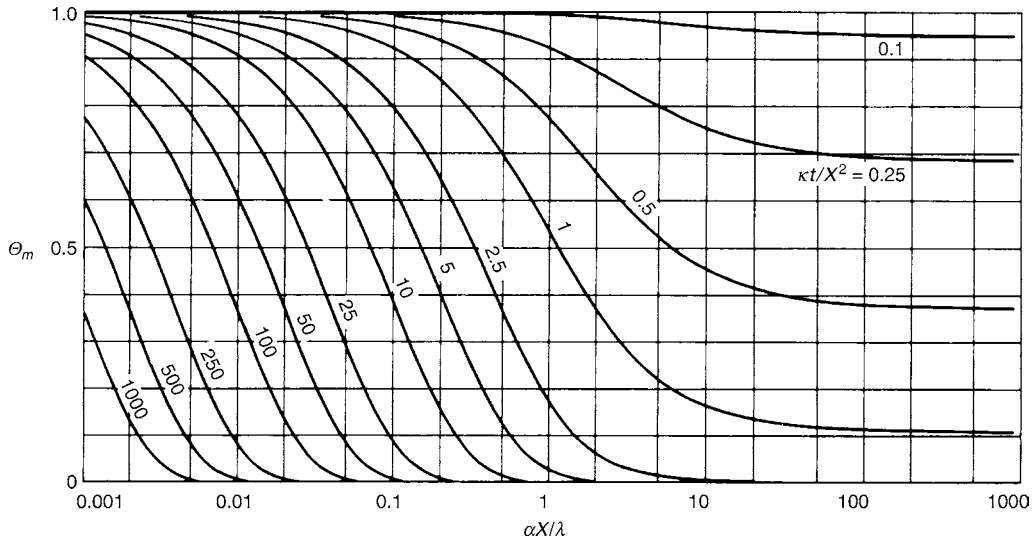
$$\overline{\Theta} = \frac{6}{(\pi)^2}\exp\left(-(\pi)^2\frac{\kappa t}{R^2}\right). \tag{39}$$

In these cases, the heat flux at the surface can also be calculated directly as in Eq. (25a):

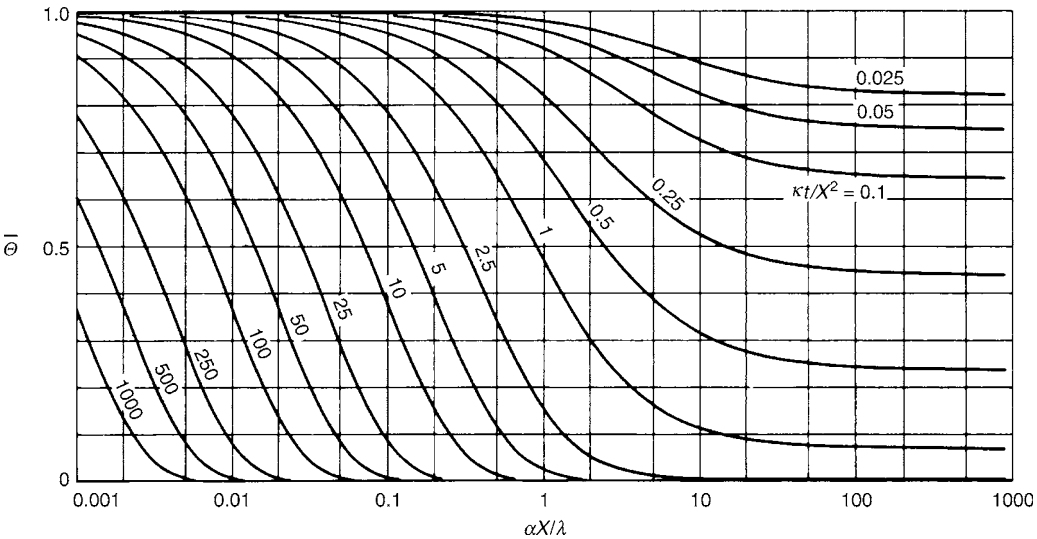
$$\dot{q}_0 = \frac{\lambda}{X/2}\exp(-(\pi/2)^2\tau)\cdot(T_I - T_\infty), \tag{40}$$



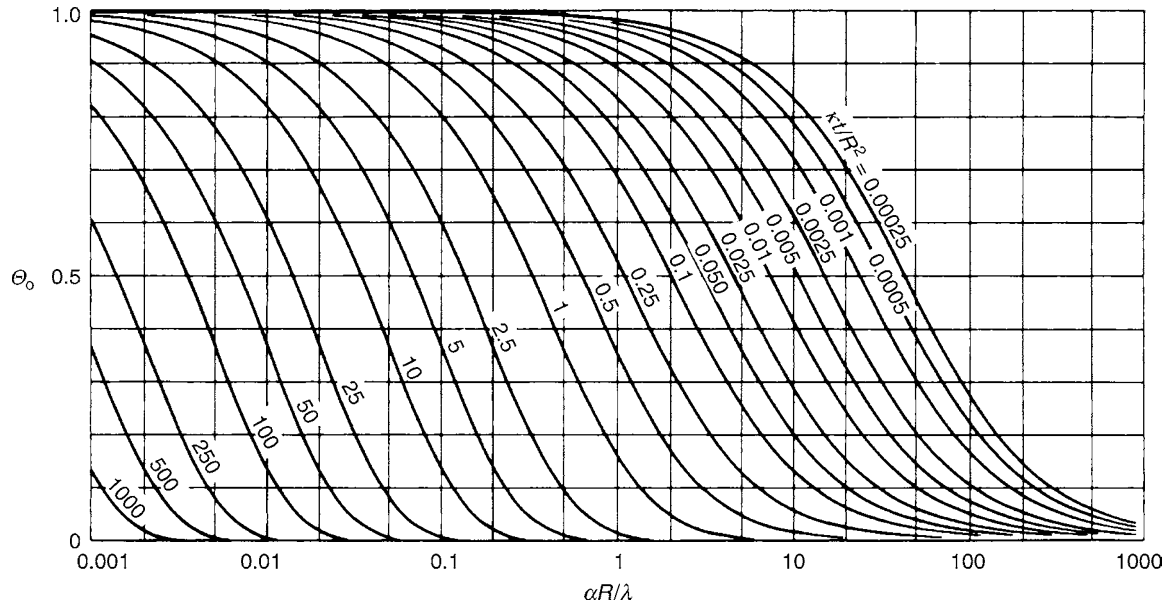
E2. Fig. 3. Normalized temperature Θ_0 at the surface of a slab.



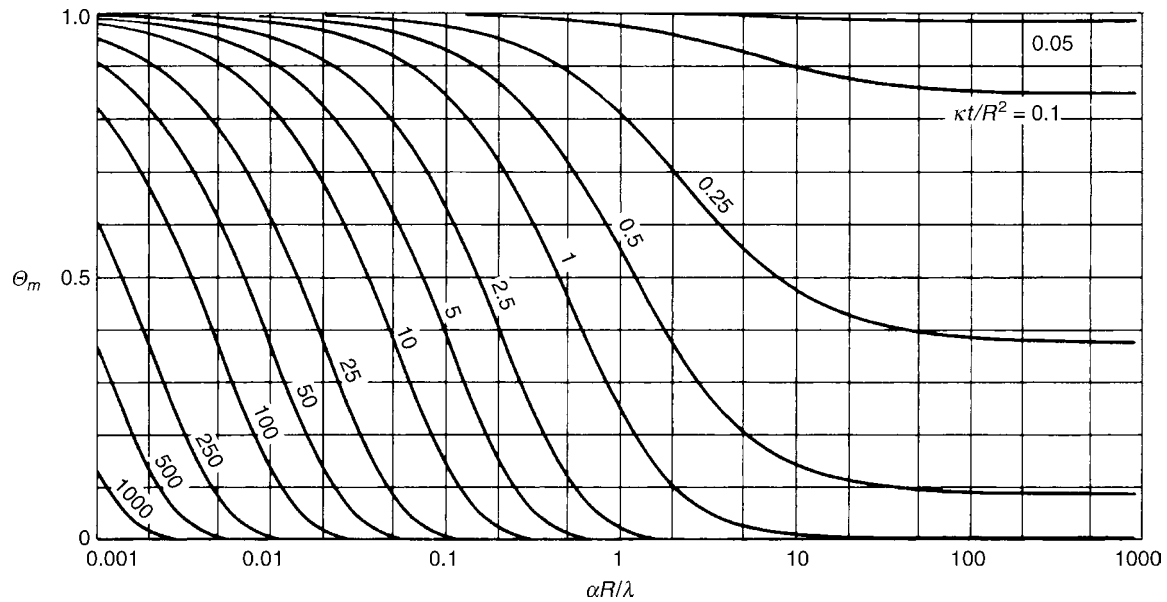
E2. Fig. 4. Normalized temperature Θ_m at the center of a slab.



E2. Fig. 5. Normalized caloric average temperature $\overline{\Theta}$ of a slab.



E2. Fig. 6. Normalized temperature Θ_0 at the surface of a cylinder.



E2. Fig. 7. Normalized temperature Θ_m at the center of a cylinder.

$$\dot{q}_0 = \frac{\lambda}{R/2}\ \exp(-(2.405)^2\tau)\cdot(T_I - T_\infty), \tag{41}$$

$$\dot{q}_0 = \frac{\lambda}{R/2}\ \exp(-(\pi)^2\tau)\cdot(T_I - T_\infty). \tag{42}$$

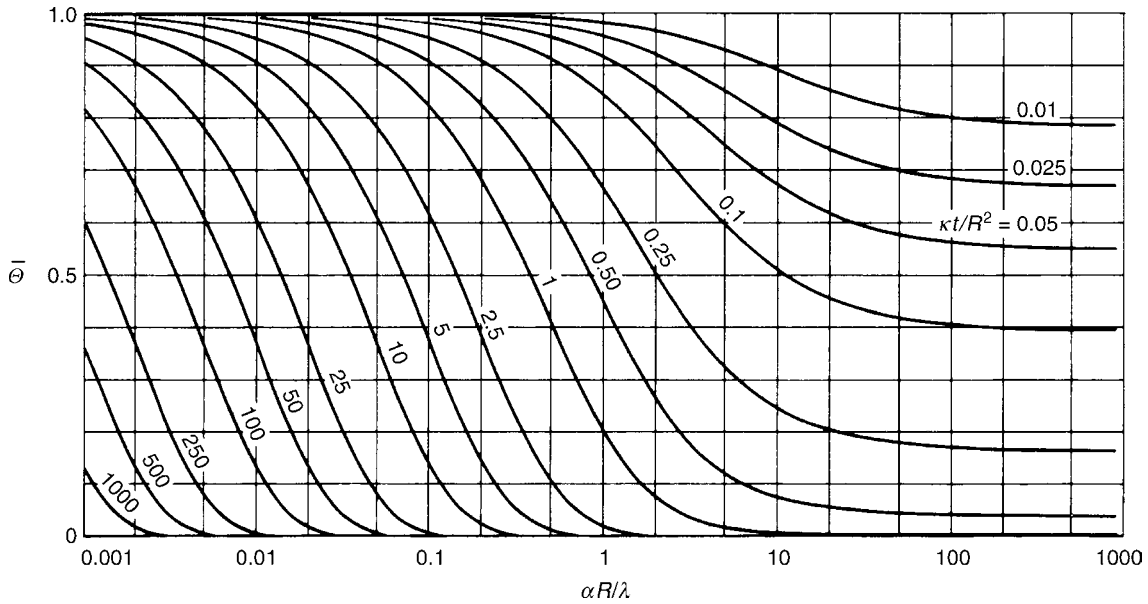
For a slab (40), a cylinder (41), and a sphere (42), $(1/\mathrm{Bi}) = 0$ and $\tau > 0.5$.

Asymptotic approximations for practical calculations of transient conduction problems – *The use of internal (time-dependent) heat transfer coefficients* – [6]:

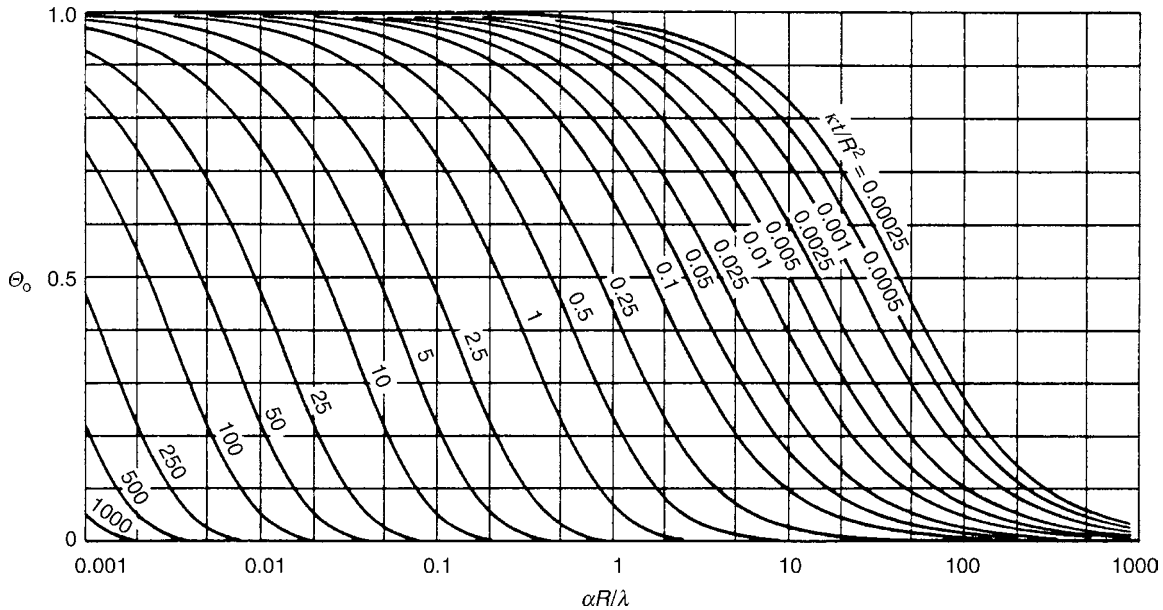
The temperature field $\Theta = \Theta(\tau, \xi, \mathrm{Bi}, a_V^*)$ can be found from the analytical solution, Eq. (28), as a functions of time, position, the outer heat transfer coefficient (in Bi), and the shape of the body. The latter enters the equation via the number $n = 0, 1, 2$, or the number $a_V^* = AR/V$ (or AX/V) that is the product of surface area and radius (or half-thickness) divided by the volume of the body, which has the values $(n+1)$, that is $a_V^* = 1, 2, 3$ for a slab, a cylinder, and a sphere, respectively.

Defining an internal heat transfer coefficient α_i for transient conduction in a stagnant body as

$$\alpha_i = \frac{\dot{Q}}{A(\overline{T} - T_0)}, \tag{43}$$



E2. Fig. 8. Normalized caloric average temperature $\overline{\Theta}$ of a cylinder.



E2. Fig. 9. Normalized temperature Θ_0 at the surface of a sphere.

which can be expressed in dimensionless form as a Nusselt number $\mathrm{Nu} = \alpha_i R/\lambda$ (or $\alpha_i X/\lambda$) by relatively simple asymptotic equations for long and for short times.

Asymptotic Nusselt numbers for long times:

$$\mathrm{Nu}_\infty = \frac{a_V^* + 2 + \mathrm{Bi}}{1 + a_V^* \mathrm{Bi}/m_1^2} \qquad \begin{array}{c|ccc} & \text{slab} & \text{cylinder} & \text{sphere} \\ a_V^* & 1 & 2 & 3 \\ m_1 & \pi/2 & 2.4048 & \pi \end{array} \quad . \tag{44}$$

Asymptotic mean Nusselt numbers for short times:

$$\mathrm{Nu}_0\sqrt{\tau} = \frac{\sqrt{\pi} + 10\mathrm{Bi}\sqrt{\tau}}{1 + 5\mathrm{Bi}\sqrt{\pi\tau}}. \tag{45}$$

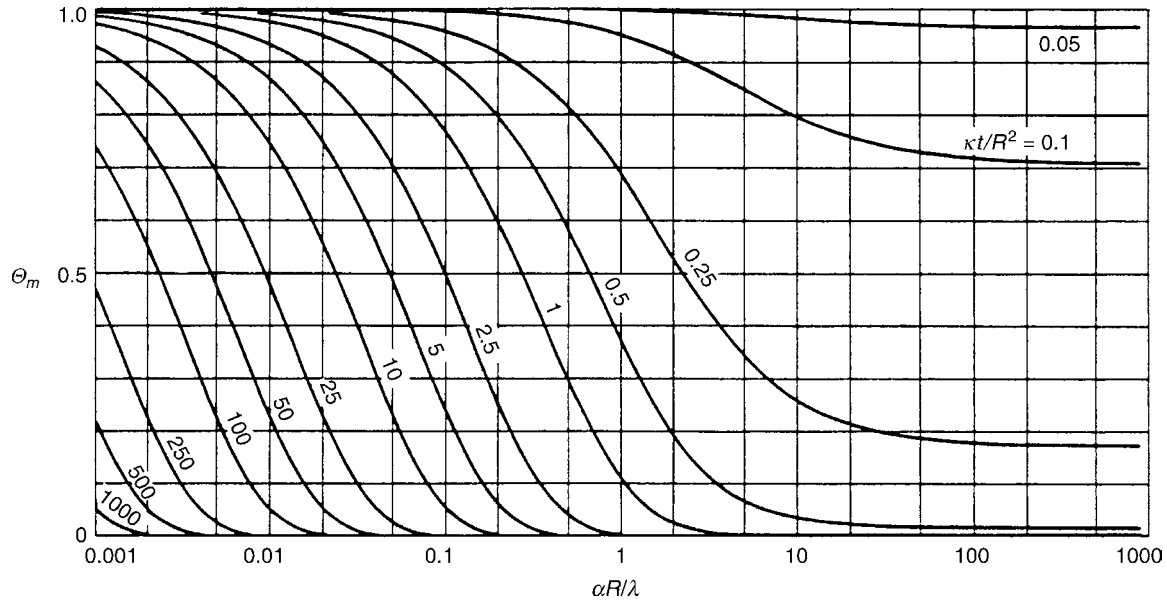
Smooth interpolation between the asymptotes (*approximately valid for all times*):

$$\mathrm{Nu} = \sqrt{\mathrm{Nu}_\infty^2 - b^2 + (\mathrm{Nu}_0 + b)^2} \qquad b = 0.2 \tag{46}$$

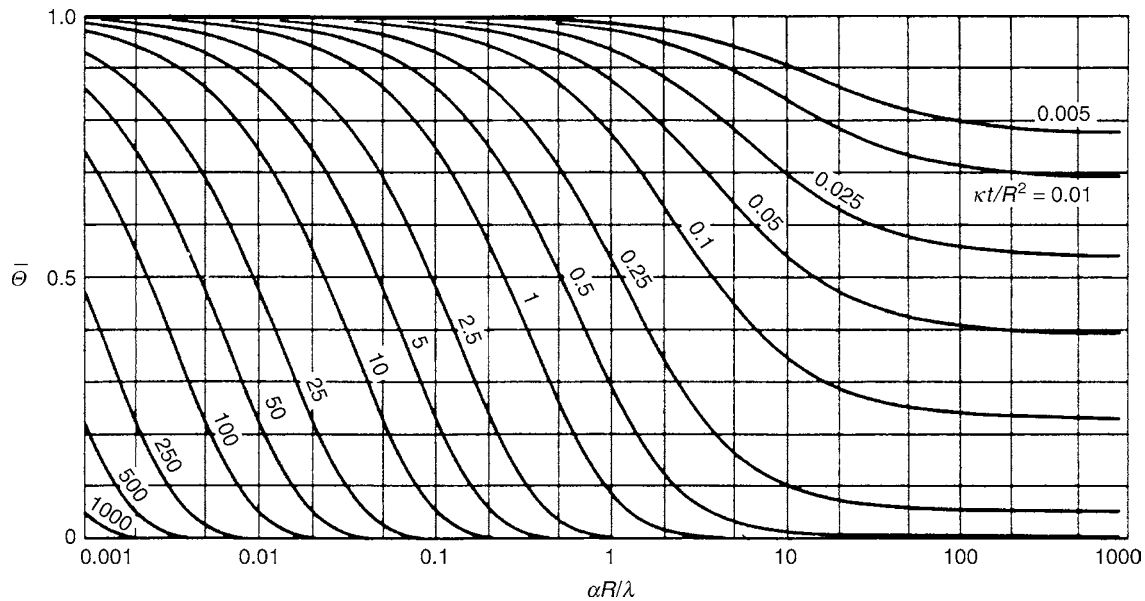
From these formulae one can now approximately calculate the average temperature $\overline{\Theta}$:

$$\overline{\Theta}(\tau) = \exp\left\{\frac{a_V^* \tau}{1/\mathrm{Bi} + 1/\mathrm{Nu}(\tau, \mathrm{Bi})}\right\} \tag{47}$$

In order to calculate also the surface temperature – from the ratio of resistances k/α_a, with $1/k = 1/\alpha_a + 1/\alpha_{it}$ – instantaneous heat transfer coefficients are needed here, no time-averaged ones as given by Eq. (45).



E2. Fig. 10. Normalized temperature Θ_m at the center of a sphere.



E2. Fig. 11. Normalized caloric average temperature $\overline{\Theta}$ of a sphere.

Instantaneous asymptotic Nusselt numbers for short times:

$$\mathrm{Nu}_{0t}\sqrt{\tau} = \frac{2.3\sqrt{\pi} + 2\mathrm{Bi}\sqrt{\tau}}{2\,(2.3 + \mathrm{Bi}\sqrt{\pi\tau})}. \tag{48}$$

Smooth interpolation between the asymptotes:

$$\mathrm{Nu}_t = \sqrt{\mathrm{Nu}_\infty^2 - b_t^2 + (\mathrm{Nu}_{0t} + b_t)^2} \qquad b_t = -0.2. \tag{49}$$

The surface temperature follows from this as

$$\Theta_0(\tau) = \Theta(\tau, \xi = 1) = \frac{\overline{\Theta}}{1 + \mathrm{Bi}/\mathrm{Nu}_t(\tau)}. \tag{50}$$

The temperature $\Theta_c = \Theta(\xi = 0)$ in the center shows a lag in its variation with time, which can be taken into account by a new time-scale $\tau_c = (\tau - \Delta\tau)$ with the variable time lag $\Delta\tau$.

$$\begin{aligned} &(0 < \Delta\tau < \Delta\tau_\infty \text{ for } 0 < \tau < \infty): \\ &\Delta\tau = \left\{1/\Delta\tau_\infty^m + 1/\tau^m\right\}^{-1/m} \end{aligned} \tag{51}$$

with

$$m = \frac{30 + \mathrm{Bi}}{10.8 + \mathrm{Bi}/4} + \frac{0.16}{\sqrt{\tau}}, \tag{52a}$$

$$\frac{1}{\Delta\tau_\infty} = 4 + \frac{6 + a_V^* + 2\mathrm{Bi}}{6 + a_V^* + (2.71 + 0.03a_V^*)\mathrm{Bi}}\,2a_V^*. \tag{52b}$$

From this, the center temperature is found with $\tau_c = (\tau - \Delta\tau)$:

$$\Theta_c(\tau) = \Theta(\tau, \xi = 0) = \exp\left\{-\frac{a_V^*\tau_c}{1/\mathrm{Bi} + 1/\mathrm{Nu}(\tau_c)}\right\}. \tag{53}$$

The argument of the exponential function in Eq. (47) is $kAt/(\rho cV)$, that is, a dimensionless time, which is called NTU (number of transfer units) in other contexts.

The deviations of the temperatures calculated from the approximate equations (44–53) compared to the exact solution in form of the Fourier's series, Eq. (28) are between +2.6% and −1% of the initial temperature difference in the most unfavorable case (for the center temperature of a sphere at large Biot numbers). The corresponding errors for the average temperature or for the surface temperature are always $< \pm 2\%$.

Example 1

An internal wall in an industrial oven consists of brickwork, 120 mm thick, with the physical properties $\lambda = 1.2$ W/mK, $c = 840$ J/kg K, and $\rho = 1600$ kg/m^3. It has a uniform initial temperature of $T_I = 370°C$. To cool it down, air of 20°C is blown into the oven. The heat transfer coefficient from the wall to the air is $\alpha_a = 10$ W/m^2 K. What are the surface, average, and center temperatures of the wall, after 2.8 h of cooling?

First, the dimensionless time τ (or the Fourier number) is calculated:

$$\tau \equiv \frac{\kappa t}{X^2} = \frac{\lambda t}{\rho c X^2} = \frac{1.2 \cdot 2.8 \cdot 3600}{1600 \cdot 840 \cdot 60^2 \cdot 10^{-6}} = 2.50.$$

The Biot number is

$$\mathrm{Bi} \equiv \frac{\alpha_a X}{\lambda} = \frac{10 \cdot 60 \cdot 10^{-3}}{1.2} = 0.50.$$

From the approximate equations (44–53) one calculates for a slab with $a_V^* = 1$, $m_1 = \pi/2$, and for $\mathrm{Bi} = \alpha_a X/\lambda = 0.5$ and $\tau = \kappa t/X^2 = 2.50$:

$\mathrm{Nu}_\infty = 2.91$, $1/\Delta\tau_\infty = 5.912$, $m = 2.893$, $\tau_c = 2.331$.

$\mathrm{Nu}_t = 2.939$, $\Theta_0 = 0.292$, $T_0 = (20 + 350{\cdot}0.292)°C = 122°C$.

$\mathrm{Nu}(\tau) = 3.059$, $\overline{\Theta} = 0.341$, $\overline{T} = (20 + 350{\cdot}0.341)°C = 139°C$.

$\mathrm{Nu}(\tau_m) = 3.069$, $\Theta_m = 0.367$, $T_c = (20 + 350{\cdot}0.367)°C = 148°C$.

From the diagrams, Figs. 3–5, the normalized average, surface, and center temperatures can be read for Bi = 0.5, and Fo = 2.5 as well. The results are practically the same.

3.1.2 Multi-dimensional Heat Flux

Solutions for some simple multi-dimensional temperature fields can be obtained by multiplication of the appropriate one-dimensional solutions.

In Cartesian coordinates, the temperature field $\Theta(x, y, z, t)$ with the initial condition

$$\Theta(x, y, z, 0) = 1 \tag{54}$$

and the boundary conditions

$$\left.\begin{aligned} \left(\frac{\lambda}{\alpha_1}\frac{\partial\Theta}{\partial x} + \Theta\right)_{|x|=X} &= 0 \\ \left(\frac{\lambda}{\alpha_2}\frac{\partial\Theta}{\partial y} + \Theta\right)_{|y|=Y} &= 0 \\ \left(\frac{\lambda}{\alpha_3}\frac{\partial\Theta}{\partial z} + \Theta\right)_{|z|=Z} &= 0 \end{aligned}\right\} \; t > 0 \tag{55}$$

is given by

$$\Theta(x, y, z, t) = \Theta_1(x, t) \cdot \Theta_2(y, t) \cdot \Theta_3(z, t), \tag{56}$$

where Θ_1, Θ_2, and Θ_3 are solutions of the corresponding one-dimensional problems with the initial and boundary conditions as given earlier.

Examples

For the quarterspace ($x > 0$, $y > 0$, $-\infty < z < \infty$), that is, a two-dimensional rectangular corner, with a boundary condition of the first kind, one obtains

$$\Theta(x, y, t) = \mathrm{erf}\,\frac{x}{\sqrt{\kappa t}}\,\mathrm{erf}\,\frac{y}{\sqrt{\kappa t}} \tag{57}$$

(see Eq. (24) for the one-dimensional solution).

For the octant ($x > 0$, $y > 0$, $z > 0$), that is, a three-dimensional rectangular corner with a boundary condition of the first kind, the field is

$$\Theta(x, y, z, t) = \mathrm{erf}\,\frac{x}{\sqrt{\kappa t}}\,\mathrm{erf}\,\frac{y}{\sqrt{\kappa t}}\,\mathrm{erf}\,\frac{z}{\sqrt{\kappa t}}. \tag{58}$$

For the (infinitely) long bar of rectangular cross section ($-X < x < X$, $-Y < y < Y$, $-\infty < z < \infty$), with a boundary condition of the third kind, one finds

$$\Theta(x, y, t) = \Theta_1(x, t) \cdot \Theta_2(y, t) \tag{59}$$

$\Theta_1(x, t)$ from Eq. (28) (slab), $\Theta_2(y, t)$ from Eq. (28) with $x \to y$, $X \to Y$.

And for the rectangular parallelepiped ($-X < x < X$, $-Y < y < Y$, $-Z < z < Z$):

$$\Theta(x, y, z, t) = \Theta_1(x, t) \cdot \Theta_2(y, t) \cdot \Theta_3(z, t) \tag{60}$$

$\Theta_{1,2,3}$ from Eq. (28) (slab).

In cylinder coordinates, the field $\Theta(r, z, t)$, with the initial condition

$$\Theta(r, z, 0) = 1 \tag{61}$$

and the boundary conditions

$$\left.\begin{aligned} \left(\frac{\lambda}{\alpha_1}\frac{\partial\Theta}{\partial r} + \Theta\right)_{|r|=R} &= 0 \\ \left(\frac{\lambda}{\alpha_3}\frac{\partial\Theta}{\partial z} + \Theta\right)_{|z|=Z} &= 0 \end{aligned}\right\} \; t > 0 \tag{62}$$

the temperature field within a finite cylinder ($0 \le r < R$, $-Z < z < Z$) is

$$\Theta(r, z, t) = \Theta_1(r, t) \cdot \Theta_2(z, t) \tag{63}$$

with

$\Theta_1(r, t)$ from Eq. (28) (cylinder)

$\Theta_2(z, t)$ from Eq. (28) (slab with $x \to z$, $X \to Z$).

Especially the last two cases, the parallelepiped, with the special case $X = Y = Z$ (cube), and the finite cylinder are of practical importance. A mathematical proof that the aforementioned multiplicative expressions are in fact solutions of the differential equation (3a) and the given boundary conditions may be found in the textbooks [1, 4]. The simple multiplication of one-dimensional solutions to get the multi-dimensional

solution is also valid for the average temperature $\overline{\Theta}$, that is, one can also apply the approximate solution from Eq. (47) correspondingly.

Example 2

An aqueous solid foodstuff ($\kappa = 0.16{\cdot}10^{-6}$ m^2/s; $\lambda = 0.6$ W/mK) in thin-walled cylindrical cans of height H ($=2X$) = 50 mm and diameter D ($=2R$) = 100 mm is to be sterilized in hot water of $T_\infty = 150$°C (under pressure). The heat transfer coefficient from the water to the cans is estimated to be $\alpha_a = 600$ W/m^2 K. How long must the cans be kept in the hot water, if they enter the bath at $T_I = 20$°C and shell reach an average temperature of 100°C?

For the finite cylinder from Eq. (63) one gets with

$\overline{\Theta}_1(t) = \overline{\Theta}\left(\frac{\kappa t}{R^2}, \frac{\alpha_a R}{\lambda}\right)$, infinite cylinder of diameter $2R$,

$\overline{\Theta}_2(t) = \overline{\Theta}\left(\frac{\kappa t}{X^2}, \frac{\alpha_a X}{\lambda}\right)$, slab of thickness $2X$.

As the time is the unknown here, the solution could be found only by iteration from the diagrams (Figs. 5 and 8) or from Eq. (29).

Even the approximate solution equation (47) cannot be solved explicitly for the time. Its iterative solution, however, is rather simple and converges quite rapidly. With the time $\tau = \tau_2 = \kappa\, t/X^2$ (with the half-thickness of the slab) as a variable, and $\tau_1 = \kappa\, t/R^2 = (H/D)^2\, \tau$ (cylinder) for $H/D = 0.5$, one finds, with $\mathrm{Bi}_2 = \alpha_a X/\lambda = 600{\cdot}0.025/0.6 = 25$, $\mathrm{Bi}_1 = \alpha_a\, R/\lambda = 50$, and $\tau_1 = 0.25\tau$, the values $\bar{\Theta}_2(\tau, \mathrm{Bi}_2)$ and $\bar{\Theta}_1(\tau_1, \mathrm{Bi}_1)$ from Eq. (47) and the product $\bar{\Theta}(\tau) = \bar{\Theta}_2\ (\tau, \mathrm{Bi}_2)\ \bar{\Theta}_1(\tau_1, \mathrm{Bi}_1)$ until the required normalized average temperature of $\bar{\Theta}(\tau) = (100 - 150)/(20 - 150) = 50/130 = 0.3846$ is reached. The final values are shown below:

	a_V^*	Bi	τ	Θ_c center	$\overline{\Theta}$ average	Θ_0 surface
$\Theta_{slab} = \Theta_2$	1	25	**0.1481**	0.8988	0.5983	0.0613
$\Theta_{cyl} = \Theta_1$	2	50	0.0370	0.9978	0.6428	0.0493
$\Theta_1 \cdot \Theta_2$				0.8968	**0.3846**	0.0030

From this the time required is found as $t = \tau X^2/\kappa = 0.1418{\cdot}25^2/0.16$ s = 578 s. So a can ought to be kept for about 10 min in the hot water, to heat its content to the required average temperature of 100°C. In the center, however, the foodstuff is only heated to $(150 - 130 \cdot 0.8968)$°C = 33.4°C, while it had already reached 149°C at the outer wall.

3.1.3 Coupled Systems

It is often found that boundary conditions cannot easily specified immediately at the surface of a single body: the volume under consideration, for which the boundary conditions can be given, may contain several bodies with different physical properties (namely λ, ρ, c_p). Again assuming that these properties are constant within each of these several bodies, the Eq. (3a) has to be applied to each of these separately. At the interfaces between these bodies the fields are coupled by the interfacial condition equations (64) and (65).

$$T_i = T_{i+1} \text{ (at the interface of body } i \text{ and } i+1). \tag{64}$$

For real interfaces of solid bodies this condition need not be strictly satisfied. Due to the incompleteness of contact, roughness, and oxide and sorptive layers, additional contact resistances might require appropriate modifications of Eq. (64)

$$\lambda_i \left(\frac{\partial T}{\partial n}\right)_i = \lambda_{i+1} \left(\frac{\partial T}{\partial n}\right)_{i+1} \text{ (at the interface of body } i \text{ and } i+1). \tag{65}$$

The unsteady change of the conductivity, λ, at the interface results in corresponding unsteady changes in the temperature gradients. The heat fluxes entering and leaving the interface have to be the same (see Eq. (65)), because the interface has no mass and therefore, no heat capacity.

A prototype example of this kind is the contact of two semi-infinite bodies of different initial temperatures T_1 and T_2 with the plane $x = 0$ as their common interface (The same is valid for the short-time contact of two bodies of finite thickness) (Fig. 12).

Instantaneously (at least within the frame of Fourier's theory) the temperature at the interface changes to the common contact temperature T_0. Thus, for each of the two temperature fields, a boundary condition of the first kind applies. The solutions from Eq. (24) are

$$\frac{T - T_0}{T_1 - T_0} = -\mathrm{erf}\,\frac{x}{\sqrt{\kappa_1 t}} \quad (x < 0), \tag{66}$$

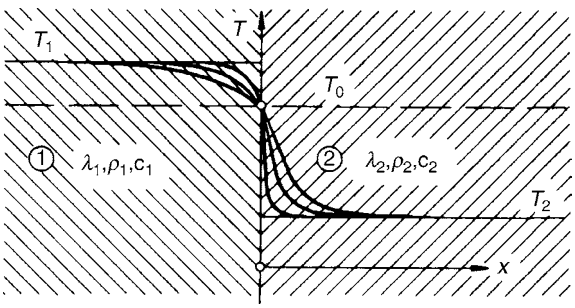
$$\frac{T - T_0}{T_2 - T_0} = \mathrm{erf}\,\frac{x}{\sqrt{\kappa_2 t}} \quad (x > 0). \tag{67}$$

The so far unknown contact temperature T_0 follows from these solutions with Eq. (65)

$$T_0 = \frac{T_1 + \vartheta_{21} \cdot T_2}{1 + \vartheta_{21}}, \quad \vartheta_{21} = \frac{\sqrt{\lambda \rho c}_2}{\sqrt{\lambda \rho c}_1}. \tag{68}$$

The contact temperature (for given initial temperatures) depends on the ratio ϑ_{21} of the two coefficients $\sqrt{\lambda \rho c}_{1,2}$ only.

T_0 is always closer to the initial temperature of the body with the higher of these coefficients.



E2. Fig. 12. Temperature field during contact of two semi-infinite solids.

The temperature differences $(T_1 - T_0)$ and $(T_0 - T_2)$ are inversely related to the corresponding coefficients:

$$\frac{T_1 - T_0}{T_0 - T_2} = \vartheta_{21}. \tag{68a}$$

This is the reason that wood feels cooler (warmer) than metals if both materials have the same temperature above (below) the hand temperature.

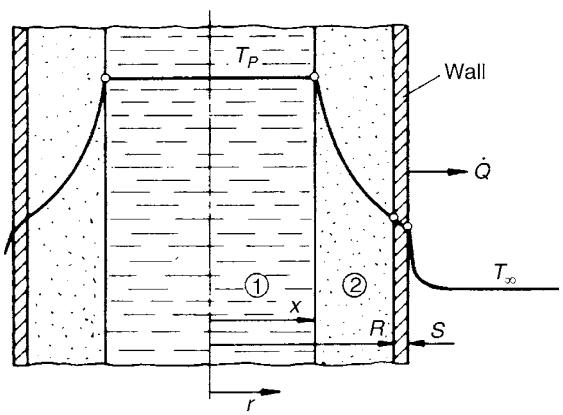
Solutions for other coupled temperature fields, as occurring in multilayered bodies, or in solids in contact with a well-stirred fluid of limited heat capacity, can be found in [1, 2]. Analytical solutions for such cases can often be obtained via the method of Laplace transforms.

3.1.4 Phase Change – Melting and Solidification of Geometrically Simple Bodies

If inside a body a phase-change point, T_P, is crossed, the isothermal surface, $T = T_P$, subdivides the body into two regions of different states (or two phases). In this case, there are also coupled systems, as in the previous Sect. 3.1.3. As an additional complication, however, the position of the interface changes with time, and at this interphase there is an enthalpy change at a constant temperature (for pure components). Exact analytical solutions for this kind of problem are known only for a limited number of special cases [1, 3, 4]. The details of the coupled temperature fields are not usually practically important in these cases, but the times for complete or partial solidification (or melting) of a body. Solidification times can be approximately calculated in a relatively simple and straightforward way if the enthalpy of the solidified shell can be neglected against the phase change enthalpy. In the following only the solidification is treated, the results may, however, be applied to melting problems as well.

Figure 13 shows the problem. It is assumed that the liquid (subscript "1") is already at the phase change temperature T_P at the beginning. The energy balance for the liquid under these conditions is

$$-\dot{Q} \approx \rho_1 \Delta h_{12} \frac{\mathrm{d}V_1}{\mathrm{d}x}\frac{\mathrm{d}x}{\mathrm{d}t}, \tag{69}$$



E2. Fig. 13. Phase change: solidification or melting of a simply shaped body.

where x denotes the position, and $\mathrm{d}x/\mathrm{d}t$ the velocity of the moving phase boundary. The change of enthalpy of the solid shell (subscript "2") is neglected during the solidification process ($c_{p2}\,(T_P - T_\infty) << \Delta h_{12}$). In this case it may be assumed that a (quasi-) steady-state temperature profile exists in the solid shell at each instant. The heat flow $\dot{Q}$ is to be expressed as

$$\dot{Q} = kA \cdot (T_P - T_\infty) \tag{70}$$

with

$$\frac{1}{k} = \frac{1}{\alpha_i(x)} + \underbrace{\left(\frac{s}{\lambda}\right)_{\text{wall}} + \frac{1}{\alpha_a}}$$

or

$$\frac{1}{k} = \frac{1}{\alpha_i(x)} + \frac{1}{k_a} \tag{71}$$

The inner conductive resistance $1/\alpha_i$ for the quasi-steady-state temperature profiles is

$$\frac{1}{\alpha_i(x)} = \frac{R}{\lambda_2}\left(1 - \frac{x}{R}\right) \text{ for a slab,} \tag{72}$$

$$\frac{1}{\alpha_i(x)} = \frac{R}{\lambda_2}\ln\left(\frac{R}{x}\right) \text{ for a cylindrical shell,} \tag{73}$$

$$\frac{1}{\alpha_i(x)} = \frac{R}{\lambda_2}\left(\frac{R}{x} - 1\right) \text{ for a spherical shell.} \tag{74}$$

From Eqs. (69–74) an ordinary differential equation for the velocity of the interface, $\mathrm{d}x/\mathrm{d}t$, is obtained. In dimensionless form, it reads

$$1 + \mathrm{Ph}\left\{\frac{1}{\mathrm{Bi}} + \frac{1}{\mathrm{Nu}(\xi)}\right\}\xi^n \frac{\mathrm{d}\xi}{\mathrm{d}\tau} = 0, \tag{75}$$

where Ph is a phase change number

$$\mathrm{Ph} \equiv \frac{\rho_1 \Delta h_{12}}{\rho_2 c_{p2}(T_P - T_\infty)}, \tag{76}$$

Bi is the Biot number

$$\mathrm{Bi} \equiv \frac{k_a R}{\lambda_2}, \tag{77}$$

ξ is the normalized coordinate of the position of the interface

$$\xi \equiv \frac{x}{R}, \tag{78}$$

τ is the dimensionless time (Fourier number)

$$\tau \equiv \frac{\lambda_2 t}{\rho_2 c_{p2} R^2} \tag{79}$$

and the dimensionless internal resistance $1/\mathrm{Nu}(\xi)$ follows from Eqs. (72–74):

$$\frac{1}{\mathrm{Nu}(x)} = \begin{cases} 1 - \xi & \text{slab} & n = 0, \\ -\ln \xi & \text{cylinder} & n = 1, \\ 1/\xi - 1 & \text{sphere} & n = 2. \end{cases} \tag{80}$$

The integration of Eq. (75) with Eq. (80) in the limits $\xi = 1$ to $\xi = 0$ gives the time of solidification τ_s. Due to the neglected change of enthalpy of the solid shell, this calculation gives a minimum time of solidification $\tau_{s,min}$:

$$\tau_{s,min} = \frac{Ph}{n+1}\left\{\frac{1}{2}+\frac{1}{Bi}\right\}. \tag{81}$$

Real times of solidification (or melting) are as much higher than the minimum calculated from Eq. (81), the smaller the phase change number Ph and the bigger the Biot number Bi is. The ratio $\tau_s/\tau_{s,min}$, that is, the factor by which the minimum time is to be multiplied to get the real solidification time is shown in Fig. 14 for slab ($n = 0$), cylinder ($n = 1$), and sphere ($n = 2$) versus $(n + 1)$/Ph, with Bi as a parameter.

There is an exact analytical solution for the slab (Neumann's solution [1]):

$$\tau_{s,plate}(Bi \to \infty) = \frac{1}{4\nu^2}, \tag{82}$$

where the parameter ν is to be calculated implicitly from

$$Ph\sqrt{\pi}\cdot \nu e^{\nu^2}\operatorname{erf}\nu = 1. \tag{83}$$

Values calculated from Eqs. (82) and (83) are shown in Fig. 14 as the open circles. The curves in this figure were calculated from an analytical approximation as shown in the figure. For the cylinder and the sphere the broken lines in Fig. 14 are based on values numerically calculated by Tao [8].

Example 3

For freezing of water (or substances containing high amounts of water, such as many foodstuffs) at a temperature of the refrigerant of $T_\infty = -18°C$, the phase change number, with the physical properties:

$\rho_1 = 1000$ kg/m^3, $\rho_2 = 917$ kg/m^3, $\Delta h_{12} = 333$ kJ/kg, $c_{p2} = 2.05$ kJ/kg K, and $T_p = 0°C$, becomes

$$Ph = \frac{1000\cdot 333}{917\cdot 2.05\cdot(0-(-18))} = 9.84.$$

And the reciprocal is 1/Ph = 0.102. The freezing time can therefore be well calculated from the simple equation (81). The correction required, even in the worst case (sphere, Bi = ∞), remains below 15% (see Fig. 16). The freezing time of a plane shell of thickness X (with the heat removal over one side and a high overall heat transfer coefficient k_a) is

$$t_{s,min}(Bi = \infty) = \frac{\rho_2 c_{p2}}{\lambda_2}\frac{1}{2}X^2\frac{\rho_1\Delta h_{12}}{\rho_2 c_{p2}(T_P - T_\infty)}.$$

With the data given earlier, and with $\lambda_2 = 2.2$ W/(K m) this results in

$$t_{s,min} = 4.2\cdot\left(\frac{X}{mm}\right)^2 s \quad (T_\infty = -18°C,\ k_a >> \lambda_2/X).$$

A layer of water of 10 mm thickness takes at least 420 s, or 7 min, to freeze under the given conditions. To reach a frozen layer of 100 mm the time needed is 4.2 10^4 s = 11 h 40 min.

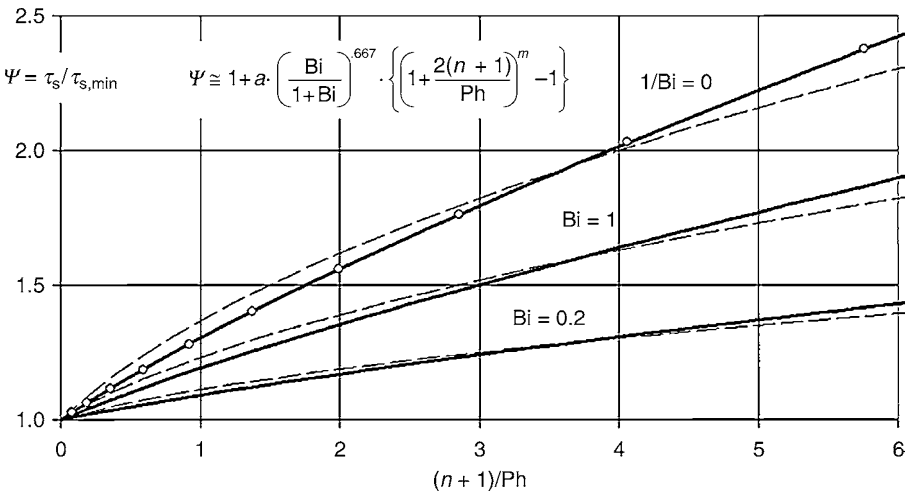
Much lower values of the phase change number, Ph, than those for water are found for metals and for organic materials. From [7] one finds for example, at $T_\infty = 20°C$

	Tin	Aluminum	Copper	Steel
Ph ≈	1.1	0.54	0.40	0.27

The required corrections of the minimum solidification time become considerably greater in these cases. Because of the high conductivity of the metals, the Biot number is usually small, however, so that the corrections again tend to be not greater than 1.

3.2 Periodic Change of Temperature of the Surroundings

Another boundary condition playing an important role in some applications is the periodic change of the temperature of the surroundings. Examples are the daily and annual changes of solar irradiation on soil and buildings, the periodic thermal load of cylinder walls of combustion engines, the temperature



E2. Fig. 14. Ratio of the time of solidification to the minimum time of solidification. Circles: Neumann's solution. Full lines: $a = 0.224$, $m = 0.778$ (slab), broken lines: $a = 0.5$, $m = 0.5$ (cylinder and sphere).

control (on–off control) by thermostats, and the periodic heat transfer in regenerators.

A simple form to specify boundary conditions of this kind is to prescribe the temperature of the surroundings (boundary condition of the third kind) as a harmonic oscillation around a constant average T_{av}, with a constant amplitude ($T_{\infty,\,max} - T_{av}$):

$$T_\infty(t) = T_{av} + (T_{\infty,max} - T_{av})\sin(\omega t). \tag{84}$$

Assuming that this boundary condition has already been maintained long enough so that the disturbances from an initial condition vanish ($t >> t_P$, with $t_P = 2\pi/\omega$), the temperature distribution inside the body becomes

$$T(x,t) = T_{av} + (T_{\infty,max} - T_{av})\hat{A}\sin(\omega t + \varphi). \tag{85}$$

Amplitude $\hat{A}$ and phase φ of this temperature wave are functions of the normalized distance from the center ξ (see Eq. (11)), the Biot number Bi (Eq. (13)), and a number M defined as

$$M \equiv \sqrt{\frac{\pi R^2}{\kappa\, t_P}} \quad \text{or} \quad M \equiv \sqrt{\frac{\pi X^2}{\kappa\, t_P}} \tag{86}$$

which might be seen as (the square root of) a reciprocal Fourier number with the time of a period $t_P = 2\pi/\omega$. For small values of M, that is, for slow changes of the temperature of the surroundings (with a great time period $t_P >> \pi R^2/\kappa$), the amplitude $\hat{A}$ is close to 1 and the phase φ is close to 0. The temperatures inside the body practically completely follow the oscillations of the surroundings. For large values of M, that is, for fast changes of the surrounding temperatures the amplitude $\hat{A}$ greatly decreases from the surface ($\xi = 1$) to the center ($\xi = 0$) of the body, accompanied by a similarly increasing negative phase lag in this direction. For sufficiently large values of M only a small zone under the surface of the body can follow the outer temperature oscillations.

The analytical expressions for the amplitude and the phase can be written for a slab, a cylinder, and a sphere in the general form

$$\hat{A}(\xi, M, \mathrm{Bi}) = \sqrt{\frac{F_R^2(M\xi) + F_I^2(M\xi)}{G_R^2(M,\mathrm{Bi}) + G_I^2(M,\mathrm{Bi})}}, \tag{87}$$

$$\varphi(\xi, M, \mathrm{Bi}) = \arctan\left(\frac{F_I G_R - F_R G_I}{F_R G_R + F_I G_I}\right). \tag{88}$$

The meaning of the functions F_R, F_I, G_R, and G_I is given in Table 4. Figures 15–20 show the amplitudes and phases at the surface of the body ($\xi = 1$) as a function of M with $\mathrm{Bi}_M \equiv (\alpha_a/\lambda)\sqrt{\kappa\, t_P/\pi}$ as a parameter for slab (15, 16), cylinder (17, 18), and sphere (19, 20).

Due to the outer heat transfer resistance, $1/\alpha_a$, the harmonic oscillation of the temperature of the surroundings (according to Eq. (84)) is transferred to the surface with a reduced amplitude and a negative phase lag as shown in Fig. 21:

$$T_0(x,t) = T_{av} + (T_{\infty,max} - T_{av})\hat{A}_0\sin(\omega t + \varphi_0). \tag{89}$$

The time lag of the surface temperature against the temperature of the surroundings can be as large as one quarter of one time period in the extreme case of very thin bodies ($M \to 0$) and poor outer heat transfer ($\mathrm{Bi}/M \to 0$) ($\varphi_0 = -\pi/2$). In that case, the amplitude of the surface temperature oscillation, however, tends to zero.

The amplitudes and phases in the center of a body can be read from Figs. 22 and 23. So the most important quantities of the temperature field are determined.

For large values of $M\xi$ (a semi-infinite body) Eqs. (87) and (88) can be simplified with

$$\eta \equiv M(1-\xi) = \sqrt{\frac{\pi}{\kappa\, t_P}}\, y \tag{90}$$

with the coordinate y inwardly directed, with the origin at the surface, and

$$\mathrm{Bi}_M \equiv \frac{\alpha_a}{\lambda}\sqrt{\frac{\kappa\, t_P}{\pi}} \tag{91}$$

to

$$\hat{A}(\eta, \mathrm{Bi}_M) = \frac{\mathrm{e}^{-\eta}}{\sqrt{1 + 2/\mathrm{Bi}_M + 2/\mathrm{Bi}_M^2}}, \tag{92}$$

$$\phi(\eta, \mathrm{Bi}_M) = -\left(\eta + \arctan\frac{1}{1 + \mathrm{Bi}_M}\right). \tag{93}$$

E2. Table 4. Functions to calculate the amplitude and the phase from Eqs. (87) and (88) at a periodic change of the temperature of the surroundings

	Slab	Cylinder[a]	Sphere

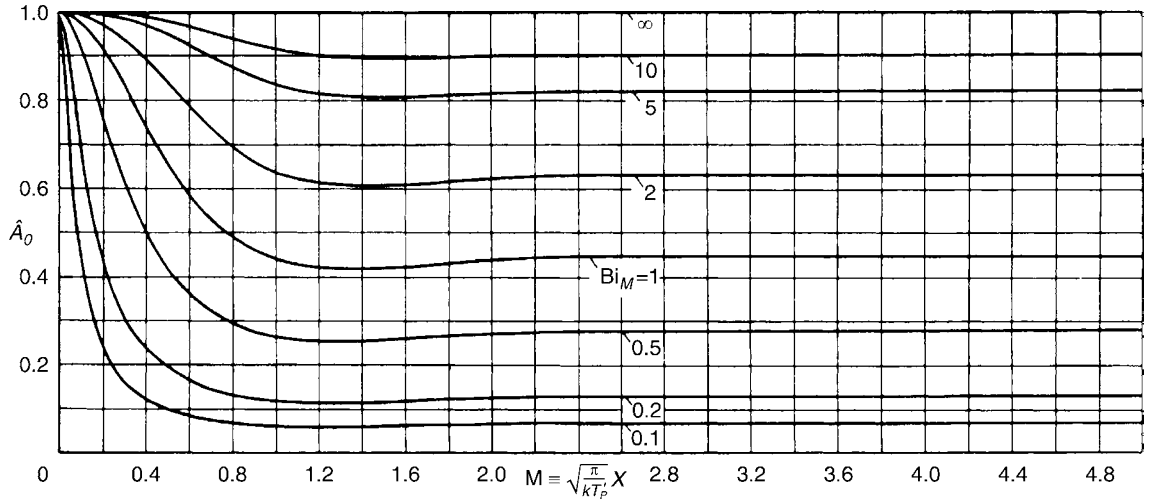
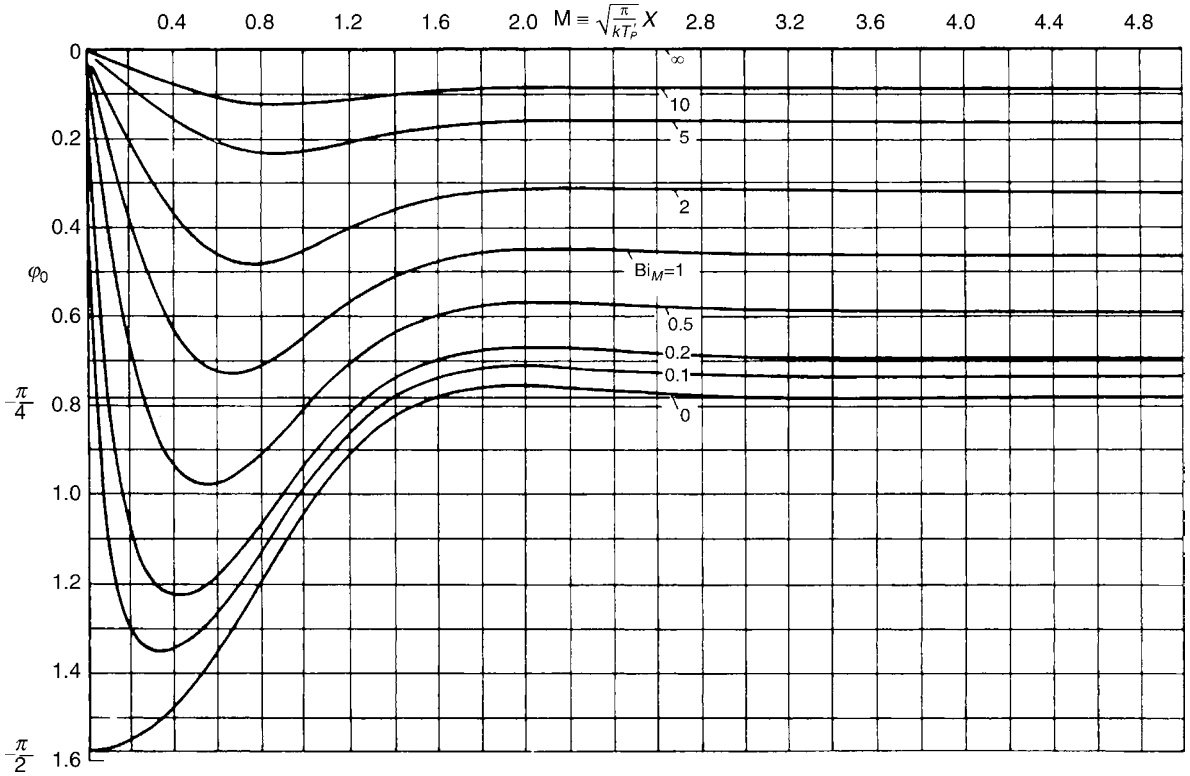
$\left.\dfrac{\mathrm{d}F_I}{\mathrm{d}(M\xi)}\right\|_{\xi=1}$	$\cosh\,M\sin\,M$ $+\sinh\,M\cos\,M$	$\mathrm{bei}_1\left(\sqrt{2}M\right) + \mathrm{ber}_1\left(\sqrt{2}M\right)$ $\left[= \sqrt{2}\,\mathrm{bei}'\left(\sqrt{2}M\right)\right]$	$\sinh M\sin M + \left(\cos M - \dfrac{\sinh M}{M}\right)\cos M$

$G_R(M,\,\mathrm{Bi}) \equiv \left\{F_R(M\xi) + \dfrac{M}{\mathrm{Bi}}\dfrac{\mathrm{d}F_R}{\mathrm{d}(M\xi)}\right\}_{\xi=1}$ $\quad G_I(M,\,\mathrm{Bi}) \equiv \left\{F_I(M\xi) + \dfrac{M}{\mathrm{Bi}}\dfrac{\mathrm{d}F_I}{\mathrm{d}(M\xi)}\right\}_{\xi\approx 1}$

[a]Tables and graphs of the functions ber, bei, ber_1, bei_1 (Kelvin's functions) can be found in [14] and [15]



E2. Fig. 15. Amplitudes $\hat{A}_0$ of the temperature wave at the surface of a slab as functions of M, with the parameter $\mathrm{Bi}_M \equiv (\alpha_a/\lambda)\sqrt{\kappa t_P/\pi}$.



E2. Fig. 16. Phase shift φ_0 of the temperature wave at the surface of a slab as functions of M, with the parameter $\mathrm{Bi}_M \equiv (\alpha_a/\lambda)\sqrt{\kappa t_P/\pi}$.

With the periodic boundary condition, Eq. (84), the direction of heat flux is changed after each half-period. The instantaneous heat flux changes, as the temperature, in a harmonic oscillation. Integrating over a half-period gives the amount of heat stored during this time span as internal energy, and which is given back to the surroundings within the next half-period. Using the abbreviations,

$$F'_R \equiv \left.\frac{\mathrm{d}F_R(M\xi)}{\mathrm{d}(M\xi)}\right|_{\xi=1}, \tag{94}$$

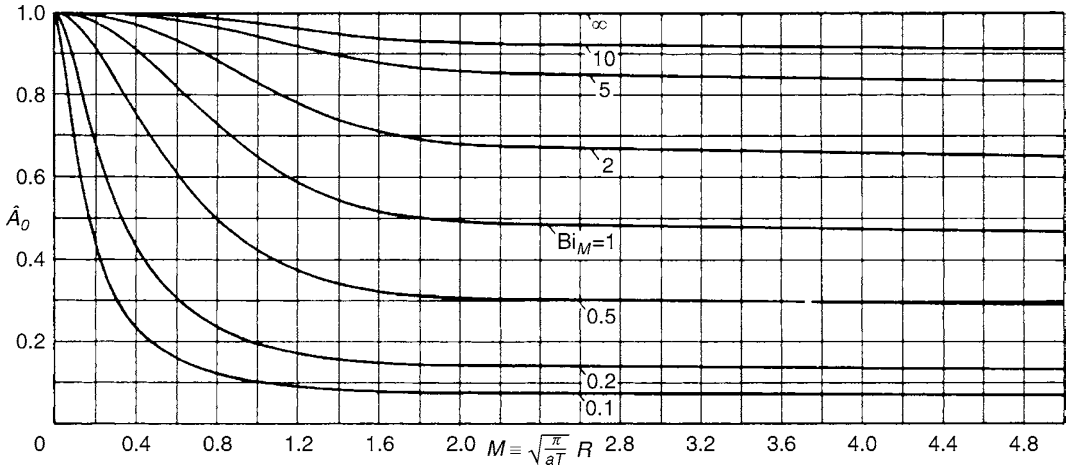
$$F'_I \equiv \left.\frac{\mathrm{d}F_I(M\xi)}{\mathrm{d}(M\xi)}\right|_{\xi=1} \tag{95}$$

(see Table 4) after some rearrangement, one obtains

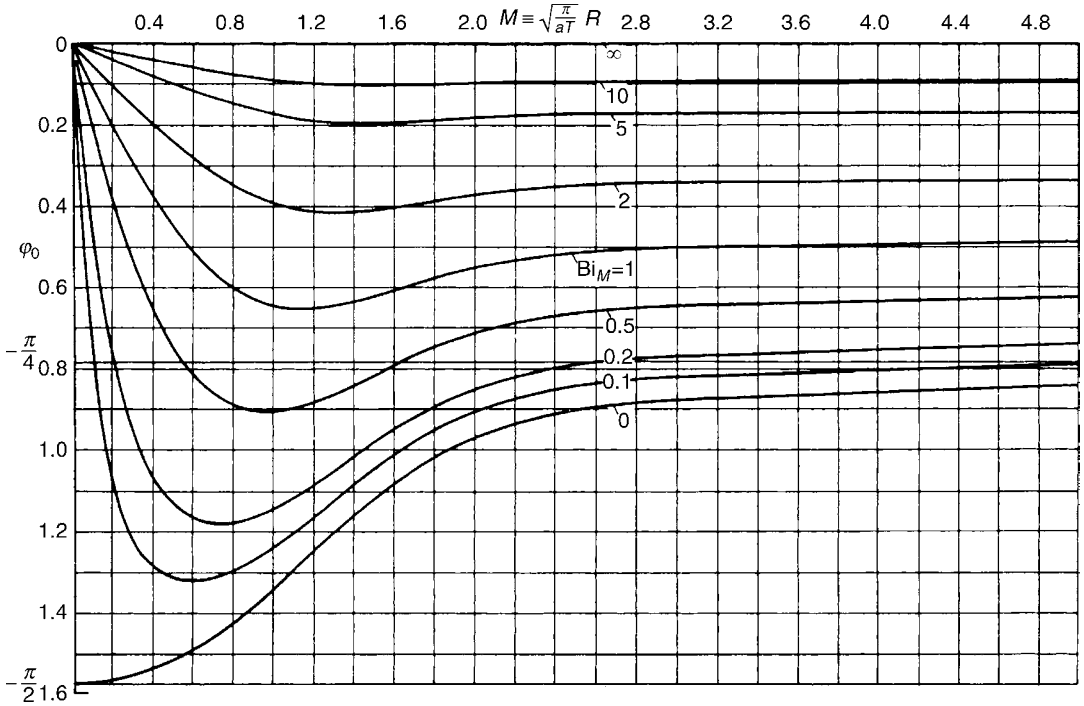
$$Q_{t_p/2} = A\frac{\lambda}{\sqrt{\kappa t_P/\pi}}\sqrt{\frac{F'^2_R + F'^2_I}{G'^2_R + G'^2_I}}\frac{2}{\pi}(T_{\infty,\max} - T_{\mathrm{av}})\frac{t_P}{2}. \tag{96}$$

Defining an overall heat transfer coefficient k by

$$Q_{t_p/2} = kA\,\Delta T_{\mathrm{av}}\frac{t_P}{2}, \tag{97}$$



E2. Fig. 17. Amplitudes $\hat{A}_0$ of the temperature wave at the surface of cylinder as functions of M, with the parameter $\mathrm{Bi}_M \equiv (\alpha_a/\lambda)\sqrt{\kappa t_P/\pi}$.



E2. Fig. 18. Phase shift φ_0 of the temperature wave at the surface of cylinder as functions of M, with the parameter $\mathrm{Bi}_M \equiv (\alpha_a/\lambda)\sqrt{\kappa t_P/\pi}$.

where the time-averaged temperature difference, ΔT_{av}, can be found from Eq. (84)

$$\Delta T_{\mathrm{av}} \equiv \frac{1}{t_P/2}\int_0^{t_P/2}(T_\infty - T_{\mathrm{av}})\,\mathrm{d}t = \frac{2}{\pi}(T_{\infty,\max} - T_{\mathrm{av}}) \qquad (98)$$

a comparison of Eqs. (96) and (97) gives

$$\frac{k\sqrt{\kappa t_P/\pi}}{\lambda} = \sqrt{\frac{F_R'^2 + F_I'^2}{G_R'^2 + G_I'^2}}. \qquad (99)$$

The right-hand side of Eq. (99) is a function of M and Bi_M. For $\mathrm{Bi}_M \to 0$ (i.e., the inner heat transfer resistance is negligible against the outer one), from Eqs. (94) and (95) and Table 4 one finds

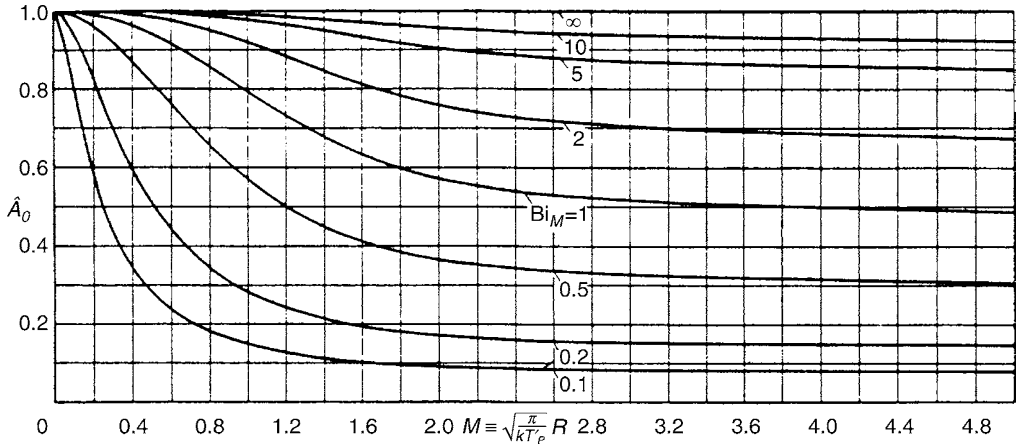
$$\lim_{\mathrm{Bi}_M \to 0} \frac{k\sqrt{\kappa t_P/\pi}}{\lambda} = \mathrm{Bi}_M \qquad (100)$$

or with Eq. (91)

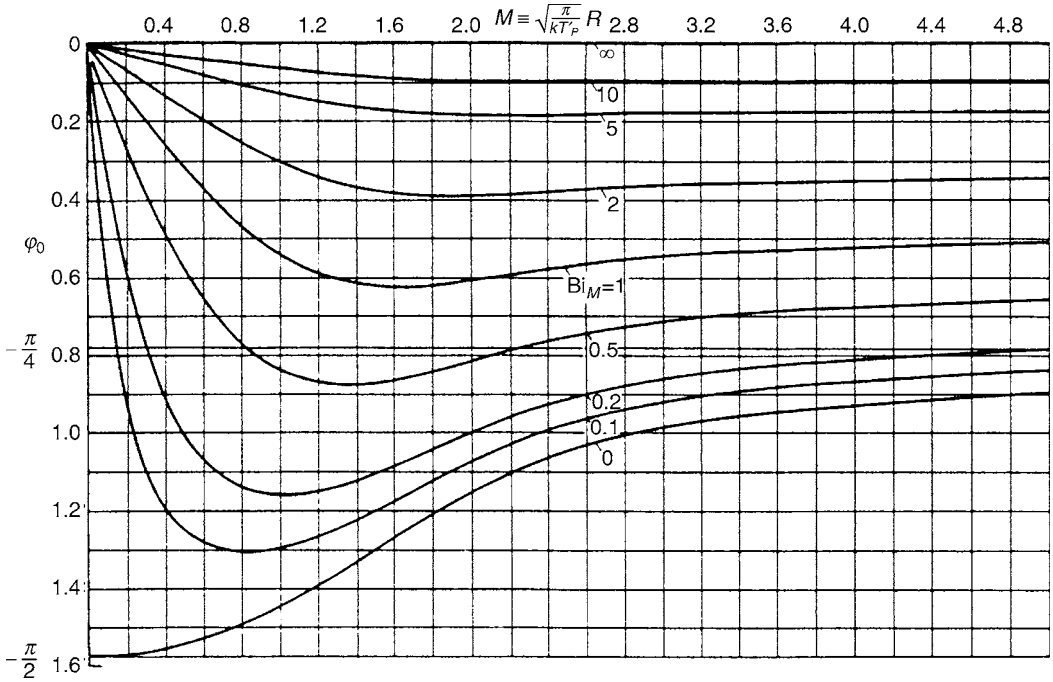
$$\lim_{\mathrm{Bi}_M \to 0} k = \alpha_a. \qquad (101)$$

In the other limit, $\mathrm{Bi}_M \to \infty$, k tends to the inner heat transfer coefficient α_i:

$$\frac{\alpha_i\sqrt{\kappa t_P/\pi}}{\lambda} = \sqrt{\frac{F_R'^2 + F_I'^2}{G_R'^2 + G_I'^2}}. \qquad (102)$$



E2. Fig. 19. Amplitudes $\hat{A}_0$ of the temperature wave at the surface of a sphere as functions of M, with the parameter $\mathrm{Bi}_M \equiv (\alpha_a/\lambda)\sqrt{\kappa t_P/\pi}$.



E2. Fig. 20. Phase shift of the temperature wave at the surface of a sphere as function of M, with the parameter $\mathrm{Bi}_M \equiv (\alpha_a/\lambda)\sqrt{\kappa t_P/\pi}$.

This inner heat transfer coefficient α_i or rather the corresponding Nusselt number

$$\mathrm{Nu}_{i,M} \equiv \frac{\alpha_i\sqrt{\kappa\, t_P/\pi}}{\lambda} \tag{103}$$

is shown in Fig. 24 for a slab, a cylinder, and a sphere versus M. For great values of M, $\mathrm{Nu}_{i,M}$ tends toward the constant value:

$$\lim_{M\to\infty} \mathrm{Nu}_{i,M} = \sqrt{2} \quad \text{or} \quad \lim_{M\to\infty} \alpha_i = \sqrt{\frac{2\pi}{t_P}}\sqrt{\lambda\rho\, c}. \tag{104}$$

For small values of M, the limiting values for a slab, a cylinder, and a sphere are (see Table 4)

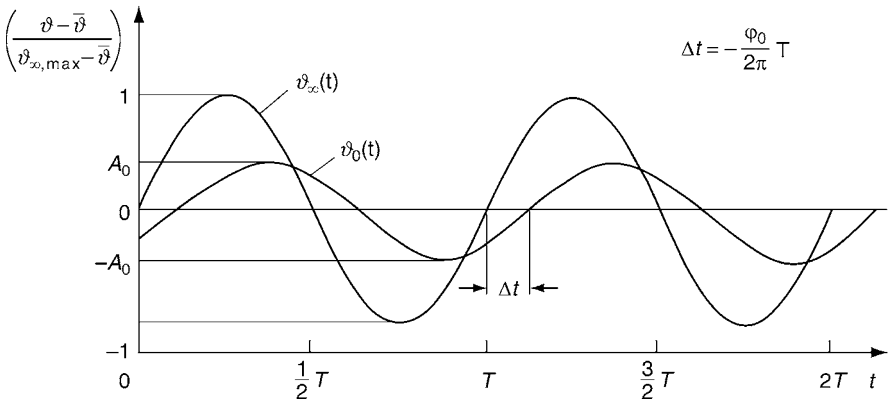
$$\lim_{M\to 0} \mathrm{Nu}_{i,M} = \begin{cases} 2M & \text{slab,} \\ M & \text{cylinder,} \\ (2/3)M & \text{sphere,} \end{cases} \tag{105}$$

or

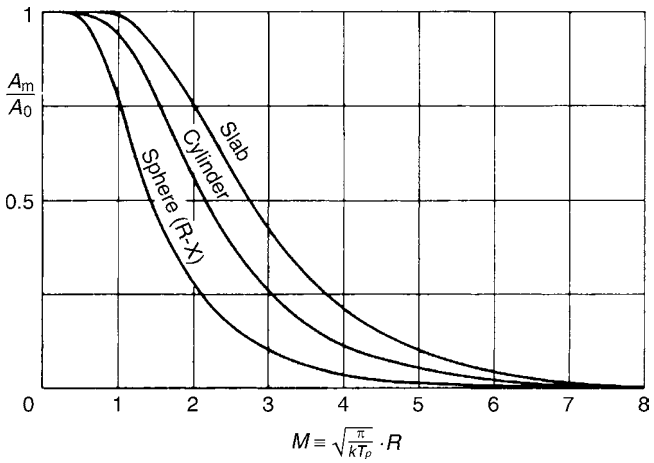
$$\lim_{M\to 0} \alpha_i = \begin{cases} 2\pi\dfrac{\lambda}{\kappa\, t_P}X & \text{slab,} \\ \pi\dfrac{\lambda}{\kappa\, t_P}R & \text{cylinder,} \\ \frac{2}{3}\pi\dfrac{\lambda}{\kappa\, t_P}R & \text{sphere.} \end{cases} \tag{105a}$$

For a slab the inner heat transfer coefficient α_i for a fixed period t_P goes through a maximum with increasing thickness of the slab (at $M = 1.2$ in Fig. 24). This wall thickness $2X_{M=1.2}$, with the greatest storage capacity, for a period of $t_P = 2\mathrm{h}$, for example, and fire-clay ($\kappa = 16 \cdot 10^{-4}\ \mathrm{m^2/h}$; [3, p. 96]) turns out to be

$$2X_{M=1.2} = 2 \cdot 1.2\sqrt{\kappa\, t_P/\pi} = 76\ \mathrm{mm}.$$



E2. Fig. 21. Time lag Δt of the surface temperature T_0 of a slab for a harmonic oscillation of the ambient temperature T_∞, at $M = 1$, and Bi = 1.



E2. Fig. 22. Amplitudes in the center of the body as functions of M.

In practice, the boundary conditions are more or less different from the simple harmonic oscillation as given in Eq. (84). By a Fourier analysis, however, they can be expressed as sums of harmonic oscillations. Equation (85) together with Eqs. (87) and (88) and Table 4 are then to be applied to each single oscillation of the Fourier analysis, and the resulting temperature variation is found from a summation of such particular solutions.

4 Finite Difference Methods (FD)

For more complex geometries and boundary conditions it might be rather difficult, if not impossible to apply analytical. In these cases numerical calculations offer an alternative, though often more tedious, way of prediction. In this chapter, only a few relatively simple numerical methods are treated. They give the reader a possibility to carry out their own numerical calculations by spreadsheet programs, for example, or may give the users of commercial software some basic information about the principles. The numerical methods used in commercial software are, partly, based on the same principles, but other numerical techniques also used in commercial software, as finite element, or finite volume methods are not treated here. These latter methods are usually less easily applied without professional help of experts.

4.1 The Explicit FD Equation

The most simple and straightforward example of the numerical methods is an explicit FD scheme for one-dimensional heat conduction, based on a difference approximation of a differential equation, as derived from Eq. (3e):

$$\frac{1}{\kappa}\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial x^2} + \frac{n}{x}\frac{\partial T}{\partial x}, \tag{106}$$

where x stands for the direction of the heat flux in the Cartesian ($n = 0$), in cylindrical ($n = 1$, $x = r$) or in spherical coordinates ($n = 1$, $x = r$). The continuous time and space coordinates (t, x) are therefore replaced by discrete points in time, $t_{I+1} = t_I + \Delta t$ and space $x_{K+1} = x_K + \Delta x$, and the space derivatives in Eq. (106) are replaced by central differences, while the time derivative is replaced by a forward difference: $(T_{I+1} - T_I)/\Delta t$:

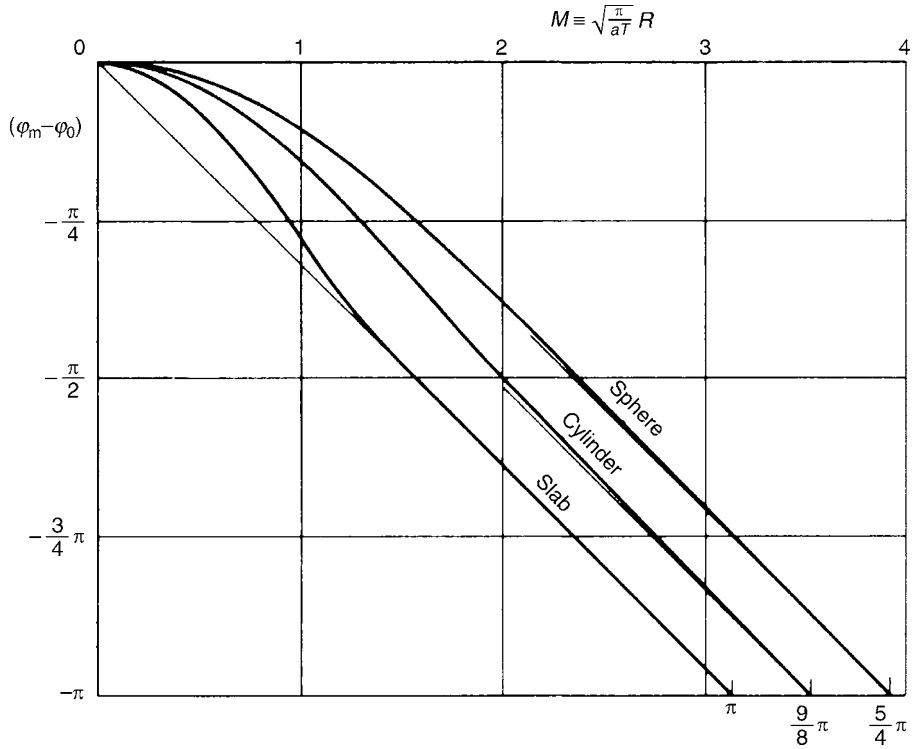
$$T_{I+1,K} \cong m\left(1 - \frac{n\Delta x}{2r_K}\right)T_{I,K-1} + (1-2m)T_{I,K} + m\left(1 + \frac{n\Delta x}{2r_K}\right)T_{I,K+1}, \tag{107}$$

where

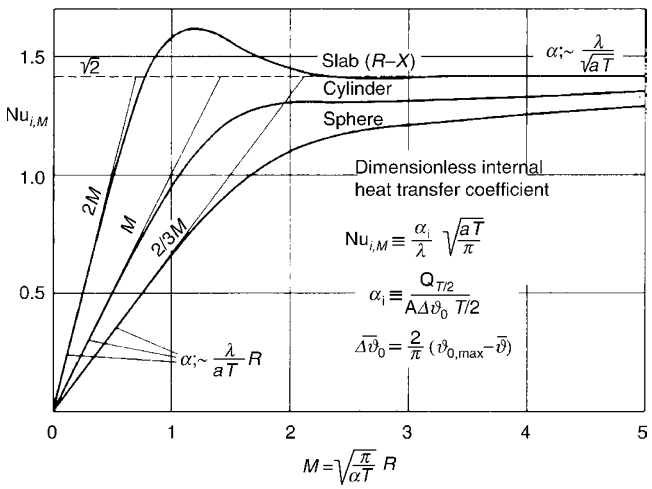
$$m = \frac{\kappa\,\Delta t}{(\Delta x)^2} \tag{108}$$

is a kind of Fourier number relating the time step Δt to the square of the chosen spatial step divided by the thermal diffusivity $(\Delta x)^2/\kappa$. This dimensionless time step, or "grid Fourier number," is often called the *module* of the difference scheme.

From the special choice of approximating the time derivative (on the left-hand side of Eq. (106) by a forward difference, the temperature T_{I+1}, at the new time level enters the difference equation just once, so that it can be explicitly solved for this "new" temperature in terms of three "old" temperatures at the positions $K-1$, K, and $K+1$. From the middle term on the right-hand side of Eq. (107) it can easily be found that the method



E2. Fig. 23. Phase shift in the center of the body as functions of *M*.



E2. Fig. 24. Dimensionless internal heat transfer coefficient $Nu_{i,M}$ as a function of *M*.

becomes unstable if the module, *m*, exceeds a value of 1/2. If time steps greater than $\Delta t_{max} = (1/2)\ (\Delta x)^2/\kappa$ are chosen, the calculation diverges leading to artificial temperature oscillations. For Cartesian coordinates ($n = 0$), the difference scheme becomes extremely simple:

$$T_{I+1,K} \cong m\,T_{I,K-1} + (1 - 2m)T_{I,K} + m\,T_{I,K+1}. \qquad (107a)$$

Using the maximum possible time step, so that $m = 1/2$ results in finding the new temperature $T_{I+1,K}$ from the arithmetic mean of the temperatures at x_{K-1} and x_{K+1} at the time t_I.

$$T_{I+1,K} = (T_{I,K-1} + T_{I,K+1})/2 (n = 0, m = 1/2). \qquad (107b)$$

This scheme has earlier been used in a graphic method [9] to construct transient temperature fields by ruler and pencil. Though $m = 1/2$ is stable in principle for one-dimensional heat flow, better results are obtained for smaller values of *m*. Especially, the choice of $m = 1/3$ makes the calculation nearly as easy, and the new temperature is found as the arithmetic mean of the three old temperatures:

$$T_{I+1,K} = (T_{I,K-1} + T_{I,K} + T_{I,K+1})/3 (n = 0, m = 1/3). \qquad (107c)$$

When using Eq. (107) for the one-dimensional problems with $n = 0, 1, 2$, the spatial coordinate should be chosen as shown in Fig. 25.

$$r_K = \Delta x(K - 1/2) \qquad (109)$$

the body of thickness *2X*, with symmetrical boundary conditions, is thus subdivided into K^* shells of thickness Δx, and

$$\Delta x/X = \Delta\xi = 1/K^*. \qquad (110)$$

To apply the boundary conditions, the positions $K = 0$ ($\Delta x/2$ left of the center) and $K = K^* + 1$ ($\Delta x/2$ right of the surface) are needed (Fig. 25). For the temperatures at these positions one finds

$$T_{I,0} = T_{I,1}\ (\text{symmetry}), \qquad (111)$$

$$T_{I,K^*+1} = T_{I,K^*}\frac{1 - b_x/2}{1 + b_x/2} + T_\infty \frac{b_x}{1 + b_x/2}, \qquad (112)$$

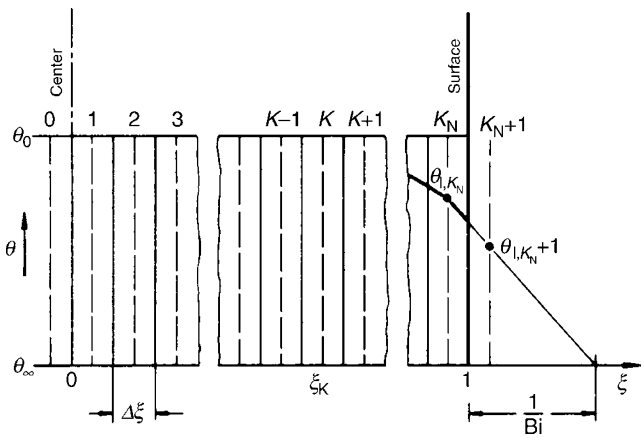
with $b_x = \mathrm{Bi}\Delta x$, $\mathrm{Bi} = \alpha_a X/\lambda$; $\Delta\xi = \Delta x/X$ (boundary condition of the third kind).

If there is no central symmetry, and the Cartesian coordinates are applied, it might be easier to use a half-shell (of thickness $\Delta x/2$) at the outermost part of the body, so that the surface temperature itself occurs in the difference scheme. A boundary condition of the third kind can then be expressed in the FD scheme as

$$T_{I,K^*+1} = b_x T_{I,K^*} + (1 - b_x) T_\infty \quad (b_x = \mathrm{Bi}\Delta\xi = \alpha_a \Delta x/\lambda). \tag{112a}$$

The module m in the term $m\,(T_{K-1} + T_{K+1})$ of an FD scheme, however, has to be doubled for $K = K^*$ to $2m$, because the volume of the outermost shell is only one half of that of an inner shell.

For a constant temperature of the surroundings, the temperatures can be normalized to make $\Theta_\infty = 0$, so that the second terms on the right-hand side of Eqs. (112) and (112a) vanish.



E2. Fig. 25. Subdivision of a body in K^* shells of thickness $\Delta\xi$ for a finite difference calculation.

For the intermediate temperatures, from $K = 1$ to K^* (or $K^* - 1$, if the surface temperature itself occurs in the scheme), Eq. (107) with Eq. (109) can be used

$$T_{I+1,K} \cong m\left(1 - \frac{n}{2K-1}\right) T_{I,K-1} + (1 - 2m) T_{I,K} + m\left(1 + \frac{n}{2K-1}\right) T_{I,K+1}. \tag{113}$$

Using Eqs. (111–113), all the problems treated analytically in Sect. 3.1.1 for a slab, a cylinder, and a sphere can also be solved numerically. Moreover, these equations can be used to calculate one-dimensional temperature fields in spherical shells, in cylindrical walls, or in slabs with unsymmetric boundary conditions (such as different temperatures and different heat transfer coefficients) and even melting or solidification problems [8].

The application of the one-dimensional form of the explicit FD equations is demonstrated in Example 4.

Example 4

The cooling (or heating) of a solid sphere with a constant initial temperature ($\Theta_{0,K} = 1$), in an environment of constant temperature ($\Theta_{I,\infty} = 0$) and a constant ambient heat transfer coefficient $\alpha_a = \lambda_i/R$ ($\mathrm{Bi} = 1$). The temperature distribution at (the dimensionless) time $\tau = 0.25$ is to be calculated.

A rather coarse subdivision of the sphere into four shells ($K^* = 4$) is chosen. Thus, the relative shell thickness becomes $\Delta\xi = 1/4$, and the time step has to be less than or equal to $\Delta\tau_{\max} = 1/2(\Delta\xi)^2$; or $\Delta\tau_{\max} = 1/32$. To get the temperature distribution at $\tau = 0.25$, one has to calculate at least 8 time steps ($8\Delta\tau = 8/32 = 0.25$). The calculation is done with the limiting time step to show that the method works even at this limiting value of the module $m = 1/2$. How to carry out the calculations is shown in Table 5. In the first row, the terms for $\Theta_{I,K}$ or $\Theta_{I+1,K}$ resulting from Eqs. (111) to (113) are given. In the last column additionally the temperature at the surface, $\Theta_{I,s}$, is shown, which does not directly appear in the difference scheme (It is calculated as the arithmetic mean of Θ_{I,K^*} and Θ_{I,K^*+1}. In the last row, the analytically calculated temperatures – as obtained from Eq. (28) – are given for comparison.

E2. Table 5. Numerical calculation of the cooling of a sphere by the explicit finite difference scheme

The Cartesian explicit FD scheme, Eq. (107a), can easily be generalized for 2D and 3D temperature fields. In place of indicating time and position by subscripts *I*, *K*, *L*, and *M*, in three-dimensional problems, it might be more appropriate to use relative space indications (related to the actual position, the temperature without a space index), such as *W*–*E*, *S*–*N*, and *D*–*U* (for west–east, south–north, down–up). The space steps are chosen equally in all directions ($\Delta x = \Delta y = \Delta z$):

$$T_{\text{new}} \cong [m\,(T_W + T_E) + (1 - 2m)T]_{\text{old}} \quad (1D,\, m \le 1/2), \tag{107d}$$

$$T_{\text{new}} \cong [m\,(T_W + T_E + T_S + T_N) + (1 - 4m)T]_{\text{old}} \quad (2D,\, m \le 1/4), \tag{114}$$

$$T_{\text{new}} \cong [m\,(T_W + T_E + T_S + T_N + T_D + T_U) + (1 - 6m)T]_{\text{old}} \quad (3D,\, m \le 1/6). \tag{115}$$

From these schemes one can see that the limiting module, $m_{\max}$, for stable calculation becomes 1/4 for 2D, and 1/6 for 3D problems. Again it might be safer to use values of 1/5 for 2D and 1/7 for 3D problems, also resulting in simple arithmetic means of the 4 + 1, or the 6 + 1 temperatures at adjacent positions, including the central position.

4.2 Implicit FD Schemes

4.2.1 The Basic Implicit FD Scheme

The explicit FD scheme, as treated in Sect. 4.1, has the advantage of being practically applied quite easily (for example, in a spreadsheet program, or a program in a higher programming language that can be written without deeper knowledge of mathematics).

A severe disadvantage, however, is caused by the stability condition (see Eqs. (107d), (114) and (115)). The time step, Δt, must always be chosen less than or equal to (1/2) $(\Delta x)^2/\kappa$ (for two or three space coordinates even with the factor 1/4 or 1/6, respectively, in place of 1/2). With a thermal diffusivity typically being in the order of magnitude of $\kappa = 10^{-6}$ m^2/s, and a subdivision of a slab of $X = 1$ cm into only 10 parallel elements, that is, $\Delta x = 10^{-3}$ m, the maximum time step for a stable calculation is half a second. Increasing the number of spatial elements by a factor 10 (for higher accuracy) reduces this maximum time step by a factor of 1/100 to 5 ms. Thus, very large numbers of time steps have to be calculated to reach a reasonable finite heating or cooling time.

This disadvantage can be avoided: Replacing the spatial derivatives on the right-hand side of Eq. (106) by corresponding FD terms not at the *I*th, but at the $I + 1$th time step (that means an approximation of the time derivative by a backward time difference). In place of Eq. (113) one gets

$$\begin{aligned} &-\left(1 - \frac{n}{2K-1}\right) m \cdot T_{K-1} + (1 + 2m) \\ &T_K - \left(1 + \frac{n}{2K-1}\right) m \quad \cdot T_{K+1}\Big|_{I+1} = T_{K,I} \end{aligned} \tag{116}$$

or shorter:

$$[a_K\ T_{K-1} + b_K\ T_K + c_K\ T_{K+1}]_{I+1} = d_K. \tag{117}$$

Equation (117), written for each grid-point, $K = 1$ to K^*, results in a system of linear equations for the K^* unknown temperatures $T_{K,I+1}$:

$$\begin{bmatrix} b_1 & c_1 & & & & & \\ a_2 & b_2 & c_2 & & & & \\ & a_3 & b_3 & c_3 & & & \\ & & & \cdot & & & \\ & & & & \cdot & & \\ & & & & & \cdot & \\ & & & & & a_{K^*} & b_{K^*} \end{bmatrix}_I \times \begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ \cdot \\ \cdot \\ \cdot \\ T_{K^*} \end{bmatrix}_{I+1} = \begin{bmatrix} d_1 \\ d_2 \\ d_3 \\ \cdot \\ \cdot \\ \cdot \\ d_{K^*} \end{bmatrix}_I . \tag{118}$$

The coefficient matrix **A**, multiplied by the column vector of the unknown temperatures, is equal to the column vector of the right sides, d_K, of the linear equations:

$$\mathbf{A}_I \times \vec{T}_{K,I+1} = \vec{d}_{K,I}. \tag{118a}$$

The solution can be easily found by matrix multiplication of the inverted matrix and the vector on the right-hand side:

$$\vec{T}_{K,I+1} = \mathbf{A}_I^{-1} \times \vec{d}_{K,I}. \tag{119}$$

Matrix inversion and matrix multiplication can be done by using appropriate tools, now widely available, even in common spreadsheet programs, for example, the functions MINV (matrix) and MMULT(matrixA; matrixB) in Excel can be used to invert the Matrix **A**, and to carry out the multiplication in Eq. (119).

The coefficients of the matrix are constant for a given time step, or module, *m*. The module, however, can be changed without stability problems. Much fewer time steps are needed for equal or better accuracy, compared with the explicit scheme.

On the right-hand side, d_K, because of $d_K = T_{K,I}$, has to be newly calculated for each time step.

How to do the calculations is shown again for a sphere, $n = 2$, with only $K^* = 4$ shells, and a Biot number of Bi = 1, as in Example 4 (Sect. 4.1).

With Eqs. (110) and (111) (symmetry, $T_0 = T_1$), (112) (the boundary condition), and (116) (the implicit difference scheme), one finds the coefficients of the matrix:

$$\begin{aligned} &K = 1,\, T_{K-1} = T_K, \\ &b_1 = 1 + (1 + n)m;\, c_1 = -(1 + n)m, \end{aligned} \tag{120}$$

$$\begin{aligned} &K = 2, \text{to } K^* - 1, \\ &a_K = -[1 - n/(2K - 1)]m;\, b_K = 1 + 2m; \\ &\quad c_K = -[1 + n/(2K - 1)]m \end{aligned} \tag{121}$$

$$\begin{aligned} &K = K^*, \\ &a_{K^*} = -[1 - n/(2K^* - 1)]m; \\ &\quad b_{K^*} = 1 + 2m - [1 + n/(2K^* - 1)]m(T_{K^*+1}/T_{K^*}). \end{aligned} \tag{122}$$

With $n = 2$, and Bi = 1, Eq. (112) gives $T_{K^*+1}/T_{K^*} = (2K^* - 1)/(2K^* + 1)$, and $b_{K^*} = 1 + m$; so the coefficient matrix in this example becomes

$$A = \begin{bmatrix} 1 + 3m & -3m & & \\ -m/3 & 1 + 2m & -5m/3 & \\ & -3m/5 & 1 + 2m & -7m/5 \\ & & -5m/7 & 1 + m \end{bmatrix}. \tag{123}$$

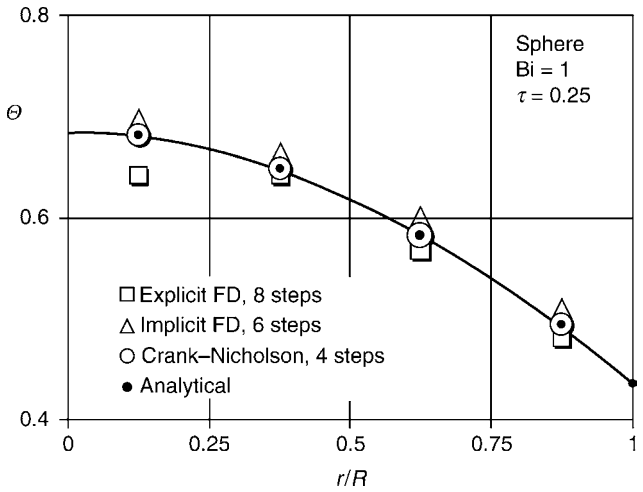
Choosing the same time step as in the explicit scheme, $m = 1/2$, for the first four steps, the temperatures at $\tau = 0.125$ (=4/32, or $I = 4$ in Table 5) are found to be

$$\Theta_1 = 0.887, \Theta_2 = 0.858, \Theta_3 = 0.794, \Theta_4 = 0.685;$$

they differ by less than 4% from the corresponding values found with the explicit scheme. Now, it is possible to continue the calculation with two larger time steps of $m = 1$ (without changing the spatial steps) to reach the same final time of $\tau = 0.25$ (=8/32, $I = 8$ in Table 5), to get:

$$\Theta_1 = 0.695, \Theta_2 = 0.664, \Theta_3 = 0.601, \Theta_4 = 0.509.$$

Still these values are relatively close to the analytical results. The greater time step, however, does not lead to divergent numerical results. Even a single time step ($m = 4$), eightfold the maximum possible of the explicit scheme, can be safely used to get a less accurate but still an approximate solution.



E2. Fig. 26. Comparison of FD calculations with the analytical solution.

4.2.2 The Crank–Nicholson Implicit FD Scheme

A higher accuracy can be obtained with the implicit FD scheme first given by Crank and Nicholson [10]. In this scheme, the right-hand side of Eq. (106) is replaced by the arithmetic mean of the corresponding difference terms at times I and $I+1$ so that the time derivative is a central difference as well (not a forward or a backward difference, as in the two preceding treated schemes). Again, a system of linear equations in the form of Eq. (117) has to be solved, but with coefficients and right sides:

$$a_K = -[1 - n/(2\ K - 1)]\ K = 2, 3, \ldots K^*,$$

$b_1 = 1 + n + 2/m\ K = 1$ (symmetry),
$b_K = 2\ (1 + 1/m)\ K = 2, 3, \ldots, K^* - 1$,
$b_{K^*} = 2(1 + 1/m) - [1 + n/(2\ K^* - 1)]\ (\Theta_{K^*+1}/\Theta_{K^*})$ (boundary condition),
$c_K = -\ [1 + n/(2\ K - 1)], K = 1, 2, \ldots, K^* - 1$,
$d_1 = [(2/m) - 1 - n)\ \Theta_1 + (1 + n)\ \Theta_2]\ K = 1$ (symmetry),
$d_K = [-\ a_K\ \Theta_{K-1} + (b_K - 4)\ \Theta_K - c_K\ \Theta_{K+1}]$
$K = 2, 3, \ldots, K^*$.

The calculation with the Crank–Nicholson scheme, using only four time steps, with $m = 1$ (i.e., twice the stable limit of the explicit scheme) gives the temperatures

$$\Theta_1 = 0.681, \Theta_2 = 0.648, \Theta_3 = 0.582, \Theta_4 = 0.491,$$

which almost perfectly agree with the analytic results (the relative deviations are less than + 0.09%, and −0.07%). Again, the scheme is stable for arbitrary values of m. Even with a single time step ($m = 4$), the relative errors are in the order of + 10%, and −11%.

The results for temperatures in the sphere obtained with the three FD schemes are shown in a plot of temperature versus radial position in Fig. 26.

4.2.3 The Alternating Directions Implicit (ADIP) Scheme for Two-Dimensional Temperature Fields

Two- or three-dimensional transient temperature fields can be solved by the explicit scheme (given in Sect. 4.1). The stability limit of the time step, however, might be a reason to look for alternatives without such time step limitations.

To apply an implicit FD scheme to two- (or even three-) dimensional problems, the method of alternate directions [11, 12], applied in two consecutive time steps, I+1, and I+2, reduces the problem to one dimension at each single step. Starting from a two-dimensional differential equation in Cartesian coordinates:

$$\frac{1}{\kappa}\frac{\partial T}{\partial t} = \frac{\partial^2 T}{\partial x^2} + \frac{\partial^2 T}{\partial y^2}. \tag{124}$$

Its FD approximation is chosen as

$$\begin{aligned} \frac{T_{I+1} - T_I}{\kappa \Delta t} &= \left.\frac{(T_E - T) - (T - T_W)}{(\Delta x)^2}\right|_{I+1} \\ &\quad + \left.\frac{(T_N - T) - (T - T_S)}{(\Delta y)^2}\right|_{I}, \\ \frac{T_{I+2} - T_{I+1}}{\kappa \Delta t} &= + \left.\frac{(T_N - T) - (T - T_S)}{(\Delta y)^2}\right|_{I+2} \\ &\quad + \left.\frac{(T_E - T) - (T - T_W)}{(\Delta x)^2}\right|_{I+1}. \end{aligned} \tag{125}$$

With equal spatial steps, $\Delta x_{(W-E)} = \Delta y_{(N-S)}$, and the module $m = \kappa \Delta t/(\Delta x)^2$, this can be rearranged to give

$$\begin{aligned} -T_W + (2 + 1/m)T - T_E|_{I+1} &= T_S - (2 - 1/m)T + T_N|_I \\ -T_S + (2 + 1/m)T - T_N|_{I+2} &= T_W - (2 - 1/m)T + T_E|_{I+1} \end{aligned}. \tag{126}$$

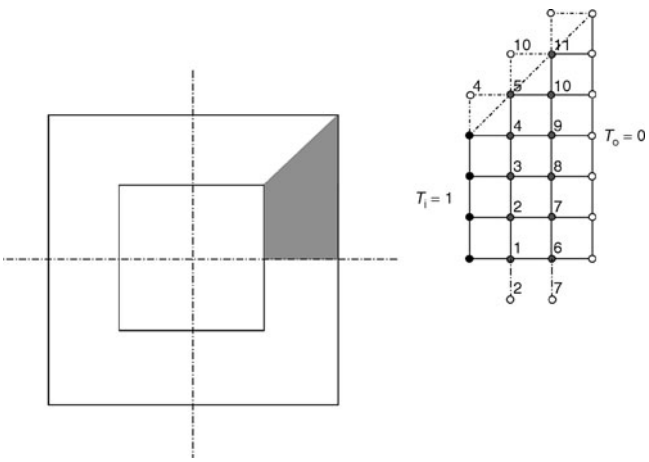
Example 5 shows a relatively simple application of this 2D FD scheme.

Example 5

The transient temperatures in the wall of a tube of square cross section, as shown in Fig. 27, are to be calculated for the case that the inner wall is suddenly brought to a temperature of $T_i = 1$, while the outer wall is kept at the constant initial temperature $T_o = 0$. The ratio of outer to inner side lengths is $2a/2b = 2$. Due to the symmetry of the geometry and the boundary

conditions, only 1/8 of the cross section suffices for a calculation. The subdivision of the wall thickness $s = a - b$ is chosen to be $\Delta x = \Delta y = s/3$. It is reasonable to use $m = 1/2$, that is, twice the stability limit of the explicit scheme for a two-dimensional problem, see Eq. (114). This makes the coefficients in the linear equation (126) equal to (−1, 4, −1), while the right-hand side reduces to the sums of the two neighboring temperatures $(2 - 1/m) = 0$. The constant temperatures (1 at the inner, and 0 at the outer sides of the wall appear in the last column vector, not in the matrix, so only the fifth line in the matrix contains three nonzero coefficients (see Fig. 25).

$$\begin{bmatrix} 4 & & & & -1 & & & & & & \\ & 4 & & & & -1 & & & & & \\ & & 4 & & & & -1 & & & & \\ & & & 4 & & & & -1 & & & \\ & & & -1 & 4 & & & & -1 & & \\ -1 & & & & & 4 & & & & & \\ & -1 & & & & & 4 & & & & \\ & & -1 & & & & & 4 & & & \\ & & & -1 & & & & & 4 & & \\ & & & & -1 & & & & & 4 & -1 \\ & & & & & & & & & -1 & 4 \end{bmatrix}_1 \times \begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \\ T_6 \\ T_7 \\ T_8 \\ T_9 \\ T_{10} \\ T_{11} \end{bmatrix}_{I+1} = \begin{bmatrix} 1+2T_2 \\ 1+T_1+T_3 \\ 1+T_2+T_4 \\ 1+T_3+T_5 \\ T_4+T_{10} \\ 2T_7 \\ T_6+T_8 \\ T_7+T_9 \\ T_8+T_{10} \\ T_9+T_{11} \\ T_{10} \end{bmatrix}_I, \tag{127}$$



E2. Fig. 27. Geometry and spatial discretization for Example 5.

$$\begin{bmatrix} 4 & -2 & & & & & & & & & \\ -1 & 4 & -1 & & & & & & & & \\ & -1 & 4 & -1 & & & & & & & \\ & & -1 & 4 & -1 & & & & & & \\ & & & -1 & 4 & & & & & -1 & \\ & & & & & 4 & -2 & & & & \\ & & & & & -1 & 4 & -1 & & & \\ & & & & & & -1 & 4 & -1 & & \\ & & & & & & & -1 & 4 & -1 & \\ & & & & & & & & -1 & 4 & -1 \\ & & & & & & & & & -1 & 4 \end{bmatrix}_2 \times \begin{bmatrix} T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \\ T_6 \\ T_7 \\ T_8 \\ T_9 \\ T_{10} \\ T_{11} \end{bmatrix}_{I+2} = \begin{bmatrix} 1+T_6 \\ 1+T_7 \\ 1+T_8 \\ 1+T_9 \\ T_4+T_{10} \\ T_1 \\ T_2 \\ T_3 \\ T_4 \\ T_5 \\ T_{10} \end{bmatrix}_{I+1}. \tag{128}$$

The solution of these systems of linear equations (127) and (128) has to be found alternately from matrix inversion and multiplication:

$$\vec{T}_{K,I+1} = \mathbf{A}_1^{-1} \times \vec{d}_{K,I} \text{ (for each odd number } I = 1, 3, 5, \ldots), \tag{129}$$

$$\vec{T}_{K,I+2} = \mathbf{A}_2^{-1} \times \vec{d}_{K,I+1} \text{ (for each even number } I = 2, 4, 6, \ldots). \tag{130}$$

These can again be done by hand calculation, using easily available mathematical tools, such as the MINV(matrix) and MMULT (matrixA;matrixB) functions in Excel (as mentioned earlier). The results of such a calculation are shown in Table 6.

The time steps, because of $\Delta\xi = 1/3$ and $m = 1/2$, are $\Delta\tau = 1/18$, so the dimensionless time is obtained directly from the number I, divided by 18. The characteristic length is the wall thickness. Table 6 gives the 11 temperatures for the time steps, I, specified in the first line.

The last two lines give the dimensionless heat flows into the wall and out of the wall:

$$Q_i^* = 8 \cdot [(1 - \Theta_1)/2 + (1 - \Theta_2) + (1 - \Theta_3) + (1 - \Theta_4)], \tag{131}$$

$$Q_o^* = 8 \cdot [\Theta_6/2 + \Theta_7 + \Theta_8 + \Theta_9 + \Theta_{10} + \Theta_{11}]. \tag{132}$$

Initially, the flow out of the wall is zero. With increasing time the two flows become equal to each other. A final steady state is reached asymptotically. For this final steady state, the

temperatures can be obtained more easily from the explicit scheme, see Eq. (114), with $T_{new} = T_{old}$, or $T = (T_E + T_N + T_W + T_S)/4$. This FD equivalent of Laplace equation can be carried out in a spreadsheet by a simple iteration process. The steady-state values of the dimensionless heat flows are the same as the so-called shape factors (see Chap. E1).

An exact analytical solution for the shape factors of n-sided hollow cylinders of regular polygonal cross section can be found in [13]. With $n = 4$, and $y = b/a = 0.5$, the shape factor from this analytical solution is $S = 10.23$. The FD result with the relatively coarse grid, $\Delta\xi = 1/3$, gives a slightly higher dimensionless flux of $S = Q^* = 10.58$ (+3.4%).

5 How to Account for Temperature-Dependent Physical Properties

In case that the temperature dependency of the physical properties, λ, and ρc_p cannot be neglected, Eq. (3) can also be brought into the form of Eq. (3a) (for constant properties) when introducing a new temperature scale by

$$\vartheta = \int_{T_0}^{T} \{\lambda/\lambda(T_0)\}\mathrm{d}T, \tag{133}$$

$$\frac{\partial\vartheta}{\partial t} = \kappa(\vartheta)\,\nabla^2\vartheta. \tag{134}$$

If the temperature dependency of λ, for example, can be given in a power law form:

$$\lambda = \lambda_0 \cdot (T/T_0)^n \tag{135}$$

one finds (for $n \neq -1$)

$$\vartheta = \frac{T_0}{n+1} \cdot \left[\left(\frac{T}{T_0}\right)^{n+1} - 1\right] \tag{136}$$

and

$$\lambda(\vartheta) = \lambda_0 \cdot \left[1 + (n+1)\frac{\vartheta}{T_0}\right]^{n/n+1}. \tag{137}$$

In a numerical calculation using FD schemes the thermal diffusivity, $\kappa = \lambda/(\rho c_p)$, $\kappa(\vartheta)$ must be kept constant for a time step, or, when using ADIP, correspondingly for two time steps with the alternating directions. Because of the narrow stability limits of the explicit scheme, the implicit methods in these cases are preferred.

Free Convection

F1 Heat Transfer by Free Convection: Fundamentals

André Thess
Technische Universität Ilmenau, Ilmenau, Germany

1 Formulation of the Problem

Free convection refers to the fluid flow which is driven by a spatially nonuniform distribution of density [1]. The nonuniformity of density can be either a result of inhomogeneous temperature distribution or nonuniform concentration of an admixture such as salt concentration in seawater. The present overview is exclusively devoted to free convection due to temperature differences.

The general formulation of heat transfer problems as relevant to practical applications is shown in Fig. 1, where Fig. 1a is for *external flows* and Fig. 1b is for *internal flows*. For external flows the heat transfer problem consists in computing the total heat flow $\dot{Q}$ from a hot body to the surrounding fluid for given values of the uniform surface temperature T_S of the hot body and of the temperature of the fluid T_∞ far away from the body. For internal flows the heat transfer problem consists in computing the total heat flow $\dot{Q}$ for given values of the uniform temperature T_1 on one part of the boundary of the fluid and of the uniform temperature T_2 on another part. Defining $\Delta T = T_S - T_\infty$ for external and $\Delta T = T_1 - T_2$ for internal flow, the heat transfer problem for free convection is equivalent to computing the dependence $\dot{Q}(\Delta T)$. This is referred to as the *constant temperature case*. A related but different problem is the *constant heat flux case* which consists in assuming a constant heat flux density at the surface of a body and computing the maximum of the (non-uniform) surface temperature. The present overview is restricted to the constant temperature case.

By virtue of the linearity of the heat transport equation the desired relation can be written in the form

$$\dot{Q} = \alpha A \Delta T \tag{1}$$

where α is the heat transfer coefficient [1] and A is the surface area of the heated body (for external flow) or the area of the heated part of the boundary (for internal flow). The present heat transfer problem is then equivalent to the computation of the heat transfer coefficient. In contrast to forced convection, where the flow field is known, the flow field in free convection is set up by ΔT, hence the heat transfer coefficient is a function of the applied temperature difference. The ultimate goal of free-convection heat transfer calculation is therefore to determine $\alpha(\Delta T)$.

The heat transfer problem under consideration can either be solved by a full numerical simulation using computational fluid dynamics (CFD) software or by using empirical correlations based on experiments and numerical simulations. The present overview is exclusively concerned with the second method which provides an approximate solution to the heat transfer problem.

2 Physical Parameters

The best documented case is that of small temperature differences, described by the condition $\Delta T \ll T_*$ where T_* is any of the quantities T_S, T_∞, T_1, and T_2 defined in Fig. 1 or the reference temperature defined by Eqs. (3) or (4) below. This case can be treated within the framework of the Boussinesq approximation where all thermophysical properties of the fluid are considered as temperature-independent except for the density in the buoyancy term of the Navier–Stokes equation. In the framework of the Boussinesq approximation the solution of the heat transfer problem requires the following quantities to be given:

ρ - density
ν - kinematic viscosity
κ - thermal diffusivity
β - isobaric volume expansion coefficient
λ - thermal conductivity
L - characteristic length
ΔT - temperature difference
g - acceleration of gravity.

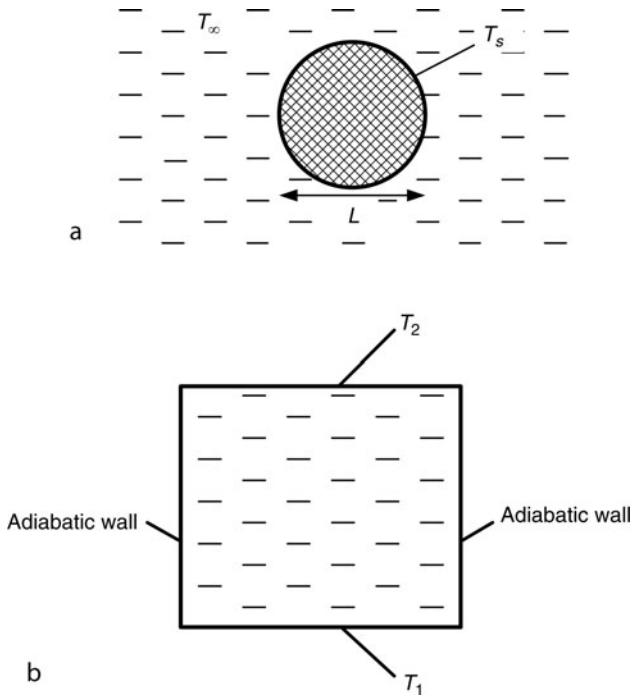
The quantities have to be given at a reference temperature T_*. The isobaric volume expansion coefficient is defined as

$$\beta = \frac{1}{\rho}\left(\frac{\partial \rho}{\partial T}\right)_p . \tag{2}$$

If the fluid under consideration is an ideal gas, its isobaric expansion coefficient can be approximated by the formula $\beta = 1/T_*$ [4].

If the condition $\Delta T \ll T_*$ is not satisfied, the full temperature dependence of the thermophysical data, i.e. $\rho(T)$, $\nu(T)$, $\kappa(T)$,

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_18,



F1. Fig. 1. Schematic of two canonical problems in free convection, (**a**) external flow around a heated sphere ($T_s > T_\infty$), (**b**) internal flow in a horizontal fluid large heated from below ($T_1 > T_2$). Gravity acts downward in both figures.

and $\lambda(T)$ has to be taken into account. For a general treatment of the problem with fully temperature-dependent material properties see [2, 3]. If such an approach is too expensive computationally or if high accuracy is not necessary, the problem with temperature-dependent thermophysical data can be approximated by a problem with temperature-independent material properties evaluated at the reference temperatures

$$T_* = \frac{1}{2}(T_S + T_\infty) \tag{3}$$

for external flow and

$$T_* = \frac{1}{2}(T_1 + T_2) \tag{4}$$

for internal flow. Assuming steady-state conditions, the goal of heat transfer calculation in the framework of the Boussinesq approximation is to determine the function

$$\alpha(\rho, \nu, \kappa, \beta, \lambda, L, \Delta T, g). \tag{5}$$

3 Nondimensional Groups

The problem of the computation of the heat transfer coefficient α is equivalent to determining the functional relationship

$$\mathrm{Nu}(\mathrm{Ra}, \mathrm{Pr}) \tag{6}$$

between the nondimensional groups Ra, Pr, and Nu, called Rayleigh-, Prandtl-, and Nusselt number, respectively. They are given as

$$\mathrm{Ra} = \frac{\beta g \Delta T L^3}{\nu\kappa}, \tag{7}$$

$$\mathrm{Pr} = \frac{\nu}{\kappa}, \tag{8}$$

$$\mathrm{Nu} = \frac{\alpha L}{\lambda}. \tag{9}$$

In literature, the Nusselt number is often expressed in the form

$$\mathrm{Nu}(\mathrm{Gr}, \mathrm{Pr}) \tag{10}$$

instead of Eq. (6), where Gr = Ra/Pr is the Grashof number. Equations (6) and (10) contain the same information and can be converted into eachother by either substituting Ra = GrPr in Eq. (6) or Gr = Ra/Pr in Eq. (10).

4 Methodology

The methodology for solving heat transfer problems with free convection involves the following steps.

1. Compile the input parameters ρ, ν, κ, β, λ, and ΔT, g
2. Compute the nondimensional groups Ra and Pr,
3. Compute Nu(Ra, Pr) using the formulas given in the VDI Heat Atlas,
4. Compute α from Nu using Eq. (9),
5. Compute $\dot{Q}$ from α using Eq. (1).

This methodology is illustrated using the following two examples.

Example 1 (External flow)

A spherical body with a diameter of $D = 5\,\mathrm{cm}$ and a surface temperature of $T_S = 100\,^\circ\mathrm{C}$ is placed in a large vessel containing water with a temperature $T_\infty = 20\,^\circ\mathrm{C}$. What is the total heat flow $\dot{Q}$ from the body to the water?

Step 1 - compilation of input parameters: With $\Delta T = 80\,\mathrm{K}$ and $T_* = 333\,\mathrm{K}$, the condition $\Delta T \ll T_*$ for neglecting the temperature depends of the material properties is not satisfied. Nevertheless, it is appropriate to start the analysis using this simplified approach and setting $T_* = (T_S + T_\infty)/2 = 60\,^\circ\mathrm{C}$. For this temperature Chap. D2 provides the values $\rho = 983.2\,\mathrm{kg/m^3}$, $\nu = 4.750 \times 10^{-7}\,\mathrm{m^2/s}$, $\kappa = 1.591 \times 10^{-7}\,\mathrm{m^2/s}$, $\beta = 5.232 \times 10^{-4}\,K^{-1}$, and $\lambda = 0.6544\,\mathrm{W/(mK)}$. Moreover, $L = 5 \times 10^{-2}\,\mathrm{m}$, $\Delta T = 80\,\mathrm{K}$, $g = 9.81\,\mathrm{m/s^2}$.

Step 2 - computation of Ra *and* Pr: With the foregoing input parameters the nondimensional groups are readily calculated as $\mathrm{Ra} = 6.792 \times 10^8$ and $\mathrm{Pr} = 2.98$.

Step 3 - computation of the Nusselt number: Using the empirical correlation $\mathrm{Nu} = 2 + 0.589\mathrm{Ra}^{1/4}/[1 + (0.469/\mathrm{Pr})^{9/16}]^{4/9}$ given in Chap. F2 the Nusselt number is obtained as Nu = 84.98.

Step 4 - computation of the heat transfer coefficient: Inserting the Nusselt number and the material properties into Eq. (9) one obtains $\alpha = 1112\,\mathrm{W/(m^2K)}$.

Step 5 - computation of the heat flux: The total heat flux is obtained by applying Eq. (1) with the surface area $A = \pi L^2$ and the computed heat transfer coefficient. The result is $\dot{Q} = 698.7\,\mathrm{W}$.

Comment: Given the approximate nature of the empirical correlation used in step 3, the results of steps 3, 4, and 5 should be considered as accurate to at most two decimal places. This provides the final result Nu $\approx$ 85, $\alpha \approx 1.1\,\mathrm{kW/(m^2K)}$, and $\dot{Q} \approx 700\,\mathrm{W}$.

Example 2 (Internal flow)
Air in a cylindrical vessel with height $L = 3.70\,\mathrm{m}$ and diameter $D = 3.70\,\mathrm{m}$ is heated from below by an isothermal bottom plate with temperature $T_1 = 30\,^\circ\mathrm{C}$ and cooled from above by an isothermal plate with $T_2 = 10\,^\circ\mathrm{C}$. There is no heat loss through the sidewall. What is the total heat flow $\dot{Q}$ from the heating to the cooling plate?

Step 1 - compliation of input parameters: With $\Delta T = 20\,\mathrm{K}$ and $T_* = 293\,\mathrm{K}$ the condition $\Delta T \ll T_*$ for neglecting the temperature dependence of the material properties is satisfied. The material properties are therefore evaluated at $T_* = (T_1 + T_2)/2 = 20\,^\circ\mathrm{C}$. For this temperature Chap. D2 provides the values $\rho = 1.188\,\mathrm{kg/m^3}$, $\nu = 1.535 \times 10^{-5}\,\mathrm{m^2/s}$, $\kappa = 2.147 \times 10^{-5}\,\mathrm{m^2/s}$, $\beta = 3.421 \times 10^{-3}\,K^{-1}$, and $\lambda = 2.569 \times 10^{-2}\,\mathrm{W/(mK)}$. Moreover, $L = 3.70\,\mathrm{m}$, $\Delta T = 20\,\mathrm{K}$, and $g = 9.81\,\mathrm{m/s^2}$.

Step 2 - computation of Ra *and* Pr: With the foregoing input parameters the nondimensional groups are readily calculated as $\mathrm{Ra} = 1.032 \times 10^{11}$ and $\mathrm{Pr} = 0.715$. The aspect ratio, to be defined in Chap. F3, is an additional parameter of the problem. Its value is $\Gamma = 1$.

Step 3 - computation of the Nusselt number: The Prandtl number of air is similar to that of helium. Therefore, the data from Chap. F3 (Sect. 2.1) can be used. Using Table 2 for $\mathrm{Ra} = 1.04 \times 10^{11}$ and $\mathrm{Pr} = 0.74$ the Nusselt number is obtained as $\mathrm{Nu} = 270$.

Step 4 - computation of the heat transfer coefficient: Inserting the Nusselt number and the material properties into Eq. (9) one obtains $\alpha = 1.875\,\mathrm{W/(m^2K)}$.

Step 5 - computation of the heat flux: The total heat flux is obtained by applying Eq. (1) with the surface area $A = \pi D^2/4$ and the computed heat transfer coefficient. The result is $\dot{Q} = 403\,\mathrm{W}$.

Comment: Given the fact that the data from Table 2 used in step 3 are not exactly for the Rayleigh and Prandtl numbers at hand, the result should be considered as accurate to at most two decimal places. This provides the final result $\dot{Q} \approx 400\,\mathrm{W}$.

1 Vertical Surfaces

The average dimensionless heat transfer coefficient [1, 2] for laminar and turbulent flows near a vertical surface in the range from $\mathrm{Ra} = 10^{-1}$ to $\mathrm{Ra} = 10^{12}$ is defined by [3]

$$\mathrm{Nu} = \left\{0.825 + 0.387[\mathrm{Ra} f_1(\mathrm{Pr})]^{1/6}\right\}^2 \tag{1}$$

The function $f_1(\mathrm{Pr})$ allows for the effect of the Prandtl number in the range $0.001 < \mathrm{Pr} < \infty$ [4]:

$$f_1(\mathrm{Pr}) = \left[1 + \left(\frac{0.492}{\mathrm{Pr}}\right)^{9/16}\right]^{-16/9} \tag{2}$$

Its numerical values for some Prandtl numbers are presented in Table 1.

The value to be inserted for the characteristic length L in Eqs. (7) and (9) of Chap. F1 for Ra and Nu is that of the height of the surface.

Equation (1) does not exactly represent the behavior in the zone of transition between laminar and turbulent flows ($10^8 \le \mathrm{Ra} \le 10^9$). However, its accuracy is adequate for engineering applications in the entire range of Rayleigh numbers.

If an error of up to 4% is permissible, Eq. (1) can also be applied for constant rates of heat flux through the surface and for the associated temperature distribution. The temperature at the center of the surface should be inserted for T_s if the heat flow rate is constant.

The following equation has been developed for heat transfer from a vertical cylinder [5]. It allows the Nusselt number for the cylinder to be determined from its height-to-diameter ratio h/D and the Nusselt number for a vertical plate of the same height, i.e.,

$$\mathrm{Nu} = \mathrm{Nu}_{\mathrm{plate}} + 0.97\frac{h}{D} \tag{3}$$

Example 1

A uniform temperature of $T_s = 40°\mathrm{C}$ is maintained over the entire surface of a vertical wall of height $h = 0.8$ m and width $b = 0.5$ m. At what rate is the heat transferred from this wall to the surrounding air ($T_\infty = 20°\mathrm{C}$)?

The properties of air at $T_* = 30°\mathrm{C}$ can be obtained from Subchap. D2.2, i.e.,

$$\lambda = 0.0268\ \mathrm{W/mK}; \quad \nu = 16.1 \times 10^{-6}\ \mathrm{m^2/s}; \quad \text{and } \mathrm{Pr} = 0.70.$$

Since $T_\infty = 273$ K, we have $\beta = 1/T_\infty = 1/293\ \mathrm{K^{-1}}$.

The characteristic length is $L = h$. Thus, the Rayleigh number is

$$\mathrm{Ra} = \frac{gl^3\beta(T_s - T_\infty)}{\nu \times \kappa} = 9.26 \times 10^8.$$

The effect of the Prandtl number is obtained from Eq. (2). Thus, $f_1(\mathrm{Pr}) = 0.345$.

Inserting the above obtained values in Eq. (1) gives

$$\mathrm{Nu} = 120,$$
$$\alpha = \frac{\mathrm{Nu}\lambda}{L} = 4.01\frac{\mathrm{W}}{\mathrm{m^2\ K}}.$$

Hence, the rate of convective heat flow is

$$\dot{Q} = A\alpha(T_s - T_\infty) = 0.8 \times 0.5 \times 4.01(40 - 20)\ \mathrm{W} = 32.1\ \mathrm{W}.$$

2 Inclined Plane Surfaces

The transfer of heat from inclined plane surfaces depends on whether the heat loss is upward or downward. If it is downward, the boundary layer hugs the plane of the surface; and if heat is transferred upward, the boundary layer separation occurs downstream after an entrance length. The following applies for heated and cooled plane surfaces.

1. No separation occurs if a heated surface transmits heat downward or if a cooled surface absorbs heat from above.
2. Separation may occur if a heated surface transmits heat upward or if a cooled surface absorbs heat from below.

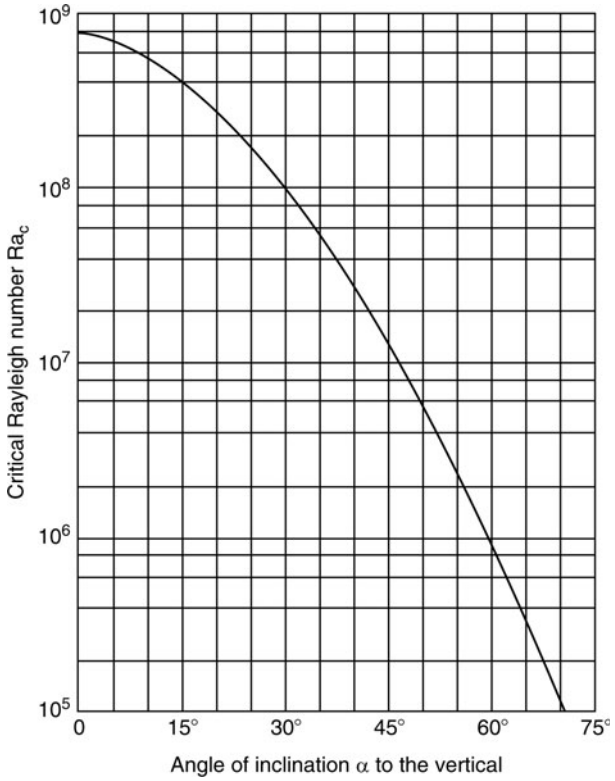
F2. Table 1. Numerical values for the function f_1 (Pr)

Pr	0.01	0.70	7	100	∞
f_1(Pr)	0.0168	0.345	0.698	0.916	1



F2. Fig. 1. Upper limit Ra_c for the laminar range as a function of the angle of inclination α in free convection at heated upper surfaces or at cooled lower surfaces [a suitable approximation is given by $Ra_c = 10^{(8.9 - 0.00178\ a\ 1.82)}$].

In Case 1, an approximate figure for the dimensionless heat transfer coefficient can be obtained from the equations for vertical surfaces by introducing the term $g \cos \alpha$, the component of gravity parallel to the vertical surface, instead of g, the acceleration due to gravity [6, 7]. Thus, the term Ra_α is substituted for Ra in Eq. (1), where

$$Ra_\alpha = Ra \cos \alpha \tag{4}$$

The only cases in which the simple generalization expressed by Eq. (1) is not valid for turbulent flow arise if heat transfer occurs at heated upper surfaces or cooled lower surfaces, i.e., for Case 2. Owing to the separation of the boundary layer, the transition into turbulent flow in these cases takes place at critical Rayleigh numbers Ra_c that are lower than their counterparts on vertical surfaces (cf. Fig. 1). The following relationship, which has been derived from the measurements in water (Pr = 7), has been proposed for the turbulent range [7]:

$$Nu = 0.56(Ra_c \cos \alpha)^{1/4} + 0.13(Ra^{1/3} - Ra_c^{1/3}) \tag{5}$$

The value of Ra_c to be inserted in this equation for a given angle of inclination α can be obtained from Fig. 1.

Example 2

A pane of glass in a solar collector is inclined at an angle of 50° to the vertical. The temperature at its surface is $T_s = 30°C$, and that of the stationary surrounding air is $T_\infty = 10°C$. The length of the pane is $h = 2$ m; and the width, $b = 1$ m. What are the heat losses by convection at the upper side of the glass pane in the collector?

The properties of air at $T_\infty = 20°C$ (Subchap. D2.2) are

$$\lambda = 0.0260 \text{ W/mK}, \quad \nu = 15.1 \times 10^{-6} \text{ m}^2/s,$$
$$\text{Pr} = 0.70, \qquad \beta = \frac{1}{T_\infty} = \frac{1}{283} \text{K}^{-1}$$

The characteristic length is $L = h = 2$ m. Hence,

$$\text{Ra} = \frac{gl^3\beta(\vartheta_s - \vartheta_\infty)}{\nu^x} = 1.703 \times 10^{10}$$

According to Fig. 1, the upper limit for the zone of laminar flow at an angle of inclination of 50° is $Ra_c = 5.5 \times 10^6$. Hence, according to Eq. (5),

$$\text{Nu} = 0.56(5.5 \times 10^6 \cos 50°)^{1/4} + 0.13[(1.703 \times 10^{10})^{1/3} - (5.5 \times 10^6)^{1/3}] = 338.$$

It follows from Eq. (9) in Chap. F1 that

$$\alpha = \frac{\text{Nu}\lambda}{l} = 4.37 \text{ W/m}^2 \text{ K}.$$

The heat losses by free convection above the pane of glass in the collector are

$$\dot{Q} = A\alpha(T_s - T_\infty) = 175 \text{ W}.$$

3 Horizontal Plane Surfaces

There are two cases of heat transfer at horizontal plane surfaces: First, upward transport of heat from a heated surface and downward transport of heat from a cooled surface of semi-infinite extent; Second, downward heat transfer from a heated surface and upward heat transfer from a cold surface. The form of the relationship for the dimensionless heat transfer coefficient is

$$\text{Nu} = f(\text{Pr},\ \text{Geometry})\text{Ra}^{1/5} \tag{6}$$

The term "Geometry" in this case refers to the shape of the plane surface. The index 1/5 has been derived from solutions of boundary layer equations for horizontal surfaces of semi-infinite extent and a stable (laminar) boundary layer. If the temperature difference is not too great, flow becomes stable in the boundary layers of plane surfaces of finite length and must be symmetrical at the centre of the surface. The characteristic length L is

$$L = \frac{ab}{2(a+b)}, \text{ for rectangular surfaces}$$

and $L = d/4$, for circular discs.

3.1 Heat Emission at Upper Surface (Lower Surface Cooled)

The equation for laminar flow [8], i.e., $\mathrm{Ra} f_2(\mathrm{Pr}) \lesssim 7 \times 10^4$, is

$$\mathrm{Nu} = 0.766[\mathrm{Ra} f_2(\mathrm{Pr})]^{1/5} \tag{7}$$

and that for turbulent flow, i.e., $\mathrm{Ra} f_2(\mathrm{Pr}) \gtrsim 7 \times 10^4$, is

$$\mathrm{Nu} = 0.15[\mathrm{Ra} f_2(\mathrm{Pr})]^{1/3} \tag{8}$$

The surface at which heat transfer takes place is considered to be part of a plane of infinite extent, in both cases.

The function f_2 (Pr) describes the effect of the Prandtl number over the entire range $0 < \mathrm{Pr} < \infty$ and is given by

$$f_2(\mathrm{Pr}) = \left[1 + \left(\frac{0.322}{\mathrm{Pr}}\right)^{11/20}\right]^{-20/11} \tag{9}$$

Its numerical values for a few Prandtl numbers are presented in Table 2.

Equations (7) and (8) are unsuitable if the conditions of the surrounding inflow depart considerably from the boundary conditions. An example of where this arises is a room with floor heating, in which case the flow of air within the room is also governed to a great extent by the transport of heat and momentum to the surroundings.

Example 3

The surface of the water in a rectangular swimming pool of $C = 10$ m length and $B = 6$ m width is covered by a floating plastic film. The temperature of the film is $T_s = 20°\mathrm{C}$, and that of the ambient air is $T_\infty = 10°\mathrm{C}$. How much heat does the film release by convection to the air?

The properties listed in Subchap. D2.2 for air at $\vartheta_m = 15°\mathrm{C}$ are

$$\lambda = 0.0257\ \mathrm{W/mK}, \quad \nu = 14.7 \cdot 10^{-6}\ \mathrm{m^2/s},$$
$$\mathrm{Pr} = 0.70; \qquad \beta = \frac{1}{T_\infty} = \frac{1}{283}\mathrm{K}^{-1}.$$

The characteristic length is

$$L = \frac{CB}{2(C+B)} = 1.875\mathrm{m}.$$

The dimensionless numbers are

$$\mathrm{Ra} = 7.402 \times 10^9$$
$$f_2(\mathrm{Pr}) = 0.401.$$

Convection is turbulent, because $\mathrm{Ra}\, f_2\,(\mathrm{Pr}) > 7 \times 10^4$. Applying Eqs. (8) and (9) thus gives

$$\mathrm{Nu} = 215.4,$$
and
$$\alpha = 2.95\ \mathrm{W/m^2K}$$

The film transfers heat by convection to the surrounding air at a rate of

$$\dot{Q} = A\alpha(T_s - T_\infty) = 1770\ \mathrm{W}.$$

3.2 Heat Emission at Lower Surface (Upper Surface Cooled)

In this case, the only known relationship [9] for the range of laminar flow, i.e., $10^3 < \mathrm{Ra}\, f_1\,(\mathrm{Pr}) < 10^{10}$, is

$$\mathrm{Nu} = 0.6[\mathrm{Ra} f_1(\mathrm{Pr})]^{1/5} \tag{10}$$

The term f_1 (Pr) in this equation is defined by Eq. (2).

The surface at which heat transfer takes place is considered to be a plane of infinite extent.

4 Horizontal Curved Surfaces

4.1 Cylinders

In analogy to Eq. (1), the relationship that applies to the average dimensionless heat transfer coefficient for free convection around a horizontal cylinder [10] is

$$\mathrm{Nu} = \{0.60 + 0.387[\mathrm{Ra} f_3(\mathrm{Pr})]^{1/6}\}^2 \tag{11}$$

The characteristic length L from which the Nusselt and Rayleigh numbers are calculated is

$$L = D \tag{12}$$

The function f_3 (Pr) describes the effect of the Prandtl number over the entire range $0 < \mathrm{Pr} < \infty$ and is given by

$$f_3(\mathrm{Pr}) = \left[1 + \left(\frac{0.559}{\mathrm{Pr}}\right)^{9/16}\right]^{-16/9} \tag{13}$$

Its numerical values for some Prandtl numbers are presented in Table 3.

4.2 Spheres

If the diameter D is taken as the characteristic length L, free convection around spheres can be described by the equations that apply to vertical planes [11]. If the temperature difference or the sphere diameter is small, the average dimensionless heat transfer coefficient tends asymptotically toward a limit, i.e.,

$$\mathrm{Nu} \to 2 \quad \text{if } \mathrm{Ra} \to 0.$$

F2. Table 2. Numerical values for the function f_2(Pr)

Pr	0.01	0.70	7	100	∞
f_2(Pr)	0.0242	0.401	0.736	0.927	1

F2. Table 3. Numerical values for the function f_3(Pr)

Pr	0.01	0.70	7	100	∞
f_3(Pr)	0.015	0.325	0.681	0.911	1

In other words, Eq. (1) is no longer valid for spheres if $\mathrm{Ra} < 10^3$. A better approximation is as follows [12]:

$$\mathrm{Nu} = 0.56\left[\left(\frac{\mathrm{Pr}}{0.846+\mathrm{Pr}}\right)\mathrm{Ra}\right]^{1/4} + 2 \tag{14}$$

4.3 Cubes

The dimensionless heat transfer coefficient for a cube is given by [13]

$$\mathrm{Nu} = 5.748 + 0.752\left(\frac{\mathrm{Ra}}{f_4(\mathrm{Pr})}\right)^{0.252} \tag{15}$$

The characteristic length in this case is $L = A/D$ and $D = 4\ V/A$, where A is the total area and V is the volume of the cube. The function $f_4(\mathrm{Pr})$ is given by

$$f_4(\mathrm{Pr}) = \left(1 - \left(\frac{0.492}{\mathrm{Pr}}\right)^{9/16}\right)^{16/9} \tag{16}$$

Example 4

The temperature at the surface of an uninsulated horizontal pipe of outer diameter $D = 0.108$ m is $T_s = 180°\mathrm{C}$. At what rate per unit length of pipe is the heat transferred by convection to a stationary atmosphere at $T_\infty = 20°\mathrm{C}$?

The properties of air at $T_* = 100°\mathrm{C}$ (cf. Subchap. D2.2) are

$$\lambda = 0.0318\ \mathrm{W/mK}; \quad \nu = 23.15 \times 10^{-6}\ \mathrm{m^2/s}$$
$$\mathrm{Pr} = 0.69, \quad \beta = \frac{1}{T_\infty} = \frac{1}{293}\mathrm{K^{-1}}.$$

The characteristic length is $L = D = 0.108$ m.

$$\mathrm{Ra} = 8.7 \times 10^6$$
$$f_3(\mathrm{Pr}) = 0.323.$$

Inserting the above obtained values in Eq. (11):

$$\mathrm{Nu} = 27.0$$
$$\alpha = 7.95\ \mathrm{W/m^2K}.$$

Thus, the heat losses per pipe length L are

$$\dot{Q}/L = \pi D\alpha(T_s - T_\infty) = 432\ \mathrm{W/m}.$$

4.4 Finned Tubes

Numerous types of finned tubes are encountered in practice. Smooth tubes with circular fins of constant thickness have been taken as an example in this case. Few results of measurements on free convection around horizontal finned tubes have been published [14–17]. An analysis of these reveals that the values for all the tubes with circular fins that were investigated do not depart by more than ±25% from the figures obtained by the following equation:

$$\mathrm{Nu} = 0.24\left(\mathrm{Ra}\frac{b}{d}\right)^{1/3} \tag{17}$$

where b is the fin spacing and d is the diameter of the tube.

In this case, an effective diameter $d_e = d + h$, where h is the height of the fins, is inserted for the characteristic length L in Eqs. (7) and (9) of Chap. F1 for the determination of the Rayleigh and Nusselt numbers. The value inserted for the temperature difference is T_s, the average temperature at the surface of the core tube. The measured values from which Eq. (17) was derived cover the $10^3 < \mathrm{Ra} < 10^7$ range. All the experiments were carried out in air (Pr = 0.70).

The only cases in which Eq. (17) should be applied are those in which the material of construction for both the tube and fins has a thermal conductivity equal to or greater than that of steel. Moreover, there should be no gaps between the tube and the fins. The values for the heat transfer external area, i.e., α determined from Eq. (17), must be expressed in terms of the total external area, i.e.,

$$\alpha = \frac{\dot{Q}}{A_{\mathrm{tot}}(T_s - T_\infty)} \tag{18}$$

Example 5

The dimensions of a horizontal steel finned tube are as follows:

Diameter of tube	$d = 0.050$ m
Height of fins	$h = 0.030$ m
Thickness of fins	$s = 0.002$ m
Fin spacing	$b = 0.020$ m.

The temperature of the tube is $T_s = 80°\mathrm{C}$, and that of the surrounding air, $T_\infty = 20°\mathrm{C}$. How much more convective heat is given off per unit time and unit length from this tube than from a smooth tube with an effective diameter $d_e' = 0.080$ m?

Properties of air at $T_* = 50°\mathrm{C}$ (cf. Subchap. D2.2):

$$\lambda = 0.0282\ \mathrm{W/mK}; \quad \nu = 19.3 \cdot 10^{-6}\mathrm{m^2/s};$$
$$\mathrm{Pr} = 0.69 \quad \beta = 1/T_\infty = 1/293\ \mathrm{K^{-1}}.$$

The effective diameter is $d_e = d + h = 0.080$ m.

$$\mathrm{Ra}_{d_e} = \frac{g d_e^3 \beta(T_0 - T_\infty)}{\nu^x} = 1.905 \times 10^6$$
$$\frac{b}{d} = \frac{0.02\ \mathrm{m}}{0.05\ \mathrm{m}} = 0.4.$$

The number of fins per unit length is

$$n = \frac{1}{b+s} = \frac{1}{(0.02+0.002)\mathrm{m}} = 45.5/\mathrm{m}.$$

The total area of heat-emitting surface per unit length L_0 of the finned tube is

$$\frac{A_{\mathrm{tot}}}{L_0} = \pi d(1 - sn) + n\frac{\pi}{2}[(d+2h)^2 - d^2] + n\pi s(d+2h),$$
$$\frac{A_{\mathrm{tot}}}{L_0} = 0.860\frac{\mathrm{m^2}}{\mathrm{m}}.$$

Inserting in Eq. (30):

$$\mathrm{Nu} = 0.24\left(\mathrm{Ra}_{d_e}\frac{b}{d}\right)^{1/3} = 21.9,$$
$$\alpha = \frac{\mathrm{Nu}\lambda}{d_e} = 7.73\frac{\mathrm{W}}{\mathrm{m^2K}}.$$

The convective heat flow rate per unit length L_0 of the finned tube is

$$\frac{\dot{Q}}{L_0} = \frac{A_{tot}}{L_0}\alpha(T_s - T_\infty) = 399\frac{W}{m}.$$

The figure is to be compared to that for convective heat transfer around a smooth tube of $d = d_e = 0.08$ m and a characteristic length of $L = d = 0.08$ m. The latter can be obtained from Eqs. (3), (24), and (26). Thus,

$$Nu = 17.33 \text{ and } \quad \alpha = 6.11\ W/m^2K.$$

The convective heat flow rate per unit length of finned tube is

$$\frac{\dot{Q}}{L_0} = \frac{A}{L_0}\alpha(T_s - T_\infty) = 92.1\frac{W}{m}.$$

Thus, the rate of convective heat loss from the finned tube is more than four times as much as that from a smooth tube with the same effective diameter.

5 Superimposed Free and Forced Convection

If buoyancy forces act in the same direction as a forced convection, the velocities and their gradients in the boundary layers increase. As a consequence, the heat transfer is generally increased. On the other hand, it was observed [18] that superimposing forced convection on predominantly free convection initially retarded the transition to turbulence because the boundary layer separation was thus restricted. The additive effect of superimposing did not become evident until higher Rayleigh numbers were attained. Since this complex behavior was not investigated in sufficient depth, the following method must be regarded merely as a rough approximation.

The following equation applies for the case in which the free convection is in the same direction as a forced vertical convection current and is derived from experimental results [19]:

$$Nu^3 = Nu_{forced}^3 + Nu_{free}^3 \qquad (19)$$

In analogy, the following applies for the case in which the free convection is in the direction opposite to the vertical current:

$$Nu^3 = \left|Nu_{forced}^3 - Nu_{free}^3\right| \qquad (20)$$

If the forced convection current is vertical, this method may be adopted for the vertical plate, the horizontal cylinder, and the sphere. The Nusselt numbers applicable to the term that allows for the forced convection can be obtained from Chaps. G1 (plate), G5 (cylinder), and G8 (individual sphere).

Superimposing free convection on *non* vertical forced convection has been the subject of such little study that it still cannot be verified whether the above method could also be adopted in this case.

Example 6

Wind flows upward over the longitudinal plane of the pane of glass in the solar collector described in Example 2. The velocity parallel to the plane and beyond the boundary layer is $u_\infty = 1$ m/s. What heat losses now result from convection on the upper side of the collector?

Let the effect of free convection be described by the Nusselt number determined in Example 2, i.e., $Nu_{free} = 338$.

The Reynolds number that applies for the effect of forced convection is

$$Re = \frac{u_\infty l}{\nu} = 1.32 \cdot 10^5.$$

This figure lies in the transition between turbulent and laminar flows. The Nusselt number that can be read off against it in the diagrams in Chap. C1 is $Nu_{forced} = 440$.

Equation (19) thus becomes

$$Nu^3 = (440^3 + 338^3)^{1/3} = 498.$$

It is thus evident that the wind, which was assumed to flow at a low velocity, increases the convective heat losses by almost 50%.

Example 7

A heat transfer unit in the form of a plate (height $h = 0.5$ m; breadth $b = 0.3$ m) is suspended vertically in a tunnel through which air flows upward at an average velocity of $u_\infty = 1$ m/s and a temperature of $T_\infty = 20°C$. The temperature on both sides of the plate is $T_s = 60°C$. Owing to baffles, flow in the channel is turbulent. At what rate does the unit emit heat by convection?

The properties of air at $T_m = 40°C$ (cf. Subchap. D2.2) are

$$\lambda = 0.0275\ W/mK, \quad \nu = 18.81 \cdot 10^{-6}\ m^2/s,$$
$$Pr = 0.69, \quad \beta = \frac{1}{T_\infty} = \frac{1}{293}\ K^{-1},$$
$$f_1(Pr) = 0.343.$$

The characteristic length is $L = h = 0.5$ m, and thus,

$$Ra = 3.26 \times 10^8$$
$$Re = \frac{u_\infty l}{\nu} = \frac{1 \cdot 0.5}{18.81 \cdot 10^{-6}} = 2.66 \cdot 10^4.$$

Equation (20) gives

$$Nu_{forced} = 144; \quad Nu_{free} = 100,$$
$$Nu = \{\left|Nu_{forced}^3 - Nu_{free}^3\right|\}^{1/3} = 126.$$

Thus,

$$\alpha = \frac{Nu\lambda}{l} = 6.9\ W/m^2K.$$

Consequently, the surfaces on both sides of the plate transfer heat by convection at the following rate to the air flowing in the channel:

$$\dot{Q} = A\alpha(T_s - T_\infty) = 82.8\ W.$$

F3 Heat Transfer by Free Convection: Internal Flows

André Thess
Technische Universität Ilmenau, Ilmenau, Germany

1 General Relationships

The general formulation of the heat transfer problem for internal flow has been described in Chap. F1 (see in particular Fig. 1b). For a comprehensive explanation of the governing equations, similarity parameters, and empirical correlations the reader is referred to [1]. The present equations are for heat transfer in the absence of radiation.

If the temperatures of the surfaces involved are fixed, the rates at which heat is transferred by convection, conduction, and radiation can be determined separately and independently. Thus, the total heat flow rate $\dot{Q}$ is given by

$$\dot{Q} = A\lambda_{\mathrm{CCR}}/L(T_1 - T_2),$$

where $\lambda_{\mathrm{CCR}} = \lambda_{\mathrm{R}} + \lambda_{\mathrm{CC}}$ is the total thermal conductivity equivalent, $\lambda_{\mathrm{R}} = 4\, s\, C_{12} T_{\mathrm{m}}^3$ is the thermal conductivity equivalent for radiation (C_{12} is the radiation transfer factor defined in Chap. K1), and $\lambda_{\mathrm{CC}} = \mathrm{Nu}_s\lambda$ is the thermal conductivity equivalent for convection and conduction.

Under different boundary conditions, the heat transfer mechanisms interact. As a rule, the integrodifferential equations that describe the problem are difficult to solve (cf. *Thermal radiation*).

2 Plane Horizontal Layers

The most extensively documented case of free convection in internal flows is that of the Rayleigh–Bénard convection. The term Rayleigh–Bénard convection refers to the buoyancy driven flow of a fluid enclosed between two horizontal plates, where the lower plate is heated and the upper plate is cooled, i.e. $T_1 > T_2$. Rayleigh–Bénard convection in cylindrical containers with height L and diameter D and adiabatic sidewalls is characterized by the Rayleigh number Ra, Prandtl number Pr (both being defined in Chap. F1) as well as by the aspect ratio $\Gamma = D/L$. The known properties of the Nusselt number Nu(Ra, Pr, Γ) are summarized next. Detailed information about the turbulent regime $\mathrm{Ra} > 10^5$ is provided in the review articles [2, 3].

If $\mathrm{Ra} < 0$, which corresponds to heating from above, the fluid is stably stratified. In this case, there is no flow and Nu = 1. If the fluid is heated from below and

$$0 \le \mathrm{Ra} < \mathrm{Ra}_c(\Gamma) \qquad (1)$$

the fluid is unstably stratified but hydrodynamically stable. The velocity is zero and Nu = 1. The critical Rayleigh number Ra_c (which is independent of Pr but which depends on Γ) can be computed using hydrodynamic stability theory [4, 5]. For isothermal solid upper and lower walls and adiabatic sidewalls, $\mathrm{Ra}_c(\Gamma) \approx 1{,}707$ if $\Gamma \gg 1$.

For $\mathrm{Ra} > \mathrm{Ra}_c$, there is convection inside the layer and hence, $\mathrm{Nu} > 1$. The spatial and temporal structure of the flows varies widely, involving weakly nonlinear (steady, oscillatory, and chaotic) regimes [6, 7] and strongly nonlinear (turbulent) regimes [2, 3]. At present there exists no formula for Nu(Ra, Pr, Γ) which is simple, accurate, and covers the whole parameter space $\mathrm{Ra}_c < \mathrm{Ra} < \infty$, $0.005 \le \mathrm{Pr} < \infty$, and $0 < \Gamma < \infty$. (The lower bound for the Prandtl number is that for sodium.) The following subsections provide three types of data. Sect. 2.1

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_20,

contains selected experimental data for water, helium, and mercury which are highly accurate but cover only a restricted range of the parameter space. These data are given explicitly for water and helium and as a power law for mercury. Sect. 2.2 provides references to empirical correlations covering a large range of parameters but involving complex mathematical expressions. The expressions are not given explicitly. Sect. 2.3 contains empirical correlations which are simple and cover a large portion of the parameter space but whose accuracy is limited.

2.1 Accurate Experimental Reference Data

Table 1 contains selected results of accurate experiments on Rayleigh–Bénard convection in water carried out in cylindrical cells with nearly adiabatic sidewalls [8, 9]. For more data including a wide range of Γ, see [8–10].

Table 2 lists selected results of accurate experiments on Rayleigh–Bénard convection in helium carried out in cylindrical cells with aspect ratios $\Gamma = 1$ and $\Gamma = 0.5$ [11, 12]. Since helium has similar Prandtl number as air, these data can be used as reference data for air as well.

For mercury Pr = 0.025 and $\Gamma = 1$ ref. [13], gives the following data:

$$\mathrm{Nu} = (0.140 \pm 0.005)\mathrm{Ra}^{(0.26 \pm 0.02)} \quad \text{for } 7.0 \times 10^6 \le \mathrm{Ra} \le 4.5 \times 10^8, \tag{2}$$

$$\mathrm{Nu} = (0.044 \pm 0.015)\mathrm{Ra}^{(0.20 \pm 0.02)} \quad \text{for } 4.5 \times 10^8 \le \mathrm{Ra} \le 2.1 \times 10^9. \tag{3}$$

For experimental data with mercury in cells with other aspect ratios see [14].

The data listed in this Section of Part F represent the most accurate experiments available today (2009). They should, therefore, be considered reference data. For older experimental data as well as data for other than cylindrical geometries, see the review articles [2, 3].

2.2 Accurate Empirical Correlations

For Rayleigh–Bénard convection with aspect ratio $\Gamma \approx 1$, empirical correlations for Nu(Pr, Ra) have been developed in [15, 16] (see also [3]). These correlations are valid for the turbulent flow regime ($\mathrm{Ra} > 10^5$) and cover all technically relevant Prandtl numbers [15] (or at least $\mathrm{Pr} > 0.6$ [16]). The correlations are given in implicit form, i.e., as $f(\mathrm{Pr}, \mathrm{Ra}, \mathrm{Nu}) = 0$. Here, they are not listed explicitly. Their numerical evaluation requires a root-finding algorithm and the computation of elementary functions.

2.3 Rough Empirical Correlations

The relationship $\mathrm{Nu} = f(\mathrm{Ra})$ for the average dimensionless heat transfer coefficient is presented graphically in Fig. 1.

For $\mathrm{Ra} > \mathrm{Ra}_c$

the following equations apply [17]: for laminar boundary layers,

$$1{,}708 < \mathrm{Ra} < 2.2 \times 10^4 : \ \mathrm{Nu} = 0.208(\mathrm{Ra})^{0.25} \tag{4}$$

and for turbulent boundary layers,

$$\mathrm{Ra} < 2.2 \times 10^4 : \ \mathrm{Nu} = 0.092(\mathrm{Ra})^{0.33}. \tag{5}$$

More involved relationships exist for air and water [18]. The values lie within the range of scattering in Fig. 1. Ra_{cr} depends on the geometry of the layer and the thermal boundary conditions. The effect of sidewalls increases the critical Rayleigh number [19, 20]. If the flow of heat is downward, Nu = 1 provided that boundary effects do not preponderate.

3 Inclined Plane Layers [21–25]

The relationship $\mathrm{Nu} = f(\mathrm{Ra})$ for the average dimensionless heat transfer coefficient is represented in Fig. 2. The following expression has been quoted for upward flow of heat [21]:

$$\mathrm{Nu} = C(\mathrm{Ra})^{0.33}\,\mathrm{Pr}^{0.074} \tag{6}$$

C depends on the angle α formed to the vertical, i.e.,

α	0°	30°	45°	60°	90°
C	4.9×10^{-2}	5.7×10^{-2}	5.9×10^{-2}	6.5×10^{-2}	6.9×10^{-2}

The following applies for the $5 \times 10^3 > \mathrm{Ra} < 10^8$ range and for downward flow of heat at an angle $\alpha = 45°$ [21]:

$$\mathrm{Nu} = 1 + \frac{0.025(\mathrm{Ra})^{1.36}}{\mathrm{Ra} + 1.3 \times 10^4}. \tag{7}$$

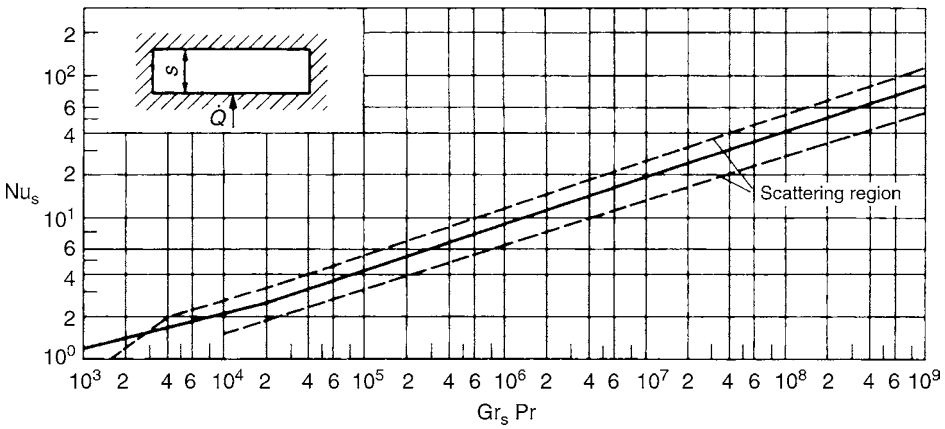
Other relationships that cover the range of scattering have been given for layers of air [22, 23]. The values quoted for $\alpha = 0°$ and $\alpha = 90°$ do not agree with those for the vertical and horizontal layers, respectively. This indicates the uncertainty of the relationships.

Critical Rayleigh numbers at which the onset of heat transfer by free convection can first be anticipated and other relationships to the angle of inclination are given in the literature [24, 25].

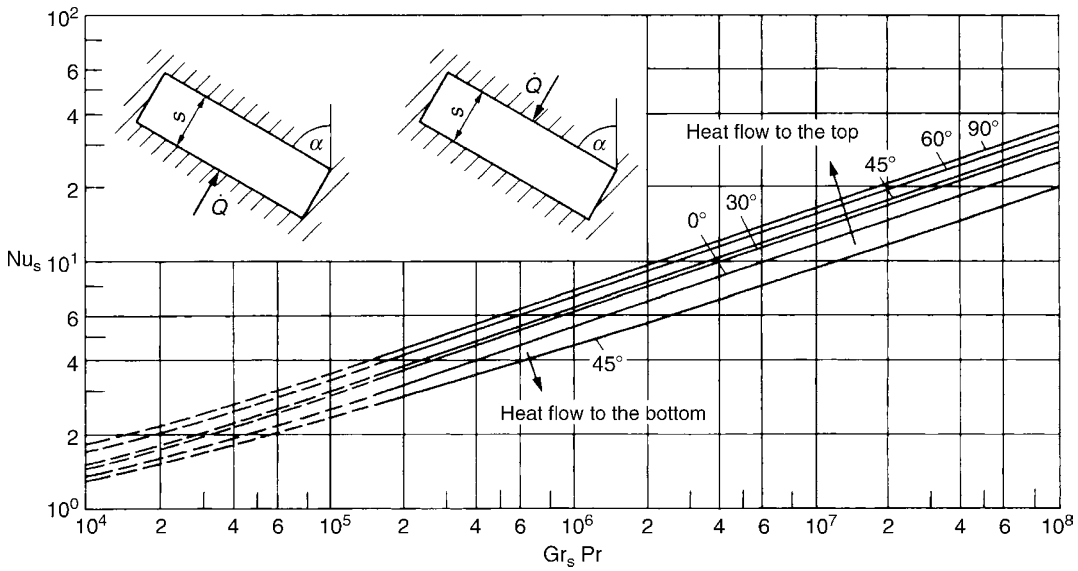
4 Vertical Layers [26–29]

In this case, Fig. 3 represents the relationship for the average dimensionless heat transfer coefficient $\mathrm{Nu} = f(\mathrm{Gr}, \mathrm{Pr}, h/L)$, in which h is the height of the vertical layer. The following equations for gases and liquids [26] can be considered most reliable in the $h/L < 80$ range:

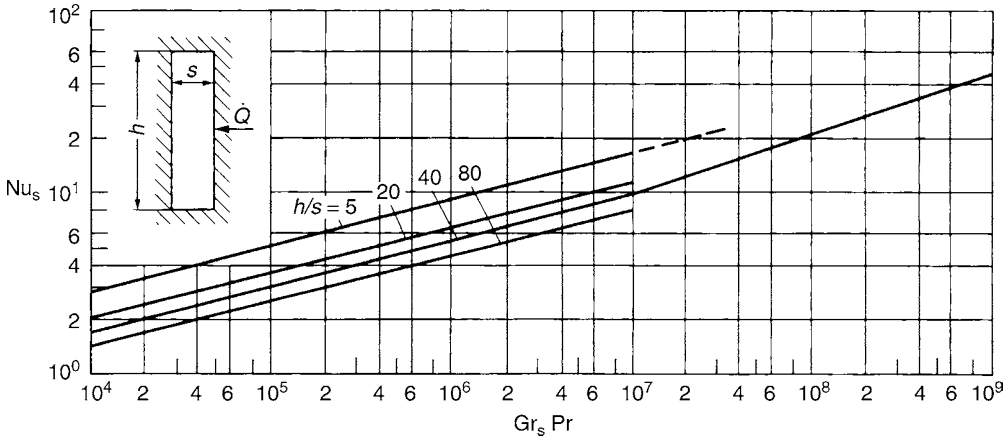
$$\mathrm{Nu} = 0.42\mathrm{Pr}^{0.012}(\mathrm{Ra})^{0.25}\left(\frac{h}{L}\right)^{-0.25} \quad (10^4 < \mathrm{Ra} < 10^7),$$
$$\mathrm{Nu} = 0.049(\mathrm{Ra})^{0.33} \quad (10^7 < \mathrm{Ra} < 10^9). \tag{8}$$



F3. Fig. 1. Average dimensionless heat transfer coefficient Nu as a function of GrPr for heat transfer in horizontal rectilinear enclosures.



F3. Fig. 2. Average dimensionless heat transfer coefficient Nu as a function of Ra for heat transfer in inclined rectilinear enclosures.



F3. Fig. 3. Average dimensionless heat transfer coefficient Nu as a function of Ra for heat transfer in vertical rectilinear enclosures.

The results obtained for $h/L = 1$, $h/L < 1$, and wider ranges of parameters have been compiled and compared [29]. No verified results are available for the range $h/s > 80$.

5 Special Cases of Plane Layers

Partitions: The following equation shows [30] the relationship between the dimensionless heat transfer coefficient Nu, the number of partitions N, the total height h, and the layer thickness L in vertical plane layers that have been divided into several partitions:

$$\mathrm{Nu}_s = 0.297\mathrm{Ra}^{1/4}(h/L)^{-1/4}(N+1)^{-1}. \qquad (9)$$

If there are 2–5 layers, the amount of heat transferred by convection can be reduced by 70–90%. Equations have been drawn up for the case in which the divisions do not extend all the way upward [31, 32].

Inclined parallelograms: Relationships have been established between heat transfer, the Rayleigh number relating to depth s of the layer, and the angle of inclination to the horizontal [33].

Honeycombs: Figures have been published for the average dimensionless heat transfer coefficient in cases when partitions of thermal insulating material in the form of cells are inclined at various angles to the horizontal [34].

5.1 Horizontal Annuli [35–38]

The dimensionless average heat transfer coefficient in this case is given by

$$\mathrm{Nu}_s = f\left(\mathrm{Ra}, \frac{r_0}{r_i}\right).$$

The relationship is presented graphically in Fig. 4. Equation (10) applies for the $\mathrm{Ra} > 7.1 \times 10^3$ range, heat flow from the inside to the outside, and $r_0/r_i \leq 8$:

$$\mathrm{Nu}_s = 0.20(\mathrm{Ra})^{0.25}\left(\frac{r_0}{r_i}\right)^{0.5}. \qquad (10)$$

In the range from $r_0/r_i = 6$ to $r_0/r_i = 8$, the relationship tends toward that for a horizontal tube.

Heat transfer coefficients are altered by vertical eccentricities e, i.e., the spacing between the axis of the cylinder that has been trued horizontally and the axis of the inner cylinder that has been displaced vertically upward or downward. If the inner cylinder has been displaced vertically upward in a ratio of $e(r_0 - r_i) = 2/3$, the heat transfer coefficient is reduced by 5%, expressed in terms of the value for a horizontally trued inner cylinder; and, if the displacement has been vertically downward in a ratio of $e/(r_0 - r_i)$, the heat transfer coefficient is increased by 10% [36].

The value for Nu in internally heated annuli inclined at an angle of 45° to the horizontal can also be obtained from Eq. (10).

5.2 Vertical Annuli [39–41]

The average dimensionless heat transfer coefficient in this case is given by

$$\mathrm{Nu}_s = f\left(\mathrm{Ra}, \frac{h}{L}, \frac{h}{r_i}, \frac{h}{r_a}\right),$$

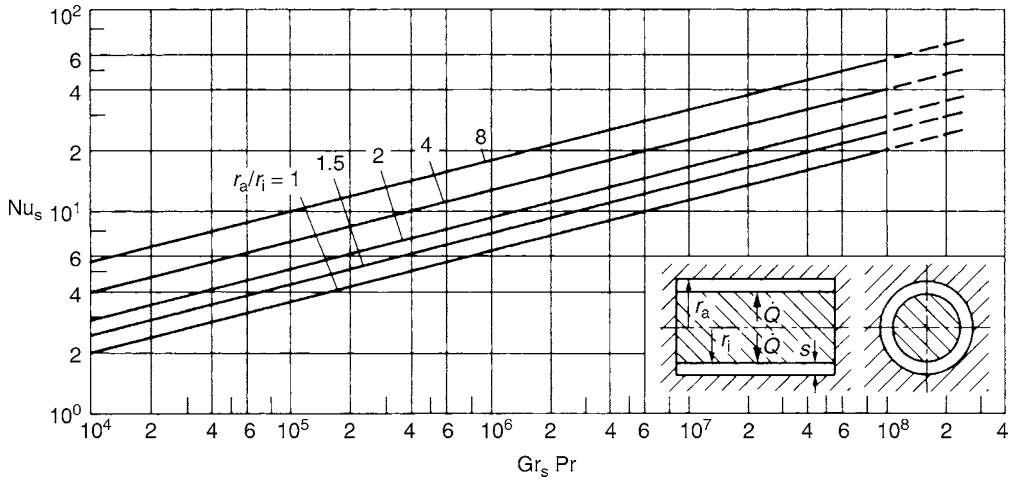
where h is the height of the vertical annular gap. The relationship is represented graphically in Fig. 5. If the flow of heat is from the inside to the outside, the following applies:

$$\mathrm{Nu}_s = \frac{C_1 \mathrm{Gr}_s\ \mathrm{Pr}(h/L)^2}{C_2(h/r_0)^4(r_i/h) + \left[\mathrm{Gr}_s\ \mathrm{Pr}(h/L)^3\right]^{n_1}(r_i/h)^{n_2}} \qquad (11)$$

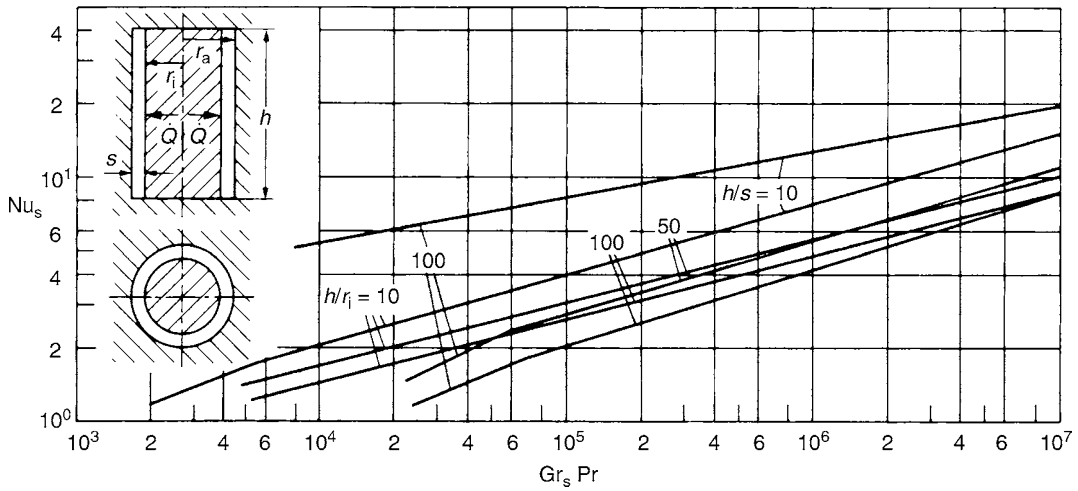
The factors C_1 and C_2 and the exponents n_1 and n_2 depend, as shown in the table below, on the magnitude N, which is given by

$$N = \left[\mathrm{Gr}_s\ \mathrm{Pr}\left(\frac{h}{L}\right)^3\right]^{-0.25}\left(\frac{h}{r_i}\right) \qquad (12)$$

	C_1	C_2	n_1	n_2
$N < 0.2$	0.48	854	0.75	0
$0.2 < N < 1.48$	0.93	1646	0.84	0.36
$1.48 < N$	0.49	862	0.95	0.80



F3. Fig. 4. Average dimensionless heat transfer coefficient Nu as a function of Ra for heat transfer in horizontal concentric annuli.



F3. Fig. 5. Average dimensionless heat transfer coefficient Nu as a function of Ra for heat transfer in vertical concentric annuli.

5.3 Spherical Gaps [42]

Equations have been devised for the determination of the average dimensionless heat transfer coefficient

$$\mathrm{Nu} = f(\mathrm{Ra}_{r_0}, \mathrm{Pr}, L/r_0)$$

applicable to externally heated spherical gaps in the range between conduction and heat transfer by free convection [42].

5.4 Porous Layers [43–50]

Other parameters must be introduced in order to describe free convection in porous layers saturated with fluid. A characteristic that can be adopted is the porosity, as defined by

$$\psi = V_{\text{interstices}}/V_{\text{total}}. \tag{13}$$

The permeability can be described by the porosity thus defined and by the diameter d of the particles in the bed, i.e.,

$$K = (d^2/150)[\psi^3/(1-\psi)^2]. \tag{14}$$

In some studies, about 180 figures have been cited instead of 150 for the first divisor. Allowance for the effect of the porous medium can be made by introducing the Darcy number $\mathrm{Da} = K/L^2$, in which L is the thickness of the layer, as a modified Rayleigh number, i.e.,

$$\mathrm{Ra}^* = \mathrm{RaDa}. \tag{15}$$

The corresponding values must be inserted for the properties of the medium. The dimensionless coefficients can then be defined as follows:

$$\mathrm{Nu}_s = \alpha s/\lambda_{\text{sat}},$$
$$\mathrm{Pr}^* = \nu_{\mathrm{F}}/a_{\text{sat}},$$
$$\mathrm{Ra}^* = g\beta_{\mathrm{F}}\Delta\vartheta LK/\nu_{\mathrm{b}}a_{\mathrm{b}},$$

where $a_{\mathrm{b}} = \lambda_{\mathrm{b}}/(\rho c_{\mathrm{p}})_{\mathrm{F}}$.

The subscript b refers to the entire porous bed saturated with the fluid, and the subscript F refers to the fluid fraction.

The thermal conductivity of the porous layer saturated with fluid λ_{sat} must be determined separately. The quotient of λ_{sat} and the known value for λ_{F} can be obtained as described in

Chap. D6. Other methods described elsewhere [50] may be adopted for simpler cases, such as those that are adequate for free convection. As a result of the difference in heat transport, the dimensionless heat transfer coefficient in porous layers is generally less than that in homogeneous layers subject to the same thermal and geometric boundary conditions. This effect reduces as the Rayleigh number increases.

5.5 Inclined Porous Rectangular Layers

The following equations have been cited in the literature [46] for the dimensionless heat transfer coefficient in porous layers inclined at angles of $\alpha' = 0$–$180°$ to the horizontal (Fig. 6). They are valid for dimensionless ratios of $h/L = 5$–32.7 and for particles of various diameters d in the bed.

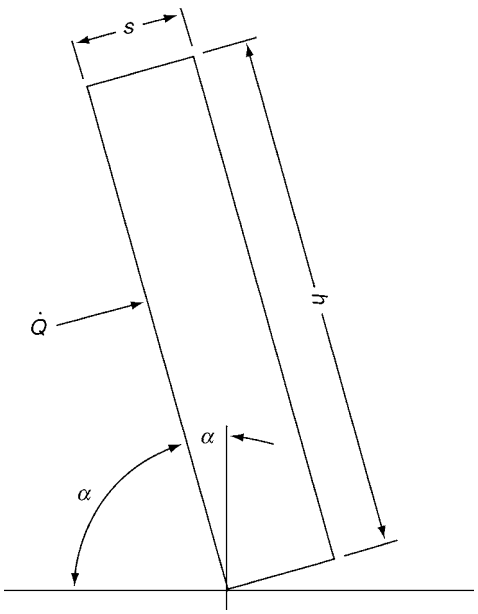
$$0° < \alpha' < 15°, \leftarrow 60 < \mathrm{Ra}^* \cos(\alpha' - 60) < 4.5 \times 10^2 :$$
$$\mathrm{Nu}_s = 0.053 \mathrm{Pr}^{*0.13} (d/L)^{-0.020} [\mathrm{Ra}^* \cos(\alpha' - 60°)]^{0.72}; \tag{16a}$$

$$15° < \alpha' < 120°, \leftarrow 60 < \mathrm{Ra}^* \cos(\alpha' - 60) < 4.5 \times 10^2 :$$
$$\mathrm{Nu} = 0.024 \mathrm{Pr}^{*0.13} (h/L)^{-0.34} [\mathrm{Ra}^* \cos(\alpha' - 60°)]^{0.52}; \tag{16b}$$

$$0° < \alpha' < 60°, \leftarrow 4.5 \cdot 10^2 < \mathrm{Ra}^* \cos\alpha' < 3 \times 10^4 :$$
$$\mathrm{Nu} = 0.067 \mathrm{Pr}^{*0.13} (d/L)^{-0.65} (\mathrm{Ra}^* \cos\alpha')^{0.52}; \tag{16c}$$

$$60° < \alpha' < 120°, \leftarrow 4.5 \cdot 10^2 < \mathrm{Ra}^* \sin\alpha' < 3 \times 10^4 :$$
$$\mathrm{Nu} = 0.062 \mathrm{Pr}^{*0.13} (h/L)^{-0.52} (\mathrm{Ra}^* \sin\alpha')^{0.64}. \tag{16d}$$

Equations are not given for larger angles of inclination, because they entail that, if the heated side faces downward, there would be no convection and only pure conduction would prevail.



F3. Fig. 6. Inclined porous enclosure.

5.6 Horizontal Porous Annuli

The following equation has been submitted for the determination of the average dimensionless heat transfer coefficient Nu in this case [48]:

$$\mathrm{Nu} = 0.255 \mathrm{Ra}^{*0.45}. \tag{17}$$

It is valid for the $10 < \mathrm{Ra}^* < 10^3$ range.

5.7 Vertical Porous Annuli

The case of a vertical annulus that is filled with a porous medium saturated with a fluid under the same geometrical boundary conditions as those illustrated in Fig. 5 has been described [34]. If the heat flux remains constant, the equation for the average dimensionless heat transfer coefficient is

$$\mathrm{Nu} = C \, \mathrm{Ra}^{nm} (h/L)^{-n}. \tag{18}$$

Numerical values for the indices and the constants in this equation are listed in Table 3.

If the direction of the constant heat flux $\dot{q}$ is from the inside to the outside, the correspondingly modified Rayleigh number Ra is given by

$$\mathrm{Ra}'' = g\beta_\mathrm{F} K L^2 \dot{q} / (\nu_\mathrm{F} a_\mathrm{b} \lambda_\mathrm{b}). \tag{19}$$

The increase in heat transfer depends greatly on the h/L ratio, particularly if the Rayleigh number is low. If the inner wall of the cylinder is isothermal, heat transfer is slightly impaired. Various other cases with peculiar geometric boundary conditions have been mentioned in the literature.

F3. Table 3. Exponents and constants for the determination of the dimensionless heat transfer coefficient by Eq. (18)

r_0/r_i	h/L	C	m	n	$\mathrm{Ra}_s'' \geq$
	1	0.312	0.413	0	100

5.8 Other Thermal and Geometric Boundary Conditions

5.8.1 Internal Heat Sources [51–56]

Internal heat sources within an enclosed fluid initiate currents in the form of convection cells. Heat is removed through the surfaces of the cooled walls in accordance with the temperature difference.

5.8.2 Thermal Radiation [51–56]

Consider the case of heat transfer in enclosures by simultaneous free convection and radiation with boundary conditions of the second or third kind. As a result of the superimposed heat radiation, the differences in temperature between the surfaces at which heat is exchanged are reduced. The consequence of this is that the coefficients of convective heat transfer decrease as the fraction of heat transported by radiation increases. The total heat flux thus rises.

The effect of radiation increases with the wall temperatures and the wall temperature differences. If radiation from the walls is augmented by gas radiation in molecular gases and vapors, the heat transfer as a whole somewhat decreases.

5.8.3 Mass Transfer [57–62]

No relationships of general validity can be offered for combined heat and mass transfer brought about by the differences in concentration and free convection. A few cases relating to vertical plane layers have been described in the literature.

Heat is not transferred solely by conduction during melting. Convection also sets in within the melt during the phase transition. Time-dependent dimensionless heat transfer equations are given in the literature for special boundary conditions.

5.8.4 Unsteady Free Convection [63]

Special cases have appeared in the literature to describe the complex relationships that exist in heat transfer by unsteady free convection in enclosures. They do not allow presentation in a generalized form.

F4 Heat Transfer by Free Convection: Special Cases

Werner Kast[2] · *Herbert Klan*[2] (*Revised by André Thess*[1])
[1]Technische Universität Ilmenau, Ilmenau, Germany
[2]Technische Universität Darmstadt, Darmstadt, Germany

1 Vertical Systems [1, 2]

Heated vertical channels act as chimneys, i.e., buoyancy forces cause the surrounding fluid to flow toward the inlet and through the channel itself. Assume a channel with a constant wall temperature T_w, a heated section of height h, and a longitudinal cross section of area f extending from the inlet to the outlet; and let fluid flow through the channel with a velocity distribution u. Then the heat transferred from the channel walls to the fluid is given by

$$\dot{Q} = \rho c_p \left[\int_0^f u(T - T_E)\, \mathrm{d}f \right]_h = A\alpha(T_w - T_E), \qquad (1)$$

where A is the area of the heated surface, T_E is the temperature of the fluid entering the channel, and ϑ is the outlet temperature distribution. The average heat transfer coefficient for the entire channel is

$$\alpha = \frac{\dot{Q}}{A(T_w - T_E)}. \qquad (2)$$

It is described by the following relationship for vertical channels:

$$\mathrm{Nu_S} = \mathrm{Nu_S}(\mathrm{Gr_S^*Pr}), \qquad (3)$$

where

$$\mathrm{Nu_S} = \frac{\alpha s}{\lambda}, \qquad (4)$$

$$\mathrm{Gr_S^*} = \frac{g\beta(T_w - T_E)s^3}{\nu^2}\frac{s}{h}, \qquad (5)$$

$$Pr = \frac{\nu}{a}. \qquad (6)$$

The coefficient of volume expansion β is determined as described in ◉ Chap. F1. The reference temperature for the properties is $\frac{1}{2}(T_w + T_E)$. If the channel is planar and heated on one side, as illustrated in Fig. 1a, the characteristic length s from which Nu and Gr are calculated is the width of the channel, i.e., $s = d$. In plane channels heated on two sides, as illustrated in Fig. 1b, the characteristic length is half the channel width, i.e., $s = d/2$; and in heated tubes, as illustrated in Fig 1c, it is the channel radius $s = r = d/2$. The heat transfer area A and the channel cross section f can then be obtained from the channel length b. The following thus apply:

Fig. 1a $A = bh$
Fig. 1b $A = 2bh$
Fig 1c $A = \pi dh$; $f = \pi d^2/4$.

The relationship $\mathrm{Nu_S} = \mathrm{Nu_S}(\mathrm{Gr_S^*Pr})$ is represented graphically for vertical tubes and plane channels in Fig. 2. In the range of low $\mathrm{Gr_S^*}$ numbers ($\mathrm{Gr_S^*} < 1$), the function $\mathrm{Nu_S}(\mathrm{Gr_S^*Pr})$ in Eq. (3) is given by

$$\mathrm{Nu_S} = C_1(\mathrm{Gr_S^*Pr}) \qquad (7)$$

where

$C_1 = 1/12 = 0.0833$ in the case shown in Fig. 1a
$C_1 = 1/3 = 0.3333$ in the case shown in Fig. 1b
$C_1 = 1/6 = 0.0625$ in the case shown in Fig 1c.

In the range of high $\mathrm{Gr^*_S}$, the function $\mathrm{Nu_S}(\mathrm{Gr_S^*Pr})$ in Eq. (3) is given by

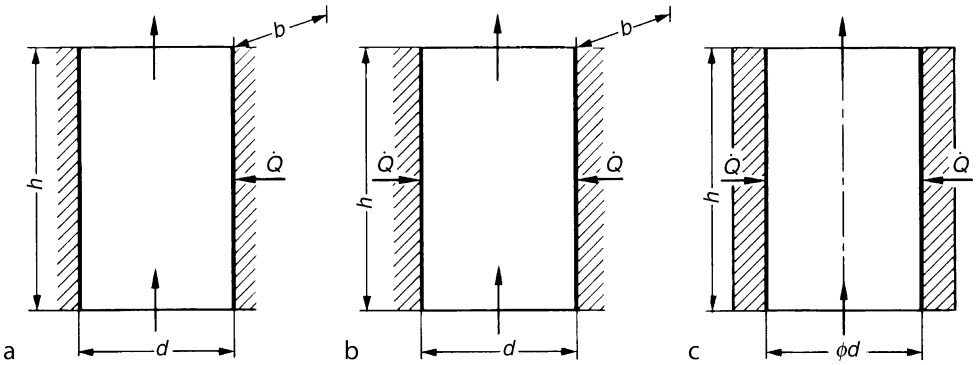
$$\mathrm{Nu_S} = C_2(\mathrm{Gr_S^*Pr})^{1/4} \qquad (8)$$

where

$C_2 = 0.61$ in the case shown in Fig. 1a
$C_2 = 0.69$ in the case shown in Fig. 1b
$C_2 = 0.52$ in the case shown in Fig 1c.

Within this range the heat transfer coefficient α is independent of the channel width s. Owing to the change in the direction of flow at the inlet, however, the asymptotes do not agree

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_21,



F4. Fig. 1. (**a**) Vertical rectilinear channel heated on one side; characteristic dimension $s = d$. (**b**) Rectilinear channel heated on two sides; characteristic dimension $s = d/2$. (**c**) Heated tube; characteristic length $s = r = d/2$.

with the equations in Chap. F2. As a consequence, a finite vertical velocity remains at the leading edge, even if the channel walls are widely spaced.

Heat transfer in the entire Gr_S^*Pr range can be approximately represented by the following equation (Fig. 3):

$$Nu_S = \left[\frac{1}{(C_1 Gr_S^* Pr)^{3/2}} + \frac{1}{[C_2 (Gr_S^* Pr)^{1/4}]^{3/2}}\right]^{-2/3} \quad (9)$$

2 Inclined Systems [2]

The following relationship applies for channels that are inclined at an angle of $\alpha = 45°$ or less to the vertical and are heated from above, from below, or from both above and below

$$Nu_S = C_2 (Gr_S^* Pr \cos\alpha)^{1/4} \quad (10)$$

where

$C_2 = 0.673$

$2 \times 10^2 < Gr_S^* Pr < 2 \times 10^5$

$0.0437 < s/h < 0.109$.

3 Open Vertical Annulus

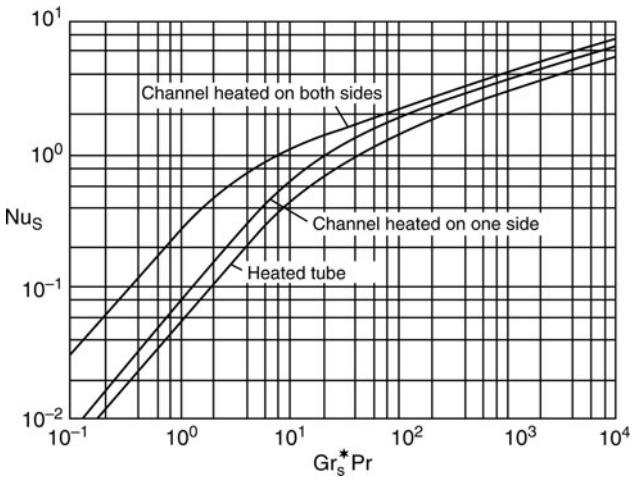
The characteristic dimension for a vertical annulus (Quoss. H.: Study No. 45, Technical University of Darmstadt, 1977) of height h is (Fig. 4)

$$s = \sqrt{r_0 r_i}\ln(r_0/r_i) \quad (11)$$

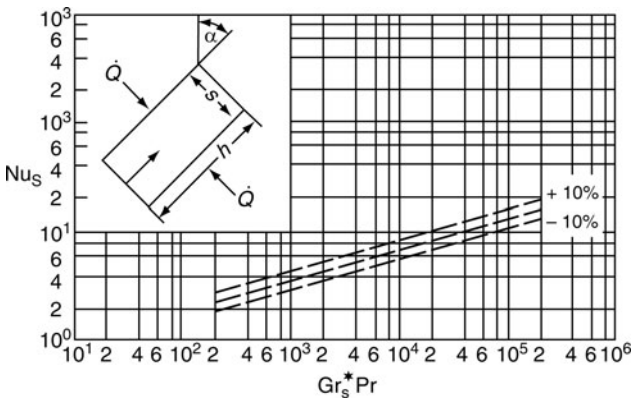
Various cases of heating exist. Heat transfer also depends on the ratio of the radii, and the only studies that have been made on the subject have been in the following range:

$$1 < r_0/r_i < 10 \quad (12)$$

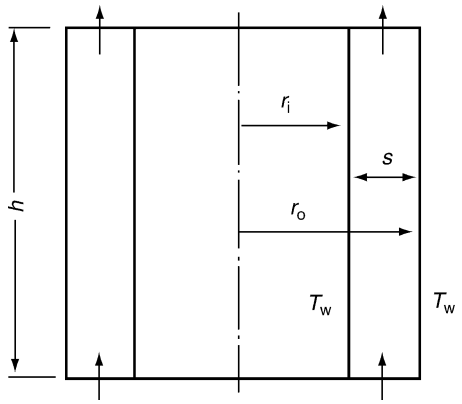
If $Gr_S^* < 10^2$, the dimensionless heat transfer coefficient that applies for isothermal heating of both walls at a temperature T_w is



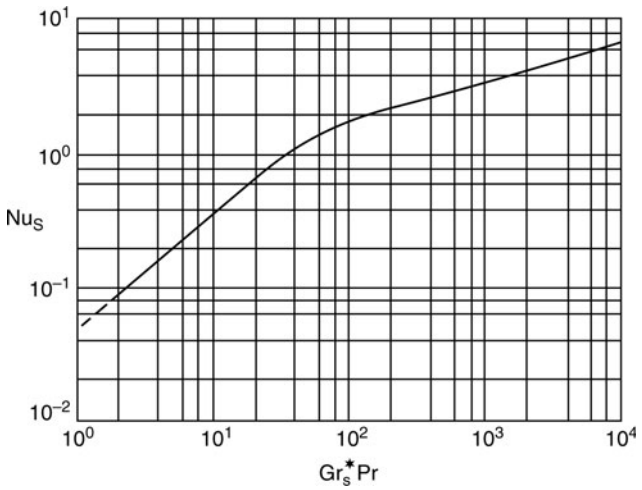
F4. Fig. 2. Nu_S as a function of Gr_S^*Pr for rectilinear vertical channels and vertical tubes.



F4. Fig. 3. Average dimensionless heat transfer coefficient in inclined rectangular channels heated from below, from above, and from both above and below.



F4. Fig. 4. Open vertical annulus.



F4. Fig. 5. Average dimensionless heat transfer coefficient for heating both the tubes forming an annulus.

$$Nu_S = C_1(Gr_S^* Pr) \tag{13}$$

where $C_1 = 0.0463$.

The relationship that applies if $Gr_S{}^* Pr > 10^2$ is

$$Nu_S = C_2(Gr_S^* Pr)^{0.25} \tag{14}$$

where $C_2 = 0.631$ (Fig. 5).

The dimensionless heat transfer coefficient for the case of isothermal heating of the outer tube and an adiabatic inner tube and for $Gr_S{}^* < 10$ is

$$Nu_S = C_1(Gr_S^* Pr) \tag{15}$$

where $C_1 = 0.0824$ for $r_0/r_i \to 1$ and $C_1 = 0.0463$ for $r_0/r_i \to 10$.

The relationship that applies if $Gr_S{}^* Pr > 10^2$ is

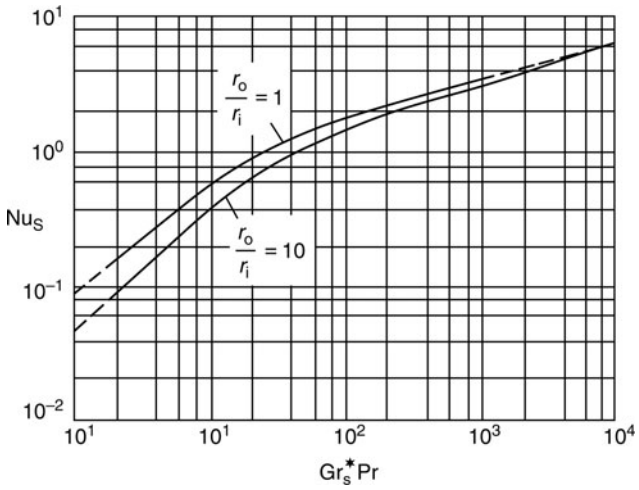
$$Nu_S = C_2(Gr_S^* Pr)^{0.25} \tag{16}$$

where $C_2 = 0.631$ (Fig. 6).

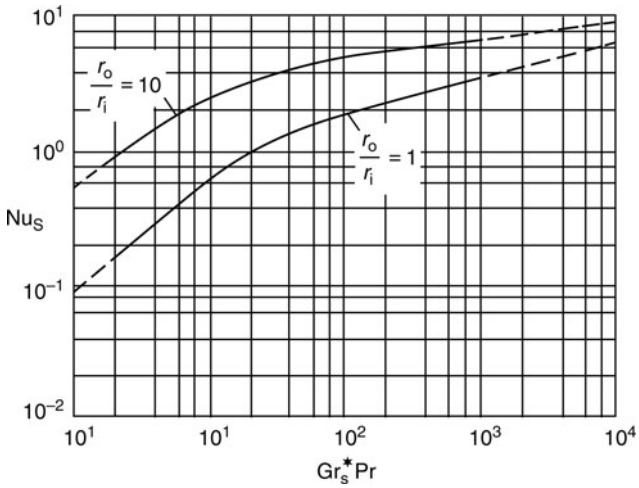
If the inner tube is isothermally heated at a temperature T_w and the outer tube is adiabatic, the dimensionless heat transfer coefficient for $Gr^*{}_S Pr < 10$ is given by

$$Nu_S = C_1(Gr_S^* Pr) \tag{17}$$

where $C_1 = 0.0858$ for $r_0/r_i \to 1$ and $C_1 = 0.5020$ for $r_0/r_i \to 10$.



F4. Fig. 6. Average dimensionless heat transfer coefficient for heated outer tube and adiabatic inner tube.



F4. Fig. 7. Average dimensionless heat transfer coefficient for heated inner tube and adiabatic outer tube.

If $Gr_S{}^* Pr > 10^2$,

$$Nu_S = C_2(Gr_S^* Pr)^{0.25} \tag{18}$$

where $C_2 = 0.631$ for $r_0/r_i \to 1$ and $C_2 = 0.8$ for $r_0/r_i \to 10$ (Fig. 7).

The following dimensionless relationship may be adopted for the entire range:

$$Nu_S = \left[\frac{1}{(C_1 Gr_S^* Pr)^{3/2}} + \frac{1}{[C_2(Gr_S^* Pr)^{0.25}]^{3/2}}\right]^{-2/3} \tag{19}$$

4 Other Geometric and Thermal Boundary Conditions

4.1 Superimposed Forced Convection [3]

Suppose that buoyancy forces drive a free convection current upward against a downward forced turbulent current in a vertical channel with a hydraulic diameter D_h. The relationship of

the dimensionless heat transfer coefficient to the Reynolds and Grashof numbers in this case is as follows:

$$\mathrm{Nu_{Dh}} = 0.0115\mathrm{Re_{Dh}^{0.8}Pr^{0.5}} \cdot \left\{1 + \left[1 - \frac{696}{\mathrm{Re_{Dh}^{0.6}}} + \frac{8300\ \mathrm{Gr_{Dh}}}{\mathrm{Re_{Dh}^{2.6}(Pr^{0.5}+1)}}\right]^{0.39}\right\} \quad (20)$$

It is valid for $0.7 < \mathrm{Pr} < 7$; for $10^4 < \mathrm{Re_{Dh}} < 2 \times 10^4$; and for $10^6 < \mathrm{Gr_{Dh}} < 2 \times 10^9$.

Heat transfer is improved by the superimposed free convection.

5 Convergent Channels [4]

Imagine that heat transfer takes place in a convergent vertical channel that is heated on both sides. The angle at which the converging walls are inclined toward the vertical lies in the $\alpha = 0°–15°$ range. In this case, the difference between the average dimensionless heat transfer coefficient and the values calculated from Eqs. (7) and (8) is negligible if the characteristic channel width is taken to be one half of the gap width at the lower end of the channel.

6 Partially Heated Channels [5]

If $\mathrm{Gr_S^*} > 100$, heat transfer in vertical channels that are heated on the one side can be improved by alternating, i.e., by applying the heat to the one side at the lower end of the channel, and to the other side at the upper end.

7 Half-open Layers

This case concerns various layouts of the heated surfaces with apertures of a thermosiphon that is exposed on the one side to the surroundings. The relationship that is given in the literature for the average dimensionless heat transfer coefficient in this case is

$$\mathrm{Nu_S} = f(\mathrm{Gr_S}, \mathrm{Pr}, h/s) \quad (21)$$

where h is the height of the heated surface and s is the depth of the layer. If the walls are inclined, the angle of inclination must again be taken into account.

F5 Thermal Output of Heating Appliances Operating with Hot Water

Werner Kast[2] · *Herbert Klan*[2] (*Revised by André Thess*[1])
[1]Technische Universität Ilmenau, Ilmenau, Germany
[2]Technische Universität Darmstadt, Darmstadt, Germany

1 Thermal Output of Space Heating Appliances (Radiators)

Radiators are intended to provide heating in buildings, which can be determined as laid down in German standard DIN 4701. This document is available in English. The appliances transmit heat by radiation and/or convection.

1.1 Types of Space Heating Appliances

Space heating systems and appliances are classified as follows without regard to their shape and material of construction:

(a) Sectional radiators
(b) Panel radiators
(c) Column radiators
(d) Special heating systems
(e) Panel heating

1.2 Thermal Output

The thermal output of a space heater $\dot{Q}$ is proportional to the average excess temperature of the heated surface ΔT^n. The numerical value of the exponent n is generally from $n = 1.25$ to $n = 1.4$; for panel heating it is from $n = 1.0$ to $n = 1.1$. The excess temperature is determined from the inlet and outlet water temperatures T_i and T_o, respectively, and the air temperature T_a, i.e.,

$$\Delta T = \frac{T_i - T_o}{\ln[(T_i - T_a)/(T_o - T_a)]}.$$

An arithmetic mean excess temperature T_m can be adopted if the temperature difference $T_i - T_o$ is small, i.e., as long as

$$\frac{T_o - T_a}{T_i - T_a} > 0.7.$$

Thus,

$$\Delta T = T_m - T_n \quad \text{where } T_m = \frac{T_i + T_0}{2}.$$

A standard rating for the thermal output $\dot{q}_n$ is adopted in German standards. It is based on the thermal output at an excess temperature of $\Delta T_n = 60$ K, i.e., at $T_1 = 90°C$, $T_r = 70°C$, and $T_a = 20°C$, and can be converted into a rating at other temperatures by the relationship

$$\frac{\dot{q}}{\dot{q}_n} = \left(\frac{\Delta T}{\Delta T_n}\right)^n.$$

The thermal output of floor heating panels is restricted by a physiologically tolerable temperature at the surface of $T_{F,\,max} = 29°C$ in living rooms, $T_{F,\,max} = 35°C$ in edge zones, and $T_{F,\,max} = 33°C$ in bathrooms. The rating for the thermal output in this case is quoted for $T_{F,\,max} = 29°C$ and a room temperature of 20°C.

Slight differences, which depend on the nature of the heating system, occur between the comfort value of the room temperature and that of the air temperature. Other factors are the layout of the rooms, differential gaps in the controllers, and heat losses. In view of all these, the areas of the heaters are made 15% greater than the design values.

Values for the thermal output of conventional heating appliances are listed in the following tables. They are expressed in terms of the length of the radiator, the number of sections in the radiator, or the area of the floor heating panels. Rough figures that can be adopted for calculation are $n = 1.3$ for radiators and $n = 1.0$ for floor heating.

The figures quoted for the output ratings are valid for radiators in which the hot water inlet is connected at the top; and the outlet (whether on the same or the opposite side), at the bottom. A considerable reduction in the thermal output can be expected if the connections are otherwise.

Paints pigmented with metal powders may considerably impair the thermal efficiency. Thus, they give rise to a decrease in thermal output of at least 4%, if the radiators are installed in niches; of at least 4%, if there is a sill above the radiator; and of at least 10%, if the radiator is covered at the front.

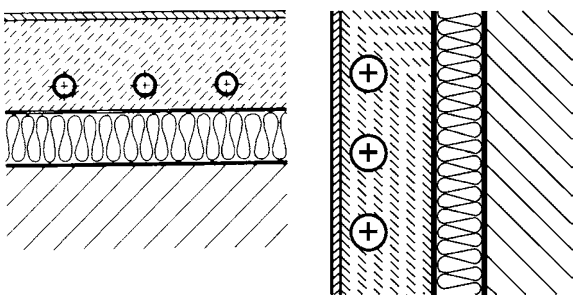
See Tables 6–13.

4 Thermal Output of Floor Heating

The heat flux $\dot{q}$ emitted by the floor heating panels installed by conventional dry and wet construction techniques can be determined as a function of the excess temperature ΔT of the hot water. It lies between $\dot{q} = 50\ \mathrm{W/m^2}$ and $\dot{q} = 90\ \mathrm{W/m^2}$ for living rooms at $T = 20°\mathrm{C}$. The actual value depends on the pipe spacing, the thickness of the concrete slab, the tube diameter, the method adopted for laying the floor, the floor covering, etc.



F5. Table 7. Panel radiators with $\Delta T = 60$ K. Vertically profiled; panels of 18 $\pm$ 3 mm thickness. Developed length of profiles at least 10% longer than the length of the panels; height of profiles $\geq$ total height $-$ 100 mm (without cover grill); (internal width) $\geq$ 35 mm

Forced Convection

G1 Heat Transfer in Pipe Flow

Volker Gnielinski
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Flow Through Pipes, Critical Reynolds Number

Pipe flow is always laminar if the Reynolds number is less than Re = 2300, and is said to be turbulent at higher values. There is no doubt that turbulent flow sets in at $\mathrm{Re} > 10^4$. In the transition region of $2300 < \mathrm{Re} < 10^4$, the type of flow is influenced by the nature of the inlet stream and the form of the pipe inlet.

2 Definition of Heat Transfer Coefficient

The average heat transfer coefficient α over a length l of a pipe is defined by

$$\dot{q} = \alpha \, \Delta T_{\mathrm{LM}}$$

The variable ΔT_{LM} is the logarithmic mean temperature difference and is given by

$$\Delta T_{\mathrm{LM}} = \frac{(T_{\mathrm{w}} - T_{\mathrm{i}}) - (T_{\mathrm{w}} - T_{\mathrm{o}})}{\ln \dfrac{T_{\mathrm{w}} - T_{\mathrm{i}}}{T_{\mathrm{w}} - T_{\mathrm{o}}}}$$

where T_{i} and T_{o} are the inlet and outlet temperatures of the flowing medium and T_{w} is the constant pipe wall temperature. The average heat transfer coefficient α is obtained by integration of the local coefficient, that is,

$$\alpha = \frac{1}{l} \int_0^l \alpha_x \mathrm{d}x.$$

3 Heat Transfer in Laminar Flow

3.1 Constant Wall Temperature

3.1.1 Hydrodynamically Developed Laminar Flow

Many authors have proposed numerical methods for determining heat transfer in thermally and hydrodynamically developed laminar flow (in long pipes) and in thermally developing and hydrodynamically developed laminar flow (the Nusselt-Graetz problem).

The asymptotes for the *local Nusselt number* at a point x, as measured from the point at which heating or cooling commences, are given by

$$\mathrm{Nu}_{x,T,1} = 3.66 \tag{1}$$

for small values of $\mathrm{Re}\,\mathrm{Pr}\,(d_{\mathrm{i}}/x)$ and

$$\mathrm{Nu}_{x,T,2} = 1.077 \sqrt[3]{\mathrm{Re}\,\mathrm{Pr}\,(d_{\mathrm{i}}/x)} \tag{2}$$

for high values of $\mathrm{Re}\,\mathrm{Pr}\,(d_{\mathrm{i}}/x)$.

Local Nusselt numbers for the range between the two asymptotes have been determined numerically and tabulated by Shah and London [1].

Local Nusselt numbers in the entire $0 < \mathrm{Re}\,\mathrm{Pr}(d_{\mathrm{i}}/x) < \infty$ range, with a deviation that attains a maximum at 6% at $10 < \mathrm{Re}\,\mathrm{Pr}\,d_{\mathrm{i}}/x < 100$ and is otherwise much smaller, can be obtained from

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_23,

$$\mathrm{Nu}_{x,T} = \left\{ \mathrm{Nu}_{x,T,1}^3 + 0.7^3 + [\mathrm{Nu}_{x,T,2} - 0.7]^3 \right\}^{1/3} \quad (3)$$

The asymptotes for the *mean Nusselt number* in a tube of the length l as measured from the point, at which heating or cooling commences, are

$$\mathrm{Nu}_{\mathrm{m},T,1} = 3.66 \quad (4)$$

for low values of $\mathrm{Re}\,\mathrm{Pr}\,d_\mathrm{i}/l$ and

$$\mathrm{Nu}_{\mathrm{m},T,2} = 1.615\ \sqrt[3]{\mathrm{Re}\,\mathrm{Pr}\,\mathrm{d_i}/\mathrm{l}} \quad (5)$$

for high values of $\mathrm{Re}\,\mathrm{Pr}\,d_\mathrm{i}/l$.

As has been demonstrated in the literature [2], the numerically determined and tabulated mean Nusselt numbers [1] in the entire $0 < \mathrm{Re}\,\mathrm{Pr}\,d_\mathrm{i}/l < \infty$ range can be represented, with deviations of less than 1%, by the following equation:

$$\mathrm{Nu}_{\mathrm{m},T} = \left\{ \mathrm{Nu}_{\mathrm{m},T,1}^3 + 0.7^3 + [\mathrm{Nu}_{\mathrm{m},T,2} - 0.7]^3 \right\}^{1/3} \quad (6)$$

3.1.2 Hydrodynamic and Thermal Development of Flow

As a result of friction between the fluid and the pipe wall, a velocity profile commences to build up at the pipe inlet. If, at the same time, heat is transferred, a temperature profile also sets in. Boundary layers are thus formed, and heat transfer in this zone is calculated in the light of the boundary layer theory.

The *local Nusselt number* can be determined from Eq. (7), which was proposed by Pohlhausen [3] for parallel flow over a flat plate and has been transformed here to apply for pipe flow.

$$\mathrm{Nu}_{x,T} = 0.332\ \sqrt[3]{\mathrm{Pr}}\sqrt{\mathrm{Re}d_\mathrm{i}/x} \quad (7)$$

The factor 0.332 in Eq. (7) is a good approximation for $\mathrm{Pr} > 0.1$. The relationship between the Prandtl number, even if it assumes small or large values, and the heat transfer coefficient is better defined by a rough equation put forward by Martin [4], that is,

$$\mathrm{Nu}_{x,T,3} = \frac{1}{2}\left(\frac{2}{1+22\,\mathrm{Pr}}\right)^{1/6} (\mathrm{Re}\,\mathrm{Pr}\,d_\mathrm{i}/x)^{1/2} \quad (8)$$

Equations (7) and (8) are valid for high values of d_i/x. As the length of the flow path x becomes greater, d_i/x becomes progressively less, and higher values for the Nusselt number are obtained from Eq. (3) than from Eqs. (7) and (8). In this case, the values that are valid are those calculated from Eq. (3).

Equation (9), which was suggested by Martin [4], yields the local values of the Nusselt number at any point x in a pipe in which laminar flow is developing thermally and hydrodynamically.

$$\mathrm{Nu}_{x,T} = \left\{ \mathrm{Nu}_{x,T,1}^3 + 0.7^3 + [\mathrm{Nu}_{x,T,2} - 0.7]^3 + \mathrm{Nu}_{x,T,3}^3 \right\}^{1/3} \quad (9)$$

where $\mathrm{Nu}_{x,T,1}$ is obtained from Eq. (1), $\mathrm{Nu}_{x,T,2}$ from Eq. (2), and $\mathrm{Nu}_{x,T,3}$ from Eq. (8).

Simultaneous thermal and hydrodynamic development of laminar flow is so rapid that the mean Nusselt number over the length l departs from the figure determined by Eq. (6) only for short pipes ($d_\mathrm{i}/l > 0.1$).

The asymptotes for the *mean Nusselt numbers* for large values of d_i/l, that is, for short pipes, are obtained by integrating Eq. (7) or Eq. (8) over the length l to give

$$\mathrm{Nu}_{\mathrm{m},T} = 0.664\ \sqrt[3]{\mathrm{Pr}}\sqrt{\mathrm{Re}\ d_\mathrm{i}/l} \quad (10)$$

and

$$\mathrm{Nu}_{\mathrm{m},T,3} = \left(\frac{2}{1+22\,\mathrm{Pr}}\right)^{1/6} (\mathrm{Re}\,\mathrm{Pr}\,d_\mathrm{i}/l)^{1/2} \quad (11)$$

Equation (11) is a good approximation for the relationship between the Nusselt and the Prandtl numbers, even if $\mathrm{Pr} < 1$. The equation proposed by Stephan [5] for the average Nusselt number in hydrodynamic and thermal development of laminar flow transforms into Eqs. (10) and (11) if the flow path is short.

As has been demonstrated [2], an equation that is valid for all lengths of pipes can be derived for the mean Nusselt number during thermal and hydrodynamic development of flow. One that has been suggested by Martin [4] is as follows:

$$\mathrm{Nu}_{\mathrm{m},T} = \left\{ \mathrm{Nu}_{\mathrm{m},T,1}^3 + 0.7^3 + [\mathrm{Nu}_{\mathrm{m},T,2} - 0.7]^3 + \mathrm{Nu}_{\mathrm{m},T,3}^3 \right\}^{1/3} \quad (12)$$

where $\mathrm{Nu}_{\mathrm{m},T,1}$ is obtained from Eq. (4), $\mathrm{Nu}_{\mathrm{m},T,2}$ from Eq. (5), and $\mathrm{Nu}_{\mathrm{m},T,3}$ from Eq. (11).

3.1.3 Definitions, the Effect of Temperature-Dependent Property Variations

The dimensionless groups are defined as follows:

$$\mathrm{Nu} = \frac{\alpha\, d_\mathrm{i}}{\lambda}; \qquad \mathrm{Re} = \frac{w\, d_\mathrm{i}}{\nu}.$$

In the theoretical derivation of the equations presented in Sects. 3.1.1 and 3.1.2, it was assumed that the properties of the medium remain constant. The equations can be adopted in practice if the properties are referred to the mean temperature of the medium $T_\mathrm{m} = (T_\mathrm{i} + T_\mathrm{o})/2$.

If the properties depend on temperature, the direction of the heat flux (heating or cooling) affects heat transfer. Experiments on laminar gas flow of air, nitrogen, and helium [6–8] in the $0.5 < T/T_\mathrm{w} < 20$ range – where T is the mean gas temperature and T_w is the wall temperature, both in Kelvin – have revealed that the heat transfer coefficient differs by less than 10%.

Sieder and Tate [9] allowed for this effect in liquids by introducing the factor $(\eta/\eta_\mathrm{w})^{0.14}$, in which η is the dynamic viscosity of the liquid at T_m and η_w is that at the wall temperature. Recent practice favors the adoption of the Prandtl number ratio instead of the viscosity ratio for the liquid at corresponding temperatures. Hufschmidt and Burck [10] found a factor of $(\mathrm{Pr}/\mathrm{Pr_w})^{0.11}$ for turbulent flow. Since the values measured by Sieder and Tate are scattered quite considerably and it is worthwhile to bring the correction factor into line with that for turbulent flow, a factor of $(\mathrm{Pr}/\mathrm{Pr_w})^{0.11}$ should also be taken for laminar flow. (Pr is the Prandtl number at T_m; and $\mathrm{Pr_w}$, that at the wall temperature.)

In Eqs. (6) and (12) $(\mathrm{Pr}/\mathrm{Pr_w})$ is equated to unity. Hence,

$$\mathrm{Nu} = \mathrm{Nu}_{\mathrm{m},T}\left(\frac{\mathrm{Pr}}{\mathrm{Pr_w}}\right)^{0.11} \tag{13}$$

3.2 Constant Heat Flux

3.2.1 Hydrodynamically Developed Laminar Flow

Theoretical relationships for the heat transfer coefficient also exist for the boundary condition of constant heat flux, i.e., $\dot{q}$ = const., along the length of the plate. An example where this occurs is the electric heating of tubes.

In thermally and hydrodynamically developed laminar flow (low values of $\mathrm{Re\,Pr}\, d_\mathrm{i}/x$, i.e., long pipes), the asymptote for the *local Nusselt number* at a point located at a distance x from the pipe inlet is given by

$$\mathrm{Nu}_{x,q,1} = 4.354 \tag{14}$$

If the flow is still developing thermally and has been developed hydrodynamically, the asymptote is given by Eq. (15). The conditions in this case are that the value of $\mathrm{Re\,Pr}\, d_\mathrm{i}/x$ is high, heating does not commence until the end is reached of the section in which hydrodynamic development takes place, and x is measured from the point at which heating commences.

$$\mathrm{Nu}_{x,q,2} = 1.302\ \sqrt[3]{\mathrm{Re\,Pr}\, d_\mathrm{i}/x} \tag{15}$$

Local Nusselt numbers in the range between the two asymptotes have been determined numerically and tabulated by Sha and London [1].

The local Nusselt numbers in the entire $0 < \mathrm{Re\,Pr}\, d_\mathrm{i}/x < \infty$ range can be obtained from Eq. (16). The maximum deviation in this case is –4% in the $100 < \mathrm{Re\,Pr}\, d_\mathrm{i}/x < 1000$ range; otherwise it is less or even positive.

$$\mathrm{Nu}_{x,q} = \left\{\mathrm{Nu}_{x,q,1}^3 + 1 + [\mathrm{Nu}_{x,q,2} - 1]^3\right\}^{1/3} \tag{16}$$

The asymptotes for the *mean Nusselt number* in a pipe of length l are

$$\mathrm{Nu}_{\mathrm{m},q,1} = 4.364 \tag{17}$$

for low values of $\mathrm{Re\,Pr}\, d_\mathrm{i}/l$ and

$$\mathrm{Nu}_{\mathrm{m},q,2} = 1.953\ \sqrt[3]{\mathrm{Re\,Pr}\, d_\mathrm{i}/l} \tag{18}$$

for high values of $\mathrm{Re\,Pr}\, d_\mathrm{i}/l$.

Equation (19) allows the same mean Nusselt numbers as those determined numerically [1] to be obtained over the entire $0 < \mathrm{Re\,Pr}\, d_\mathrm{i}/l$ range. The deviation is less than 1%.

$$\mathrm{Nu}_{\mathrm{m},q} = \left\{\mathrm{Nu}_{\mathrm{m},q,1}^3 + 0.6^3 + [\mathrm{Nu}_{\mathrm{m},q,2} - 0.6]^3\right\}^{1/3} \tag{19}$$

3.2.2 Hydrodynamic and Thermal Development of Flow

Gauler [11] has calculated the *local Nusselt number* for the thermal and hydrodynamic development of flow, which is explained in the first paragraph of Sect. 3.1.2, for the case of parallel flow over a flat plate. Rearrangement of his equation to apply for flow through a pipe gives

$$\mathrm{Nu}_{x,q} = 0.459\ \sqrt[3]{\mathrm{Pr}}\sqrt{\mathrm{Re}\ d_\mathrm{i}/x}\quad \text{for}\quad \mathrm{Pr} \approx 1 \tag{20}$$

and

$$\mathrm{Nu}_{x,q} = 0.464\ \sqrt[3]{\mathrm{Pr}}\ \sqrt{\mathrm{Re}\ d_\mathrm{i}/x}\quad \text{for}\quad \mathrm{Pr} \to \infty \tag{21}$$

For practical purposes, the equation applicable to $\mathrm{Pr} > 0.7$ can be obtained with sufficient accuracy by taking the average of the two factors in Eqs. (20) and (21), i.e.,

$$\mathrm{Nu}_{x,q,3} = 0.462\ \sqrt[3]{\mathrm{Pr}}\ \sqrt{\mathrm{Re}\ (d_\mathrm{i}/x)}\ \text{for}\ \mathrm{Pr} > 0.7 \tag{22}$$

Equation (22) is applicable for large values of (d_i/x). Increasing flow length results in small values of (d_i/x), and one obtains from Eq. (22) smaller values of the local Nusselt number than from Eq. (16).

Spang [12] numerically calculated local Nusselt numbers for thermally and hydrodynamically developing laminar flow with $\dot{q}$ = const. The values for $0.7 < \mathrm{Pr} < 1{,}000$ are very well represented by

$$\mathrm{Nu}_{x,q} = \left\{\mathrm{Nu}_{x,q,1}^3 + (\mathrm{Nu}_{x,q,2} - 1)^3 + \mathrm{Nu}_{x,q,3}^3\right\}^{1/3} \tag{23}$$

with $\mathrm{Nu}_{x,q,1}$ from Eq. (14), $\mathrm{Nu}_{x,q,2}$ from Eq. (15), and $\mathrm{Nu}_{x,q,3}$ from Eq. (22).

Laminar flow develops very quickly. Therefore, for $(d_\mathrm{i}/l) > 0.1$, *mean Nusselt numbers* in flows with simultaneous thermal and hydrodynamic development differ only slightly from the values calculated from Eq. (19), which was for the case where fully developed flow was established before heating started. The asymptote for the mean Nusselt number for simultaneous development at large values of (d_i/l) (i.e., for short tubes) results from an integration of Eq. (22) over the length of the tube, giving the following equation:

$$\mathrm{Nu}_{\mathrm{m},q,3} = 0.924\ \sqrt[3]{\mathrm{Pr}}\ \sqrt{\mathrm{Re}\,(d_\mathrm{i}/l)} \tag{24}$$

A comparison with the calculated values of Spang [12] shows that an equation for the thermally and hydrodynamically developing flow for all tube lengths can be obtained from

$$\mathrm{Nu}_{\mathrm{m},q} = \left\{\mathrm{Nu}_{\mathrm{m},q,1}^3 + 0.6^3 + (\mathrm{Nu}_{\mathrm{m},q,2} - 0.6)^3 + \mathrm{Nu}_{\mathrm{m},q,3}^3\right\}^{1/3} \tag{25}$$

with $\mathrm{Nu}_{\mathrm{m},q,1}$ from Eq. (17), $\mathrm{Nu}_{\mathrm{m},q,2}$ from Eq. (18), and $\mathrm{Nu}_{\mathrm{m},q,3}$ from Eq. (24).

3.2.3 Explanations, Effect of Temperature-Dependent Property Variations

The explanations given in Sect. 3.1.3 also apply in this case. Herwig [13] published a theoretical study on the effect exerted on heat transfer by temperature-dependent property variations for the case of completely developed pipe flow at $\dot{q}$ = const. The results practically correspond to those obtained from Eq. (13). Since no experimental data can be found in the literature that would allow the effect of variations in properties to be

determined, the procedure recommended is precisely that described in Sect. 3.1.3.

4 Heat Transfer in Turbulent Flow Through Pipes

4.1 Nusselt Number for Fully Developed Turbulent Flow

Transition from laminar to turbulent flow starts at Re = 2100 to Re = 2300. The flow is fully turbulent at Re $\geq 10^4$. If the flow is turbulent, almost the same Nusselt number applies for the two boundary conditions: "constant wall temperature" and "constant heat flux."

An equation put forward by Gnielinski [14] for heat transfer during turbulent flow of gases and liquids through pipes is

$$\mathrm{Nu_m} = \frac{(\xi/8)\,\mathrm{Re\,Pr}}{1 + 12.7\sqrt{\xi/8}\left(\mathrm{Pr}^{2/3} - 1\right)}\left[1 + \left(d_\mathrm{i}/l\right)^{2/3}\right] \qquad (26)$$

where

$$\xi = \left(1.8\log_{10}\mathrm{Re} - 1.5\right)^{-2} \qquad (27)$$

Equation (26) was obtained by modifying an equation that was derived from the theory of momentum transport by Petukhov and Kirillov [15] and is valid for completely developed pipe flow. It was enlarged by a factor proposed by Hausen [16] to take into account the dependence of the heat transfer coefficient from the length of the pipe. According to Konakov [17], the friction factor for turbulent flow in smooth pipes may be calculated from Eq. (27).

Explanations and ranges of validity are as follows:

$$\mathrm{Nu_m} = \frac{\alpha\, d_\mathrm{i}}{\lambda};\ \mathrm{Re} = \frac{w d_\mathrm{i}}{\nu};\ 10^4 \leq \mathrm{Re} \leq 10^6;$$
$$0.1 \leq \mathrm{Pr} \leq 1000;\ d_\mathrm{i}/l \leq 1.$$

The physical properties of the fluids are referred to the mean temperature $T_\mathrm{m} = (T_\mathrm{i} + T_\mathrm{o})/2$.

Section 4.4 deals with the effect of the temperature dependence of the physical properties on the heat transfer coefficient.

On a large number of experimental data, Gnielinski [14] has tested the validity of Eq. (26). The Prandtl numbers of the data were between 0.6 and 1,000. Martin [18] compared the Nusselt numbers resulting from Eq. (26) with those from a new calculation procedure for the heat transfer with turbulent flow in tubes from Churchill and Zajic [19]. He found that the results of this calculation procedure agree very well with those from Eq. (26) up to a Prandtl number of Pr = 0.1. The range of validity of Eq. (26) may therefore be widened up to Pr = 0.1.

From Eq. (26), it may be inferred that the Nusselt number for fully developed turbulent flow depends markedly from the length of the tube only at the entrance. The *local Nusselt number* results from a differentiation of Eq. (26), giving

$$\mathrm{Nu_x} = \frac{(\xi/8)\ \mathrm{Re\,Pr}}{1 + 12.7\sqrt{\xi/8}\ \left(\mathrm{Pr}^{2/3} - 1\right)}\left[1 + \frac{1}{3}\left(d_\mathrm{i}/x\right)^{2/3}\right] \qquad (28)$$

with ξ from Eq. (27).

4.2 Nusselt Number in the Transition Region Between Laminar and Fully Developed Turbulent Flow

After the critical Reynolds number (approximately 2300) is exceeded, the development of turbulence depends on many influencing factors, for example, the shape of the entrance of the tube, the manner in which the fluid flows towards the tube entrance and the disturbances in the velocity of the flow.

Rotta [20] observed that water entering a tube from a container was changing at short intervals between laminar and turbulent flow. To describe the temporal sequences, he introduced an "intermittency factor" γ, where $\gamma = 1$ if the flow is turbulent permanently, and $\gamma = 0$ if the flow is permanently laminar.

According to these observations, Gnielinski [21] proposed an equation to describe by interpolation the regime between permanent laminar and turbulent flow. This equation represents very well the experimental data of numerous authors. The equation is as follows:

$$\mathrm{Nu} = (1-\gamma)\,\mathrm{Nu}_{\mathrm{lam},2300} + \gamma\,\mathrm{Nu}_{\mathrm{turb},10^4} \qquad (29)$$

where γ is given by

$$\gamma = \frac{\mathrm{Re} - 2300}{10^4 - 2300}, \quad \text{and} \quad 0 \leq \gamma \leq 1 \qquad (30)$$

$\mathrm{Nu_{lam,2300}}$ is the Nusselt number at Re = 2300 calculated from Eq. (12) or Eq. (25) according to the boundary condition. $\mathrm{Nu_{turb,10^4}}$ is the Nusselt number from Eq. (26) at $\mathrm{Re} = 10^4$.

Therefore, one gets:

For *constant wall temperature* laminar flow, from Eq. (12)

$$\mathrm{Nu}_{\mathrm{m},T,2300} = \left\{49.371 + \left(\mathrm{Nu}_{\mathrm{m},T,2,2300} - 0.7\right)^3 + \mathrm{Nu}^3_{\mathrm{m},T,3,2300}\right\}^{1/3} \qquad (31)$$

with

$$\mathrm{Nu}_{\mathrm{m},T,2,2300} = 1.615\ (2300\,\mathrm{Pr}\,d_\mathrm{i}/l)^{1/3} \qquad (32)$$

and

$$\mathrm{Nu}_{\mathrm{m},T,3,2300} = \left(\frac{2}{1 + 22\,\mathrm{Pr}}\right)^{1/6}(2300\,\mathrm{Pr}\,d_\mathrm{i}/l)^{1/2} \qquad (33)$$

For *constant heat flux*, laminar flow, from Eq. (25)

$$\mathrm{Nu}_{\mathrm{m},q,2300} = \left\{83.326 + \left(\mathrm{Nu}_{\mathrm{m},q,2,2300} - 0.6\right)^3 + \mathrm{Nu}^3_{\mathrm{m},q,3,2300}\right\}^{1/3} \qquad (34)$$

with

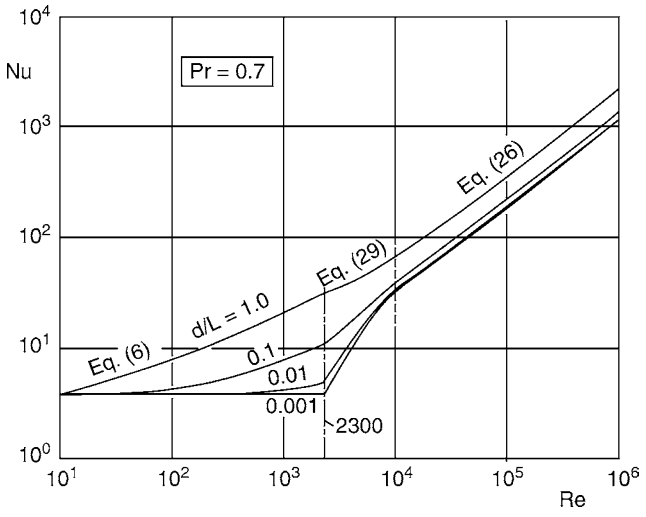
$$\mathrm{Nu}_{\mathrm{m},q,2,2300} = 1.953\ (2300\,\mathrm{Pr}\,d_\mathrm{i}/l)^{1/3} \qquad (35)$$

and

$$\mathrm{Nu}_{\mathrm{m},q,3,2300} = 0.924\ (\mathrm{Pr})^{1/3}(2300\ d_\mathrm{i}/l)^{1/2} \qquad (36)$$

For *constant wall temperature or constant heat flux* and turbulent flow from Eq. (26)

$$\mathrm{Nu}_{\mathrm{m},10^4} = \frac{(0.0308/8)10^4\,\mathrm{Pr}}{1 + 12.7\sqrt{0.0308/8}\left(\mathrm{Pr}^{2/3} - 1\right)}\left[1 + \left(d_\mathrm{i}/l\right)^{2/3}\right] \qquad (37)$$



G1. Fig. 1. Nu_m in dependence of Re according to the Eqs. (6), (26), and (29) for heat transfer in circular pipes at Pr = 0.7.

Range of validity:

$$2300 \leq Re \leq 10^4; \quad 0.6 \leq Pr \leq 1000; \quad d_i/l \leq 1.$$

This equation of interpolation avoids the "jump" at Re = 2300 in the Nusselt number resulting from the equation included in the former edition of this handbook. A continuous calculation of the Nusselt number is achieved by using Eq. (29) combined with the other equations. This is demonstrated in Fig. 1 for the boundary condition "constant wall temperature" and Pr = 0.7.

The physical properties of the fluids are referred to the mean temperature $T_m = (T_i + T_o)/2$.

4.3 Nusselt Number for Approximate Calculations

For estimate purposes, less complicated equations are often sufficient. As it is shown in [14], the following equations also represent a large number of experimental data in the transition region. The equations are as follows:

For $0.5 \leq Pr \leq 1.5$

$$Nu_m = 0.0214\left(Re^{0.8} - 100\right)Pr^{0.4}\left[1 + \left(d_i/l\right)^{2/3}\right] \qquad (38)$$

and for $1.5 < Pr < 500$

$$Nu_m = 0.012\left(Re^{0.87} - 280\right)Pr^{0.4}\left[1 + \left(d_i/l\right)^{2/3}\right] \qquad (39)$$

Note that these approximate equations give considerably higher values of the Nusselt number than does Eq. (29) for small values of (d_i/l). They should not be used in this region.

4.4 Effect of Temperature Dependent Property Variations

If the properties of the medium are affected by temperature, the direction of the heat flux (heating or cooling) influences heat transfer. Allowance for this effect in *liquids* can be made – as it is in laminar flow – by the factor $(Pr/Pr_w)^{0.11}$, where Pr is the Prandtl number at T_m and Pr_w is that at the wall temperature T_w. In Eqs. (26), (38), and (39), Pr/Pr_w has been equated to unity.

Hence the following applies for liquids:

$$Nu = Nu_m\left(\frac{Pr}{Pr_w}\right)^{0.11} \qquad (40)$$

Equation (40) is valid for $0.1 < Pr/Pr_w < 10$.

Hackl and Gröll [22] measured the heat transferred from hot oils to a cooled pipe wall in order to determine the effect of temperature-dependent property variations up to $Pr/Pr_w = 10^{-4}$. They suggested two empirical equations to represent the results of their experiments.

These results have also been the subject of comments by Hausen [23], and were developed by Gregorig [24] into a correction function, which he recommended for the case of cooling liquids with high Prandtl numbers, e.g., viscous oils.

The Prandtl number of *gases* depends very little on temperature. Consequently, a factor $(T/T_w)^n$ is adopted to allow for the effect on heat transfer exerted by the variations in properties. In this case,

$$Nu = Nu_m(T/T_w)^n \qquad (41)$$

where T is the average gas temperature and T_w is the wall temperature of the pipe, both in Kelvin.

If the gas is cooled, i.e., $T/T_w > 1$, the exponent n becomes $n = 0$. If it is heated, i.e., $T/T_w < 1$, the exponent depends on the nature of the gas. Gnielinski [14] correlated values measured in the $1 > T/T_w > 0.5$ range with $n = 0.45$. A value quoted in the literature for carbon dioxide in the same T/T_w range is $n = 0.12$. Heinmann [25] quotes a value of $n = -0.18$ for superheated steam at $1 > T/T_w > 0.67$ and at pressures between 21 bar and 100 bar. Gregorig [26] drew up a nomogram that allows for the variations in properties over a wide range of temperatures.

5 Example of a Calculation

Water of a temperature at the inlet of $T_i = 10°C$ is flowing in a tube with an inner diameter of $d_i = 10$ mm and a length of 1,000 mm with a velocity of $w = 0.5$ m/s. The tube is heated from the outside by condensing steam of water in a way that the temperature at the inner wall has a constant temperature of $T_w = 100°C$. How large is the temperature of the water at the outlet of the tube?

Solution

To calculate the dimensionless numbers in the equations, the physical properties of the water are needed. Because of the temperature dependence of these properties, the problem can be solved only by iteration.

1. Approximate calculation of the Reynolds number to see whether the flow is laminar or turbulent or the Reynolds number is within the transition region $2300 \leq Re \leq 10^4$: $Re = wd_i/\nu$; at 20°C is $\nu = 1.004 \times 10^{-6} m^2/s$, therefore $Re = 0.5 \times 0.01/1.004 \times 10^{-6} = 4980$. The Reynolds

number is within the transition region. The heat transfer coefficient α has to be calculated from the Sects. 4.2 and 4.4.
2. The physical properties of the water have to be taken from Subchap. D2.1.
3. The Prandtl number at the wall temperature $\vartheta_i = 100°C$ remains at $Pr_w = 1.757$. The heat transfer area of the tube is $A = \pi\, d_i\, l = \pi \times 0.01 \times 1.0 = 0.0314\ m^2$.
4. For the further steps of calculation, see Table 1.

Because the physical properties at the reference temperature $T_m = 31.1°C$ differ only marginally from that at 31.0°C, a further step of iteration is not necessary. The temperature of the water at the end of the tube is therefore $T_o = 52.2^0C$.

6 Effect of the Shape of the Tubes Inlet

Equations (12), (26), and (29) yield mean Nusselt numbers for tubes fitted without fillets in a tube support plate, as is illustrated in Fig. 2. The effect of the shape of the tube inlet on the local Nusselt number was investigated by Grass [27] and by Boelter et al. [28].

7 Noncircular Pipes

There are no standard equations for *laminar* flow in pipes of noncircular cross section. Information on the heat transfer coefficient in these cases can be obtained from the literature [1].

According to statements from the literature, the Nusselt numbers for heat transfer in *turbulent* flow in smooth straight ducts of noncircular cross section can also be calculated from Eq. (26) by using the hydraulic diameter of the duct in evaluating Nu, Re, and d_i/l. The hydraulic diameter is defined as

$$d_h = \frac{4S}{P} \tag{42}$$

where S is the flow cross-sectional area and P is the wetted perimeter of the duct.

G1. Table 1. Steps of iteration for the example of a calculation

Step of iteration	1. Step	2. Step
T_o (approximately)	50	52
T_i	10	10
$T_m = \frac{T_i + T_o}{2}$	30	31
$\nu\,(T_m)\,/10^{-6}m^2/s$	0.801	0.786
$\lambda\,(T_m)\,/W/(m\ K)$	0.6155	0.6171

G10 Impinging Jet Flow Heat Transfer

Wilhelm Schabel · Holger Martin
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Introduction: Impinging Jets from Round and Slot Nozzles

Heating, cooling of products, and drying of coatings with large surface area is often carried out in devices consisting of arrays of round or slot nozzles through which liquid or gas jets (most frequently air) impinge vertically upon the product surface.

Figure 1 shows the different cases of impinging flow that are subsequently discussed. It is assumed that the jets consist of the same fluid as the surrounding fluid. The flow pattern of impinging jets can be subdivided into three characteristic regions (Fig. 2).

At the exit of the nozzle, a *free jet* is formed which is widened and decelerated due to mixing with the surrounding fluid. At a certain distance over the surface, the free jet is transformed into a *stagnation flow* where the vertical component of the velocity is reduced to zero, whereas the horizontal component increases from zero to a maximum value at a certain distance from the stagnation point. The stagnation flow is transformed into a *wall jet* which, like the free jet, is characterized by widening and deceleration [1].

For most technically relevant applications, the flow will be turbulent. Exact information regarding the limits of laminar impinging flow cannot be found in the literature. The Reynolds number is written with the average velocity at the exit of the nozzle w and hydraulic diameter of the nozzle D:

$$\mathrm{Re} = \frac{wD}{\nu} \tag{1}$$

Even for small values of $\mathrm{Re} \geq 100$, the jet flow will be turbulent. For round nozzles, the hydraulic diameter is equal to the (inner) diameter of the nozzle opening. For slot nozzles with the slot width B and the slot length $L_s >> B$, the hydraulic diameter is defined as

$$D = 2B \tag{2}$$

2 Definitions in Heat and Mass Transfer

Average heat transfer coefficients at a surface impinged upon by jets are defined as the heat flux divided by the difference of the fluid temperatures at the exit of the nozzle (N) and the surface (S) of the material which is below the nozzle at a distance H:

$$\alpha = \frac{\dot{Q}}{A(T_\mathrm{N} - T_\mathrm{S})} \tag{3}$$

Local heat transfer coefficients $\alpha(x)$ or $\alpha(r)$ at a substrate surface are technically relevant if the material underneath the nozzle array does not move. Detailed information and recent experimental results regarding this topic can be found in Hofmann et al. [2]. Diagrams with measured local heat and mass transfer coefficients and further details can be found in a review on this subject published in 1977 [1].

The dimensionless numbers used in this chapter are

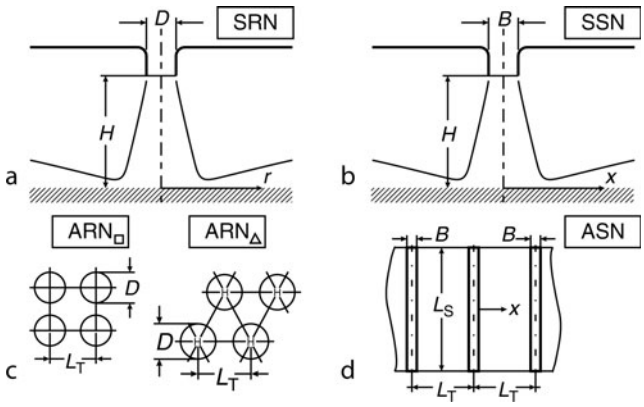
$$\mathrm{Nu} = \frac{\alpha D}{\lambda} \quad \text{or} \quad \mathrm{Sh} = \frac{\beta D}{\delta} \tag{4}$$

$$\mathrm{Re} = \frac{wD}{\nu},$$

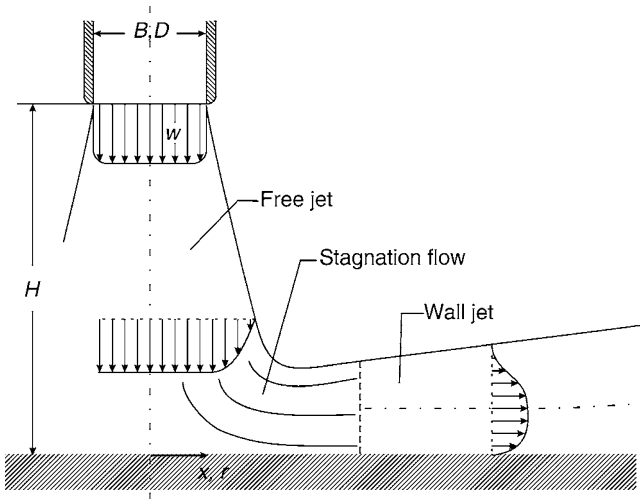
see Eq. (1)

$$\mathrm{Pr} = \frac{\nu}{a} \quad \text{or} \quad \mathrm{Sc} = \frac{\nu}{\delta} \tag{5}$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_32,



G10. Fig. 1. Arrays of nozzles. (**a**) The single round nozzle (SRN), (**b**) the single slot nozzle (SSN), (**c**) the array of round nozzles (ARNs), and (**d**) the array of slot nozzles (ASNs).



G10. Fig. 2. Impinging flow from round and slot nozzles.

For the calculation of these numbers, the temperature dependent properties should be used at the arithmetic mean temperature of the fluid between the nozzle exit (N) and the surface (S) $T_m = (T_N + T_S)/2$. The average mass transfer coefficient can be calculated analogously from the equations for the average heat transfer coefficient if Nu is replaced by Sh, and Pr by Sc (Part A).

3 Single Round Nozzle (SRN) and Single Slot Nozzle (SSN)

For a SRN, the integral heat and mass transfer coefficients, i.e. the mean value over a circle of the radius r around the stagnation point, can be expressed as follows:

$$\mathrm{Nu_{SRN}} = \frac{1 - 1.1/r^*}{r^* + 0.1(h^* - 6)} \cdot F(\mathrm{Re}) \cdot \mathrm{Pr}^{0.42} \qquad (6)$$

$$F(\mathrm{Re}) = 2[\mathrm{Re}(1 + 0.005 \cdot \mathrm{Re}^{0.55})]^{0.5}$$

Range of validity:

$$2.5 \le (r^* = r/D) \le 7.5,$$
$$2.0 \le (h^* = H/D) \le 12,$$
$$2\,,\,000 \le \mathrm{Re} \le 400,\,000.$$

Equation (6) from Schlünder and Gnielinski [3] is based on their own experimental results and on the evaluation of data from other sources. The function $F = F(Re)$ was originally graphically correlated, then described by power-law correlations in three different ranges of the Reynolds number $F = a\mathrm{Re}^m$ [4, 5]. According to Martin [1] it can be described by the aforementioned equation over the complete range of Reynolds numbers investigated.

For the SSN with $D = 2B$, the empirical equation for integral heat and mass transfer coefficients over the area of a rectangle $2x \cdot L_s$ (around the stagnation line at $x = 0$) is given according to Schlünder et al. [4] by:

$$\mathrm{Nu_{SSN}} = \frac{1.53 \cdot \mathrm{Re}^m}{x^* + h^* + 1.39} \cdot \mathrm{Pr}^{0.42} \qquad (7)$$

$$m = 0.695 - \frac{1}{x^* + h^{*1.33} + 3.06}$$

Here the exponent m of the Reynolds number depends on the geometric ratios and varies from 0.56 to 0.68 within the range of validity given next.

Range of validity:

$$2 \le (x^* = x/D) \le 25,$$
$$2 \le (h^* = H/D) \le 10,$$
$$3,\,000 \le \mathrm{Re} \le 90,\,000.$$

4 Arrays of Round Nozzles

For ARNs (see Fig. 1c) an empirical equation for integral average heat and mass transfer coefficients at the surface is given by Krötzsch [5] and in a modified form by Martin [1] as

$$\mathrm{Nu_{ARN}} = G \cdot \mathrm{Re}^{\frac{2}{3}} \cdot \mathrm{Pr}^{0.42}$$

$$G = \frac{d^* \cdot (1 - 2.2d^*)}{1 + 0.2 \cdot (h^* - 6) \cdot d^*} \cdot \left[1 + \left(\frac{10 \cdot h^* \cdot d^*}{6}\right)^6\right]^{-0.05} \qquad (8)$$

Range of validity:

$$0.004 \le (d^{*2} = f) \le 0.04,$$
$$2 \le (h^* = H/D) \le 12,$$
$$2,000 \le \mathrm{Re} \le 100,000.$$

Equation (8) is also recommended by Polat [6]. In Eq. (8) $d^* = \sqrt{f}$, where f is the relative nozzle area, i.e. the ratio of nozzle exit cross-sectional area to surface area of the product. For a square-shaped arrangement ($\mathrm{ARN}_\square$, from Fig. 1) it can be found that

$$f = \frac{\pi}{4}\frac{D^2}{L_T^2} \qquad (9)$$

$$d^* = \sqrt{f} = 0.8862 \frac{D}{L_T} \tag{10}$$

and for the triangle arrangement (ARN_Δ, Fig. 1),

$$f = \frac{\pi}{2\sqrt{3}} \frac{D^2}{L_T^2} \tag{11}$$

$$d^* = \sqrt{f} = 0.9523 \frac{D}{L_T} \tag{12}$$

5 Arrays of Slot Nozzles (ASN)

For arrays of slot nozzles (ASN see Fig. 1d, $D = 2B$), the relative nozzle area is simply:

$$f = \frac{B}{L_T} \tag{13}$$

$$d^* = f = 0.5 \frac{D}{L_T} \tag{14}$$

The integral average heat and mass transfer coefficients at the product surface are empirically expressed by Martin [1] based on his own experimental results [7] and evaluation of data from other sources.

$$\mathrm{Nu_{ASN}} = \frac{2}{3} f_o^{3/4} \left(\frac{2\mathrm{Re}}{f/f_o + f_o/f} \right)^{2/3} \mathrm{Pr}^{0.42} \tag{15}$$

$$f_o = \left[60 + 4 \cdot (h^* - 2)^2 \right]^{-1/2}$$

Range of validity:

$$0.008 \le (f = B/L_T) \le 2.5 \cdot f_o,$$
$$1 \le (h^* = H/D) \le 40 \quad \text{with } D = 2B,$$
$$1,500 \le \mathrm{Re} \le 40,000.$$

Equation (15) and the other equations given in this chapter are recommended by Polat [6] for practical applications as well.

6 Optimization of the Nozzles Spacing and Geometry

The problem of optimizing the nozzle arrangement with regard to the expense in fan power per product area means to identify the array that yields the highest average heat and mass transfer coefficient at the product surface at a given fan power per unit area. It was addressed by Krötzsch [8] for ARNs and by Martin [7] and Martin and Schlünder [9] for ASNs. A detailed summary of these calculations of optimization can be found in Martin's work [1]. The results of this optimization are also recommended by Polat [6] as a starting point for design. An absolute optimum for this problem cannot be found. The three main geometric nozzle parameters are

1. the hydraulic diameter of the nozzles D,
2. the nozzle-to-plate distance H and
3. the nozzle-to-nozzle spacing L_T,

which characterize a periodic array of round or slot nozzles. All three dimensions should be chosen in proper relation to each other. Variation of D with fixed values for the ratios H/D, L_T/D, however, cannot lead to an optimal value for the nozzle diameter. It can be easily seen that minimization of all three lengths leads to a monotonic increase of the heat and mass transfer coefficients especially due to reducing the flow distance to the product surface ($L_T/2$). In order to obtain a meaningful optimum, i.e., a maximum mean heat or mass transfer coefficient for a given fan power per unit surface area, it is necessary that one of the lengths has to fixed and is given as a secondary condition. The optimal ratios of the other two lengths and the one given as a secondary condition can then be determined unambiguously so that the best heat and mass transfer possible under the chosen conditions can be achieved. For safety reasons, most often the nozzle-to-plate distance H is the length limiting the optimization problem. In technical applications, less than a few centimeters of distance between a fast moving, maybe sagging or even flagging, product sheet and the nozzles can probably not be achieved. Particularly for coated products in the first drying regime the viscosity of the liquid film is too low and surface defects occur due to the impact of the impinging flow. A proper distance, H, has to be determined e.g. experimentally. From my experience in coating industry, a range of distances between 1 cm to 10 cm can be obtained and found in practical applications.

With the secondary condition H = constant the approximate optimum values for the nozzle geometry for arrays of round and slot nozzles are given [1] as

$$D_{opt} \approx \frac{1}{5} H \tag{16}$$

$$L_{Topt} \approx \frac{7}{5} H \tag{17}$$

The optimum values for the relative nozzle areas that can be derived analytically from the given equations are

$$f_{opt\ ARN} = 1.52\% \tag{18}$$

$$f_{opt\ ASN} = 7.18\% \tag{19}$$

(The approximate Eqs. (16) and (17) result with Eqs. (9–12) in slightly differing values of $f_{opt} \approx 1.6\%$ for the squared arrangement of an $ARN_\square$ (1.85% for ARN_Δ) and for the triangle arrangement $f_{opt} \approx 7.14\%$ for ASN.) From the result of this optimization, it can be deducted that for achieving the same heat and mass transfer coefficients with the same fan power, an optimal ARN requires a smaller volume flow and a higher velocity at the nozzle exit, whereas an optimal ASN requires a higher volume flow but a lower velocity at the nozzle exit as following:

$$w_{ARN} = 1.68 \cdot w_{ASN} \tag{20}$$

$$\dot{V}_{ASN} = 2.82 \cdot \dot{V}_{ARN} \tag{21}$$

Therefore, ASNs should be preferably used for products that might be damaged by too high flow velocities, such as polymeric thin film coatings at the early stage of drying (constant rate period), where the viscosity is low.

The factors 1.68 and 2.28 in Eqs. (20) and (21) are derived from $\left(f_{opt\ ASN}/f_{opt\ ARN}\right)^{1/3} = 1.68$ and the square of this value [1].

If it is taken into account that a part of the total pressure drop is needed for overcoming the flow resistances within the

air supply system and is therefore not available at the nozzles, the optimum relative nozzle areas f_{opt} become smaller than the values obtained from Eqs. (18) and (19), as Steinberg [10] has shown.

The ratio of the pressure drop available at the nozzles and the total pressure drop can be written as

$$\frac{\Delta p_{nozzle}}{\Delta p_{total}} = \frac{1}{1 + K \cdot f^2} \tag{22}$$

Here the resistance constant K is the ratio of the pressure drop $\Delta p_s = \Delta p_{total} - \Delta p_{nozzle}$ of the air supply system and the dynamic pressure of the incident flow towards the nozzle $(\rho/2)(w * f)^2$ with

$$K = \frac{\Delta p_s}{(\rho/2)(w * f)^2}.$$

The constant K in its denominator contains the square of the very small incident flow velocity $w * f$ in the plenum chamber above the nozzles. Depending on the design of the air supply system with filters, perforated plates, baffles, etc., K may well reach values in the order of 1,000–10,000. To find the optimal ratios of the geometric parameters, taking a constant resistance number; K, of the air supply system into account, the maximum of the function $G_H(f, h^*)$ has to be determined with K as a parameter. This function can be derived by applying the optimization conditions: constant fan power per unit area of transfer surface

$$P = \Delta p \frac{wfA}{A} = \text{const.}$$

and constant nozzle-to-plate distance H

$$H = \text{const.}$$

to Eqs. (8) and (15) for the heat transfer for impinging flow from arrays of round and slot nozzles [1, 10].

$$\frac{\alpha H}{\lambda}\left(\frac{\rho \xi_{nozzle}}{2P}\right)^{2/9}\left(\frac{\nu}{H}\right)^{2/3}\mathrm{Pr}^{-0.42} = G_H(f, h^*) \tag{23}$$

For ARNs, i.e., $f = d^{*2}$, $h^* = H/D$, it follows from Eq. (8)

$$\begin{aligned} G_{H,\,ARN} &= G_1 G_2 G_3 \\ G_1 &= h^{*1/3}\frac{d^*(1 - 2.2 \cdot d)}{1 + 0.2 \cdot (h^* - 6) \cdot d^*} \\ G_2 &= \left[1 + \left(10\frac{h^* \cdot d^*}{6}\right)^6\right]^{-0.05} \\ G_3 &= \left[f\left(1 + Kf^2\right)\right]^{-2/9} \end{aligned} \tag{24}$$

For ASNs, i.e., $f = B/L_T$, $h^* = H/(2B)$ and $f_o = \left[60 + 4 \cdot (h^* - 2)^2\right]^{-1/2}$ Eq. (15) yields

$$\begin{aligned} G_{H,\,ASN} &= G_1 G_2 G_3 \\ G_1 &= \frac{2}{3} h^{*1/3} f_o^{3/4} \\ G_2 &= \left(\frac{2}{f/f_o + f_o/f}\right)^{2/3} \\ G_3 &= \left[f\left(1 + Kf^2\right)\right]^{-2/9} \end{aligned} \tag{25}$$

The maximum of G_H can be found numerically or analytically from Eq. (24) or (25) for given values of the air supply system flow resistance number K. For $K = 0$ the solution results in the same ratios of geometric parameters as given earlier in Eqs. (16) and (17).

Tables 1 and 2 show values that were obtained by evaluating Eqs. (24) and (25). They can be used to find an optimal spatial arrangement of the nozzles. It can be seen in Table 1 that the ratio $(L_T/H)_{opt}$ is nearly constant for ARN:

$(L_T/H)_{opt} \approx 1.3$ for square spacing and

G10. Table 1. Optimal spatial arrangement for arrays of round nozzles with a constant fan power per unit area of transfer surface P, constant nozzle-to-plate distance H, and a constant flow resistance number K of the air supply system $\left(1/h^* = D/H,\ d^* = \sqrt{f}\right)$

$(L_T/H)_{opt} \approx 1.4$ for triangular spacing

For ASNs $(L_T/H)_{opt}$ ranges from 1.4 for $K = 0$ to nearly 2 for large values of K (Table 2). The ratio of the pressure drop of the air supply system and the actual pressure drop in the nozzles $(\Delta p_s/\Delta p_{nozzle} = kf^2$ according to Eq. (22)) under these optimal conditions is lower than 1.

7 Influence of Downstream Flow Conditions

Optimal arrays of nozzles have a relatively small nozzle spacing $(L_{T\,opt} \approx 1.4H)$. Therefore, it can be difficult to provide sufficiently large cross-sectional areas for the downstream flow [9]. The problems linked to a lateral downstream flow leading to increasing and inhomogeneous heat transfer coefficients in cross web direction and in directions to the edges, are addressed in detail by Martin [1].

An upward downstream flow between the nozzles is in any case more favorable for the heat and mass transfer but cannot always be implemented easily.

8 Influence of the Nozzle Shape

It is known that the design of the nozzles influences the relation between the impressed pressure drop Δp and the velocity of the fluid w at the exit of the nozzle.

$$\Delta p = \frac{\xi \rho w^2}{2} \tag{26}$$

For a well-designed nozzle, the coefficient ξ has the value $\xi_{nozzle} \approx 1.0$. For sharp-edged orifices (holes in a perforated plate) it can reach values of up to

$$\xi_{orifice} \approx 2.69 \tag{27}$$

(In [1] instead of ξ the term $(1 + \zeta_D)$,with $0 \le \zeta_D \le 1.69$, was used). The expression

$$\mu = \frac{1}{\sqrt{\xi}} \tag{28}$$

is also called *discharge coefficient* C_D in the review by Polat [6]. For sharp-edged round and slot orifices, the jet is constricted and the cross-sectional area reduces by the factor ε (see Fig. 3). For the diameter of a round jet from an orifice it can, therefore, be written as

$$D' = \sqrt{\varepsilon} \cdot D \tag{29}$$

The width of a planar jet from a slot orifice is analogously

$$B' = \varepsilon \cdot B \tag{30}$$

Therefore, the speed of the contracted jet is increased to

$$w' = \frac{w}{\varepsilon}. \tag{31}$$

For sharp-edged orifices the contraction coefficient has the value

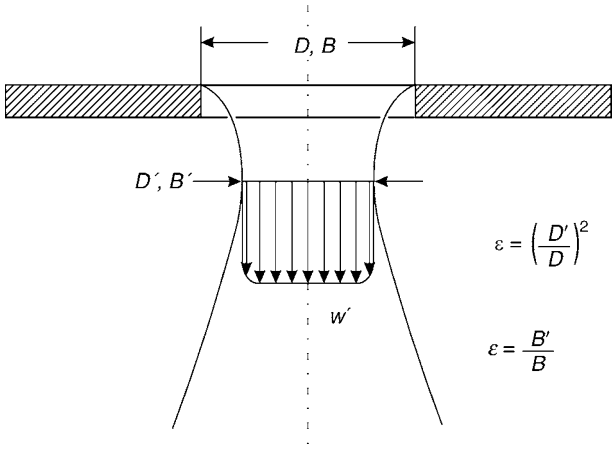
$$\varepsilon_{orifice} = 0.61 \tag{32}$$

For this limiting case, the value of ε is the same as the value of the discharge coefficient μ [11]. If for the calculations concerning orifice plates, the increased velocity at the smallest cross-section w' is taken instead of the exit velocity w, it follows from Eqs. (26), (27), (31), and (32) that:

$$\xi'_{orifice} \approx 2.69 \cdot (0.61)^2 = 1.00 \tag{33}$$

The significantly larger coefficient for orifices $\xi_{orifice} \approx 2.69$ (when referring to w and the cross section at the nozzle exit) therefore, only results from the contraction of the jet and not from frictional losses. Friction only plays a role for nozzles (without flow separation) with increasing length of the nozzle (ξ_{nozzle} will be slightly larger than 1, e.g. 1.05 for short and 1.15 for long nozzles), whereas for orifice plates the flow is virtually inviscid. For more detailed calculations of the fluid dynamics, experimental values for the coefficient ξ should be used if possible.

If in the equations for Nu (or Sh) the diameter D, the slot width B, and the exit velocity w are replaced by the corresponding variables for the smallest cross-sectional area D', B', w' they can also be applied for calculation of the round and slot orifice plates which are much easier to manufacture [1, 6].



G10. Fig. 3. Jet contraction at hole and slot aperture plates.

9 Examples

9.1 Example 1

An ARN is to be designed with a given nozzle-to-plate distance H = 40 mm. The resistance of the air supply system can be neglected ($kf^2 << 1$).

According to Eq. (16), the optimal diameter of the nozzle is $D_{opt} = (1/5) \cdot 40\ \text{mm} = 8\text{mm}$.

The optimal relative nozzle area is, according to Eq. (18), $f = 0.0152$.

With $H/D = h^* = 5$, $f^{1\backslash 2} = d^* = (0.0152)^{1/2} = 0.1233$

the value of the geometry function from Eq. (8) can be calculated as

$$G = 0.09212 \cdot 0.9619 = 0.08861$$

If the nozzle exit velocity of the air is w = 48 m/s and the air from the nozzles has a temperature of 120°C, whereas the product surface has a temperature of 40°C, the material properties of air are to be calculated at an average temperature $T_m = (120 + 40)/2°\text{C} = 80°\text{C}$. According to Chap. D2,

$$\lambda = 0.0300\ \text{W/mK},\ \nu = 21.4 \cdot 10^{-6}\,\frac{\text{m}^2}{\text{s}},\ \text{Pr} = 0.708$$

thus

$$\text{Re} = 48 \cdot 8\,000/21.4 = 17\,944$$

and

$$\text{Nu}_{\text{ARN}} = \text{G} \cdot \text{Re}^{2/3} \cdot \text{Pr}^{0.42} = 52.53.$$

Finally, the heat transfer coefficient is found to be $\alpha_{\text{ARN}}(48\ \text{m/s}) = 197\,\text{W}/(\text{m}^2\,\text{K})$.

9.2 Example 2

For an optimal ASNs with the reduced exit velocity according to Eq. (20) $w = 48/1.68\,\text{m/s} \approx 29\,\text{m/s}$, H = 40 mm and $D(= 2B)$ = 8 mm (that is B = 4 mm), thus

$$H/D = h^* = 5$$

and according to Eq. (19) $f = 0.0718$

with Eq. (15) $f_0 = [60 + 4 \cdot (h^* - 2)]^{-1/2} = 0.1021$

$$\text{Nu}_{\text{ASN}} = 0.1000 \cdot \text{Re}^{2/3}$$

$$\text{Re} = 29 \cdot 8\,000/21.4 = 10\,841\,, \quad \text{Nu}_{\text{ASN}} = 48.99.$$

The resulting heat transfer coefficient is only 6.5% lower than that for the ARN

$$\alpha_{\text{ASN}}(29\ \text{m/s}) = 184\,\text{W}/(\text{m}^2\,\text{k}).$$

As α is proportional to $w^{2/3}$ for arrays of round and slot nozzles, the velocity

$$w = (197/184)^{3/2} \cdot 29\,\text{m/s} \approx 32\,\text{m/s}$$

results in the same values for α for both kinds of arrays:

$$\alpha_{\text{ASN}}(32\ \text{m/s}) = \alpha_{\text{ARN}}(49\ \text{m/s}) = 197\,\text{W}/(\text{m}^2\text{K})$$

9.3 Example 3

If the array from example 1 were made from perforated plates instead of an ARN, the contraction coefficient of the orifices would be $\varepsilon = 0.610$ according to Eq. (32). In order to obtain the same heat transfer coefficient (as in example 1 with the round nozzles), D and w in Eq. (8) have to be replaced by $D' = 8$ mm and $w' = 48$ m/s, respectively. The orifices would have to have a diameter of

$$D = \frac{D'}{\sqrt{\varepsilon}} = \frac{8\ \text{mm}}{\sqrt{0.61}} = 10.25\ \text{mm}$$

leading to a higher relative nozzle area of $f = \frac{f'}{\varepsilon} = \frac{0.0152}{0.61} = 0.0249$, and a correspondingly lower (nominal) outlet velocity of $w = \varepsilon w' = 29.3$ m/s, so that the velocity, $w' = 48$ m/s, in the narrowest cross section of the jet has the same value as at the outlet of the nozzles (with $\varepsilon_{\text{nozzle}} = 1$) from example 1.

The spacing L_T according to Eq. (10) or (11) would stay the same, e.g. for ARN_Δ:

$$L_T = D' \cdot \frac{0.9523}{\sqrt{f'}} = D \cdot \frac{0.9523}{\sqrt{f}} = 61.79\ \text{mm}.$$

9.4 Example 4

The corresponding array of slot orifices (as in example 2 with slot nozzles) has the slot width $B = B'/\varepsilon = 4\ \text{mm}/0.61 = 6.56\,\text{mm}$ (for the same value for ε) and a relative nozzle area of

$$f = \frac{f'}{\varepsilon} = \frac{0.0718}{0.61} = 0.118.$$

The spacing L_T also stays unchanged:

$$L_T = \frac{B}{f} = \frac{B'}{f'} = \frac{4\ \text{mm}}{0.0718} = 55.7\ \text{mm}.$$

9.5 Example 5

The design of the air supply system (see Chaps. L1–L3 and handbooks on fluid dynamics) for the array of slot orifices in example 4 is such that the resistance number K for the whole system, except for the nozzles, is $k \approx 500$. If the spatial arrangement and the geometry of the nozzles are left unchanged, i.e. $H = 40$ mm, $B = 40$ mm, and $L_T = 55.7$ mm, at a constant fan power per unit area of product surface it can be found from Eqs. (23) and (25):

$$\frac{\alpha}{\alpha_{max}} = \frac{G_H}{G_{Hmax}} = \frac{(1 + Kf'^2)^{-2/9}}{1} = \frac{1}{(1 + 500 \cdot 0.0718^2)^{2/9}}$$

$$= \frac{1}{3.578^{2/9}} = 0.753$$

$$\alpha = 0.753 \cdot 184 \frac{W}{m^2 K} = 139 \frac{W}{m^2 K}$$

The result is a heat transfer coefficient which is approximately 25% lower. In order to obtain the same heat transfer as in examples 4 and 2, the fan power would have to be increased by the factor $1/(0.753)^{9/2} = 3.58$ according to Eq. (23).

If instead the optimal spatial arrangement for $K = 500$ from Table 2 is taken $f' = 3.564\%$, $B' = 0.06289 \cdot H$ and $B = B'/\varepsilon = B'/0.61$ and $L_T = 1.765 \cdot H$ with $H = 40$ mm

$$B = 4.12 \text{ mm and } L_T = 70.6 \text{ mm}$$

The result is a more favorable ratio of $\alpha/\alpha_{max} = 0.835$ and therefore,

$$\alpha = 0.835 \cdot 184 \ W/m^2 K = 154 \ W/m^2 K.$$

This means that the heat transfer is only reduced by 16% compared to the ideal case ($K = 0$). Accordingly, the fan power would have to be increased by the factor $1/(0.835)^{9/2} = 2.25$ in order to achieve the same heat transfer coefficient of 184 W/(m² K) as in example 2 for K = 500 instead of factor 3.58 for the unchanged spatial arrangement.

10 Further Information

Heat transfer in impinging flow can also apply to jets of liquid or multiphase (spray) jets. In combustion technology, impinging jet flames are used. *The equations given in this chapter are mostly based on experimental investigations on air jets.* In principle, they are also applicable to liquid jets in a liquid environment. For liquid jets in a gaseous environment, for spray jets, and for impinging jet flames, other works from literature should be consulted. An overview of the literature can be found in some works [1, 6] as well as in a more recent article by Viskanta [12] with 103 references before 1992.

G2 Heat Transfer in Concentric Annular and Parallel Plate Ducts

Volker Gnielinski
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Introduction

The simplest form of a two-fluid heat exchanger is a double pipe made up of two concentric circular tubes. One fluid flows through the inside tube and the other in co-current- or countercurrent flow through the annular passage. Heat exchangers of this type are common practice if liquids at high and very high pressures have to be either heated or cooled.

Beside separate double-pipe heat exchangers, heating or cooling jackets for tubes are of this type. But annular passages may also occur as heat exchangers in other types, for example, to heat a fluid by electricity, either a heating-rod is put into the middle of a circular tube, or the fluid in the annulus is heated or cooled from the outer tube, and an inert rod is placed in the middle of the tube to increase the velocity of the fluid in the gap. Finally, the fluid flowing in the annulus is either heated or cooled from both sides, from the inner tube and from the outside of the outer tube.

2 Flow in the Annulus; Hydraulic Diameter

When a fluid is flowing in the annulus between two concentric tubes, the characteristic dimension to be taken for the determination of the amount of heat transferred between it and the walls of the tubes is the hydraulic diameter, which is given by

$$d_h = d_o - d_i \tag{1}$$

where d_o is the inner diameter of the outer tube and d_i is the outer diameter of the inner tube. Annular flow is laminar at Reynolds numbers less than Re = 2,300, and is considered to be turbulent at higher values. The annular flow is most certainly turbulent at Re $>10^4$. In the transition zone $2{,}300 < \mathrm{Re} < 10^4$, the inlet conditions decide the type of the flow.

Annuli are geometrically similar only if they have the same diameter ratio

$$a = (d_i / d_o) \tag{2}$$

Heat transfer coefficients are dependent on this ratio because of the shape of the velocity profile. With annular flow, the maximum velocity is shifted to the inner wall of the duct as $a = (d_i/d_o)$ decreases. According to the theory, the lesser the radius of the curvature of a surface, the thinner the boundary layer under otherwise identical conditions. Hence, the smaller the diameter ratio, the greater the heat transfer coefficient on the inner side of the annulus. If d_i becomes infinitely small – $a = (d_i/d_o) \rightarrow 0$ – (an infinitesimal thickness wire at the center) the heat transfer coefficient α on the inner side becomes

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_24,

infinitely large. Nevertheless, heat transport at the inner side would become negligibly small, because the area of the inner tube thus tends to be zero.

The coefficient on the outer side, on the other hand, decreases with the diameter ratio. The limiting case $a = 1$ is the parallel-plate geometry.

3 Definition of Heat Transfer Coefficient and the Dimensionless Numbers

The definition of the average heat transfer coefficient α over a length l is the same as in pipe flow (cf. Chap. G1). The dimensionless numbers are defined as follows:

$$\mathrm{Nu} = \frac{\alpha\, d_\mathrm{h}}{\lambda};\ \mathrm{Re} = \frac{w\, d_\mathrm{h}}{\nu}.$$

The physical properties are referred to the mean fluid temperature $T_\mathrm{m} = (T_\mathrm{in} + T_\mathrm{out})/2$.

4 Boundary condition

Heat can be transferred to the fluid flowing in the annulus:

- From the inner tube, in which case the outer tube is insulated
- From the outer tube, in which case the inner tube is insulated
- From both the inner and the outer tubes, in which case it is assumed that the temperatures on the two walls are equal, that is, $T_\mathrm{wi} = T_\mathrm{wo}$.

These boundary conditions are reviewed in Fig. 1. Others are dealt with in the literature together with any effects that may be exerted by any eccentricity of the tubes on heat transfer in laminar flow [1, 2].

5 Heat Transfer in Laminar Flow, Constant Wall Temperature

5.1 Hydrodynamically Developed Laminar Flow

For the thermal boundary condition of constant wall temperature, Stephan [3] has calculated asymptotic values of the Nusselt number for the thermally and hydrodynamically developed laminar flow. In Fig. 2, Stephan's solutions are presented graphically as a function of $a = (d_\mathrm{i}/d_\mathrm{o})$ for the three boundary conditions.

Martin [4] has developed approximate expressions for the three curves on Fig. 2 which are:

Boundary condition 1 (inner surface heated):

$$\mathrm{Nu}_{1,\mathrm{i}} = 3.66 + 1.2\, a^{-0.8} \tag{3}$$

Boundary condition 2 (outer surface heated):

$$\mathrm{Nu}_{1,\mathrm{o}} = 3.66 + 1.2\, a^{0.5} \tag{4}$$

Boundary condition 3 (both surfaces heated at equal wall temperatures):

$$\mathrm{Nu}_{1,\mathrm{b}} = 3.66 + \left[4 - \frac{0.102}{a + 0.02}\right] a^{0.04} \tag{5}$$

In the same paper Stephan [3] also calculated the mean fluid temperatures and Nusselt numbers for thermally developing and hydrodynamically developed laminar flow in annuli and drew up equations for their approximate determination.

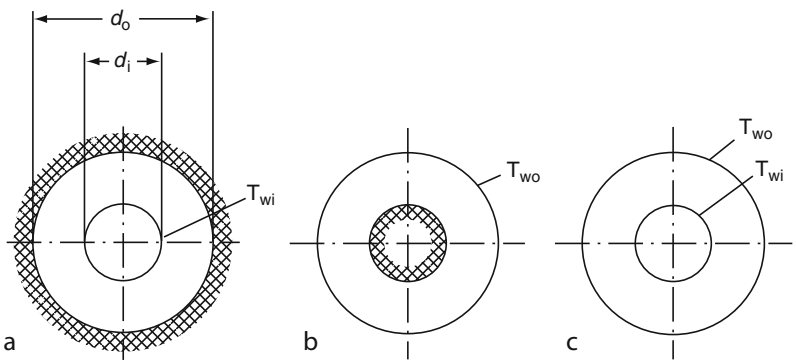
The asymptotes to the calculated data for large values of $\mathrm{Re\ Pr\ d_h}/l$ for the different boundary conditions are obtained from the equation

$$\mathrm{Nu}_2 = f_g \sqrt[3]{\mathrm{Re\ Pr}\ d_\mathrm{h}/l} \tag{6}$$

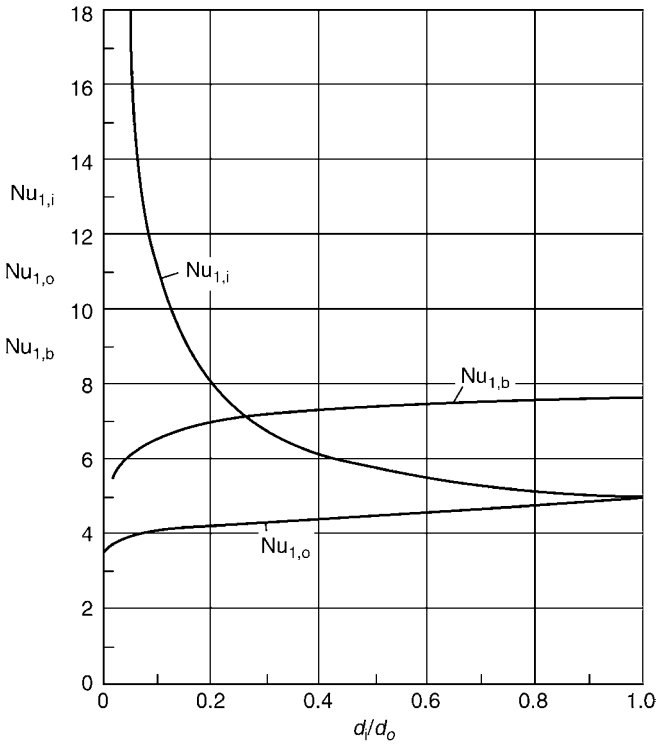
where f_g is given by [3]

Boundary condition 1:

$$f_{g\,\mathrm{i}} = 1.615\, \left[1 + 0.14\, a^{-1/2}\right] \tag{7}$$



G2. Fig. 1. Boundary conditions for heat transfer in an annular gap 1. Heat transferred at the inner tube (subscript i); the outer tube insulated 2. Heat transferred at the outer tube (subscript o); the inner tube insulated 3. Heat transferred at both tubes (subscript b); the walls of each are at the same temperature $T_\mathrm{wi} = T_\mathrm{wo}$.



G2. Fig. 2. Graphical representation of Eqs. (3), (4), and (5) for the determination of Nu_1 as a function of(d_i/d_o) ratio for the three boundary conditions.

Boundary condition 2:

$$f_{g\,o} = 1.615\left[1 + 0.14a^{1/3}\right] \tag{8}$$

Boundary condition 3:

$$f_{g\,b} = 1.615\left[1 + 0.14\,a^{0.1}\right] \tag{9}$$

From the following Eq. (10), mean Nusselt numbers can be calculated for hydrodynamically developed and for both thermally developing and thermally developed flow. The length l in this case is measured from the point at which heating or cooling commences.

$$\mathrm{Nu_m} = \left(\mathrm{Nu_1^3} + \mathrm{Nu_2^3}\right)^{1/3} \tag{10}$$

Nu_1 and Nu_2 are to be calculated from the Eqs. (3–9) according to the boundary conditions.

The effect of temperature dependent variations in physical properties is as described in Chap. G1. Hence

$$\mathrm{Nu} = \mathrm{Nu_m}\left(\frac{\mathrm{Pr}}{\mathrm{Pr_w}}\right)^{0.11} \tag{11}$$

Pr is the Prandtl number at T_m; and Pr_w, that at the wall temperature.

5.2 Thermally and Hydrodynamically Developing Flow

At the annulus inlet, a velocity profile begins to build up as a result of friction between the fluid and the walls. If, at the same time, heat is transferred, a temperature profile also begins to form. Hydrodynamic and thermal boundary layers develop simultaneously. In this region heat transfer can be determined from the boundary layer theory.

The asymptote for large values of $\mathrm{RePr}(d_h/l)$ is

$$\mathrm{Nu_3} = \left\{\frac{2}{1 + 22\mathrm{Pr}}\right\}^{1/6}(\mathrm{RePr}d_h/l)^{1/2} \tag{12}$$

The following equation, in analogy to those for pipe flow, was proposed by Martin [4] for the mean Nusselt number for thermally and hydrodynamically developing flow:

$$\mathrm{Nu_m} = \left(\mathrm{Nu_1^3} + \mathrm{Nu_2^3} + \mathrm{Nu_3^3}\right)^{1/3} \tag{13}$$

Nu_1, Nu_2 and Nu_3 are to be calculated from the Eqs. (3–9) and (12) for the boundary conditions concerned.

Allowance for the variation in physical properties with temperature is made by Eq. (11).

6 Heat Transfer for Turbulent Flow

6.1 Fully Developed Turbulent Flow

Transition to turbulent flow in annular ducts starts at Re = 2, 300. The flow is fully turbulent at $\mathrm{Re} \geq 10^4$ Heat transfer coefficients for turbulent flow in concentric annular ducts are dependent on the ratio $a = (d_i/d_o)$ in addition to Re, Pr, and (d_h/l), since annuli are not geometrically similar unless the diameter ratio a is identical. Furthermore, they are dependent on the boundary conditions mentioned at the beginning of this Chapter and shown in Fig. 1.

According to Gnielinski [5], a great number of data on heat transfer for fully developed turbulent flow can be correlated by a modified equation of Petukhov and Kirillov [6]. The modified equation reads

$$\mathrm{Nu_m} = \frac{(\xi_{\mathrm{ann}}/8)\mathrm{Re\ Pr}}{k_1 + 12.7\sqrt{\xi_{\mathrm{ann}}/8}\,(\mathrm{Pr}^{2/3} - 1)}\left[1 + \left(\frac{d_h}{l}\right)^{2/3}\right]F_{\mathrm{ann}} \tag{14}$$

with

$$k_1 = 1.07 + \frac{900}{\mathrm{Re}} - \frac{0.63}{(1 + 10\mathrm{Pr})} \tag{15}$$

The friction factor ξ_{ann} of an annular duct differs from the friction factor of a circular tube (cf. Eq. (27) of Chap. G1). Because of the different velocity profile in annular flow ξ_{ann} itself depends on the ratio $a = (d_i/d_o)$.

Comparing a large number of experimental data on the friction factor of annular duct flows, Gnielinski [7] found

$$\xi_{\mathrm{ann}} = \left(1.8\log_{10}(\mathrm{Re}^*) - 1.5\right)^{-2} \tag{16}$$

with

$$\mathrm{Re}^* = \mathrm{Re}\frac{[1 + a^2]\ln a + [1 - a^2]}{[1 - a]^2 \ln a} \tag{17}$$

For the boundary condition "heat transfer at the inner wall, outer wall insulated" (Fig. 1a), the best correlation of the experimental data was to be achieved with

$$F_{\mathrm{ann,i}} = 0.75\,a^{-0.17} \tag{18}$$

and for the boundary condition "heat transfer at the outer wall, inner wall insulated" (Fig. 1b)

$$F_{\mathrm{ann,o}} = (0.9 - 0.15\, a^{0.6}) \tag{19}$$

No experimental data could be found for heat transfer from both walls to the annular flow (Fig. 1c). Following the proposal of Stephan [3] one gets for this boundary condition

$$F_{\mathrm{ann,b}} = \frac{0.75\, a^{-0.17} + (0.9 - 0.15\, a^{0.6})}{1 + a} \tag{20}$$

In the above equations, the ranges of validity are $10^4 \le \mathrm{Re} \le 10^6$, $0.6 \le \mathrm{Pr} \le 1000$, $0 \le (d_\mathrm{h}/l) \le 1$. The physical properties used in the equations have to be calculated at the mean bulk temperature of the fluid $T_\mathrm{m} = (T_\mathrm{in} + T_\mathrm{out})/2$.

6.2 Effect of Temperature Dependent Property Variations

The direction of heat flux (heating or cooling the fluid) influences the heat transfer when the physical properties are temperature-dependent. No special investigations for annular ducts about this influence are known. Therefore, the correction factors for the circular tubes (Chap. G1, Sect. 4.4) are adopted. According to this the factor K is introduced. For liquids

$$K = \left(\frac{\mathrm{Pr}}{\mathrm{Pr_w}}\right)^{0.11} \tag{21}$$

Pr is the Prandtl number at T_m; and $\mathrm{Pr_w}$, that at the wall temperature.

For gases the variation of fluid properties with temperature can be taken into account by simple power laws. The correction factor K as multiplier to Eq. (14) can be written in the principal form

$$K = \left(\frac{T_\mathrm{m}}{T_\mathrm{w}}\right)^{n} \tag{22}$$

Where T_m is the absolute bulk temperature of the gas ($T_\mathrm{m} = (T_\mathrm{m} + 273.1)/K$) and T_w is the absolute wall temperature.

The exponent n is n = 0 in the case of cooling the gas [$(T_\mathrm{m}/T_\mathrm{w}) > 1$]. Heating the gas [$(T_\mathrm{m}/T_\mathrm{w}) < 1$] leads to different values for each gas. Gnielinski [8] correlated the data he collected for gases by taking $n = 0.45$ in the range $0.5 < (T_\mathrm{m}/T_\mathrm{w}) < 1.0$. According to the literature n should be approximately 0.12 for carbon dioxide and –0.18 for overheated steam in the same temperature ratio.

The effect of variable physical properties is therefore taken into account with

$$\mathrm{Nu} = \mathrm{Nu_m} K \tag{23}$$

6.3 Transition Region Between Laminar and Fully Developed Turbulent Flow, $2{,}300 \le \mathrm{Re} \le 10^4$

Chap. G1, Sect. 4.2 reports on the development of turbulence in tubes. The same relationships may be assumed for concentric annular ducts. Nusselt numbers experimentally determined in the transition region can be represented by the same equation suggested for the tube case:

$$\mathrm{Nu_m} = (1 - \gamma)\, \mathrm{Nu_{lam,2300}} + \gamma\, \mathrm{Nu_{turb,10^4}} \tag{24}$$

with

$$\gamma = \frac{\mathrm{Re} - 2{,}300}{10^4 - 2{,}300} \quad \text{and} \quad 0 \le \gamma \le 1 \tag{25}$$

$\mathrm{Nu_{lam,2300}}$ is the Nusselt number for the appropriate boundary conditions for laminar flow at Re = 2,300 (see Eq. (13)) and $\mathrm{Nu_{turb,10^4}}$ is the Nusselt number for turbulent flow and the same boundary conditions at fully developed turbulent flow at $\mathrm{Re} = 10^4$.

6.3.1 Heat Transfer from the Inner Tube with Outer Tube Insulated

For the boundary condition in Fig. 1a, where heat transfer is at the inner tube wall with outer tube insulated, the Nusselt number is calculated from Eq. (24) with the laminar term is estimated as follows:

$$\mathrm{Nu_{lam,2300,i}} = \left(\mathrm{Nu_{1,i}^3} + \mathrm{Nu_{2,2300,i}^3} + \mathrm{Nu_{3,2300}^3}\right)^{1/3} \tag{26}$$

where $\mathrm{Nu_{1,i}}$ is calculated from Eq. (3)

$$\mathrm{Nu_{1,i}} = 3.66 + 1.2\, a^{-0.8} \tag{27}$$

and where $\mathrm{Nu_{2,2300,i}}$ is calculated from Eq. (6)

$$\mathrm{Nu_{2,233,i}} = f_{g,\mathrm{i}}(2300\mathrm{Pr}\ d_\mathrm{h}/l)^{1/3} \tag{28}$$

with $f_{g,\mathrm{i}}$ from Eq. (7), $\mathrm{Nu_{3,2300,i}}$ is given by Eq. (12)

$$\mathrm{Nu_{3,2300}} = \left\{\frac{2}{1 + 22\mathrm{Pr}}\right\}^{1/6} (2{,}300\mathrm{Pr}d_\mathrm{h}/l)^{1/2} \tag{29}$$

The turbulent term in Eq. (24) is estimated from the expressions

$$\mathrm{Nu_{turb,10^4,i}} = \frac{(\xi_\mathrm{ann}/8)\, 10^4\mathrm{Pr}}{k_1 + 12.7\sqrt{\xi_\mathrm{ann}/8}\,(\mathrm{Pr}^{2/3} - 1)} \left[1 + \left(\frac{d_\mathrm{h}}{l}\right)^{2/3}\right] \left(0.75\, a^{-0.17}\right) \tag{30}$$

with ξ_ann from Eq. (16) at

$$\mathrm{Re}^* = 2{,}300\, \frac{[1 + \mathrm{a}^2]\ln \mathrm{a} + [1 - \mathrm{a}^2]}{[1 - \mathrm{a}]^2 \ln \mathrm{a}} \tag{31}$$

and k_1 from Eq. (15) at

$$k_1 = 1.07 + \frac{900}{2{,}300} - \frac{0.63}{(1 + 10\mathrm{Pr})} \tag{32}$$

6.3.2 Heat Transfer from the Outer Tube with Inner Tube Insulated

For the boundary condition in Fig. 1b, where heat transfer is from the outer tube with inner tube insulated, Eq. (24) may be used again with the laminar expression:

$$\mathrm{Nu_{lam,2300,o}} = \left(\mathrm{Nu_{1,o}^3} + \mathrm{Nu_{2,2300,o}^3} + \mathrm{Nu_{3,2300}^3}\right)^{1/3} \tag{33}$$

where $Nu_{1,o}$ is calculated from Eq. (4)

$$Nu_{1,o} = 3.66 + 1.2\, a^{0.5} \tag{34}$$

and where $Nu_{2,2300,o}$ is calculated from Eq. (6)

$$Nu_{2,o} = f_{g,o}\sqrt[3]{Re\ Pr}\ d_h/l \tag{35}$$

with $f_{g,o}$ from Eq. (8). $Nu_{3,2300}$ is given by Eq. (29).

The turbulent term in Eq. (24) is calculated from the expression

$$Nu_{turb,10^4,o} = \frac{(\xi_{ann}/8)\,10^4 Pr}{k_1 + 12.7\sqrt{\xi_{ann}/8}\,(Pr^{2/3}-1)}\left[1+\left(\frac{d_h}{l}\right)^{2/3}\right](0.9 - 0.15\, a^{0.6}) \tag{36}$$

with ξ_{ann} from Eqs. (16) and (31) and k_1 from Eq. (32).

6.3.3 Heat Transfer from Both Surfaces (Equal and Constant Wall Temperature)

For the boundary condition in Fig. 1c, where heat transfer is from the inner and the outer tube, with equal and constant wall temperatures, one may again use Eq. (24) with the laminar term being calculated from:

$$Nu_{lam,2300,b} = \left(Nu_{1,b}^3 + Nu_{2,2300,b}^3 + Nu_{3,2300}^3\right)^{1/3} \tag{37}$$

where $Nu_{1,b}$ is calculated from Eq. (5)

$$Nu_{1,b} = 3.66 + \left[4 - \frac{0.102}{a + 0.2}\right] a^{0.04} \tag{38}$$

and where $Nu_{2,2300,b}$ is calculated from Eq. (6)

$$Nu_{2,b} = f_{g,b}\sqrt[3]{Re\ Pr\ d_h/l} \tag{39}$$

with $f_{g,b}$ from Eq. (9). $Nu_{3,2300}$ is given by Eq. (29).

The turbulent term in Eq. (24) is calculated from the expression

$$Nu_{turb,10^4,b} = \frac{(\xi_{ann}/8)\,10^4 Pr}{k_1 + 12.7\sqrt{\xi_{ann}/8}\,(Pr^{2/3}-1)}\left[1+\left(\frac{d_h}{l}\right)^{2/3}\right]\left\{\frac{0.75\, a^{-0.17} + (0.9 - 0.15\, a^{0.6})}{1 + a}\right\} \tag{40}$$

with ξ_{ann} from Eqs. (16) and (31) and k_1 from Eq. (32).

7 Example of Calculation

Within a double pipe, the heat exchanger decane shall be heated from 0°C to 40°C. The mass flow rate of the decane is (a) 0.05 kg/s, (b) 1 kg/s, (c) 0.2 kg/s. The inner diameter of the outer tube is d_o = 40 mm and the outer diameter of the inner tube is d_i = 20 mm. Hot water runs through the inner tube so that the mean wall temperature of the tube is adjusted to 100°C. The outer tube is insulated. How long must the double pipe be?

Solution: The problem concerns a heat transfer in an annular duct, the boundary condition is 1.

List of the given data:

$$T_{in} = 0°C;\ d_i = 0.02m \quad (a)\ \dot{M} = 0.05kg/s$$

$$T_{out} = 40°C;\ d_o = 0.04\,m \quad (b)\ \dot{M} = 1kg/s$$

$$T_w = 100°C;\ d_h = 0.02\,m \quad (c)\ \dot{M} = 0.2kg/s$$

$$a = d_i/d_o = 0.5$$

The physical properties of decane at $T_m = (T_{in} + T_{out})/2 = 20°C$ and $T_w = 100°C$ are taken from Part D. They are given in Table 1.

The heat transfer coefficients to be calculated are dependent on the length of the double pipe. Therefore, the calculation must be done iteratively.

Because the temperatures at the entrance and the exit together with the wall temperature are given, the logarithmic mean temperature difference ΔT_{LM} remains a constant during the iteration and can be calculated in advance:

$$\Delta T_{LM} = \frac{(T_w - T_{in}) - (T_w - T_{out})}{\ln\dfrac{T_w - T_{in}}{T_w - T_{out}}}$$

$$\Delta T_{LM} = \frac{(100-0) - (100-40)}{\ln\dfrac{100-0}{100-40}} = 78.3\,K.$$

To find out which equations have to be used to calculate the heat transfer coefficients for problems (a), (b), and (c), the Reynolds numbers must be known:

$$Re = \frac{w \cdot d_h}{\nu} = \frac{\dot{M}(d_o - d_i)\cdot 4}{\pi(d_o^2 - d_i^2)\cdot\eta} = \frac{\dot{M}\cdot 4}{\pi(d_o + d_i)\eta};$$

(a) $Re = \dfrac{0.05 \cdot 4 \cdot 10^5}{\pi \cdot 0.06 \cdot 92.1} = 1,152$ laminar,

(b) $Re = \dfrac{1 \cdot 4 \cdot 10^5}{\pi \cdot 0.06 \cdot 92.1} = 23,041$ fully turbulent,

(c) $Re = \dfrac{0.2 \cdot 4 \cdot 10^5}{\pi \cdot 0.06 \cdot 92.1} = 4,608$ transition region $2{,}300 < Re < 10^4$

Calculations to (a)

The steps of iteration are included in Table 2.

Comment: Only the indicated decimal numbers were used.

Calculations to (b)

Not from the length of the tube-dependent values:

Equation (15)

$$k_1 = 1.07 + \frac{900}{Re} - \frac{0.63}{(1 + 10Pr)} = 1.07 + \frac{900}{23,041} - \frac{0.63}{1 + 10 \cdot 15.88}$$

$$= 1.1051$$

G2. Table 1. Phsysical properties of Decane

T	T_m = 20°C	T_w = 100°C
λ/W/m K	0.126	0.104
$\eta 10^5$/N s/m^2	92.1	36.4
c_p/J/kg K	2173	2474

$Pr = \eta \cdot c_p/\lambda$	15.88	8.66

Equation (17)

$$\mathrm{Re}^* = \mathrm{Re}\frac{[1+\mathrm{a}^2]\ln \mathrm{a} + [1-\mathrm{a}^2]}{[1-\mathrm{a}]^2 \ln \mathrm{a}} = 23,041\frac{[1+0.5^2]\ln 0.5 + [1-0.5^2]}{[1-0.5]^2 \ln 0.5} = 23,041 \cdot 0.672 = 15,481.59$$

Equation (16)

$$\xi_{\mathrm{ann}} = (1.8\log_{10}(\mathrm{Re}^*) - 1.5)^{-2} = (1.8\log_{10}(\mathrm{Re}^*) - 1.5)^{-2} = 0.02740$$

Equation (18)

$$F_{\mathrm{ann,i}} = 0.75\ a^{-0.17} = 0.75 \cdot 0.5^{-0.17} = 0.8438$$

Equation (21)

$$K = [\mathrm{Pr}(T_\mathrm{m})/\mathrm{Pr}(T_\mathrm{w})]^{0.11} = 1.069$$

Steps of iteration to (b)

The steps of iteration are included in Table 3

Calculations to (c)

Not from the length of the tube-dependent values:

Equation (3)

$$\mathrm{Nu}_{1,\mathrm{i}} = 3.66 + 1.2\ a^{-0.8} = 3.66 + 1.2 \cdot 0.5^{-0.8} = 5.75$$

Equation (7)

$$f_{g\,\mathrm{i}} = 1.615\ \left[1 + 0.14\ a^{-1/2}\right] = 1.615\left(1 + 014 \cdot 0.5^{-1/2}\right) = 1.935$$

Equation (15)

$$k_1 = 1.07 + \frac{900}{\mathrm{Re}} - \frac{0.63}{(1+10\mathrm{Pr})} = 1.07 + \frac{900}{10^4} - \frac{0.63}{1+10 \cdot 15.88} = 1.156$$

Equation (17)

$$\mathrm{Re}^* = \mathrm{Re}\frac{[1+\mathrm{a}^2]\ln \mathrm{a} + [1-\mathrm{a}^2]}{[1-\mathrm{a}]^2 \ln \mathrm{a}} = 10^4\frac{[1+0.5^2]\ln 0.5 + [1-0.5^2]}{[1-0.5]^2 \ln 0.5} = 10^4 \cdot 0.671915 = 6719.15$$

Equation (16)

$$\xi_{\mathrm{ann}} = (1.8\log_{10}(\mathrm{Re}^*) - 1.5)^{-2} = (1.8\log_{10}(\mathrm{Re}^*) - 1.5)^{-2} = 0.03443$$

Equation (18)

$$F_{\mathrm{ann,i}} = 0.75\ a^{-0.17} = 0.75 \cdot 0.5^{-0.17} = 0.8438$$

Equation (21)

$$K = [\mathrm{Pr}(T_\mathrm{m})/\mathrm{Pr}(T_\mathrm{w})]^{0.11} = 1.069$$

G2. Table 2. Steps of iteration to (a)

Step of iteration	1	2	3
Length of the annular tube	20 m	19 m	18.8 m
Eq. (3): $\mathrm{Nu}_{1,\mathrm{i}} = 3.66 + 1.2\,a^{-0.8}$	5.75	5.75	5.75
Eq. (7): $f_{g\,\mathrm{i}} = 1.615\ \{1 + 0.14\,a^{-1/2}\}$	1.935	1.935	1.935
Eq. (6): $\mathrm{Nu}_{2,\mathrm{i}} = f_{g,\mathrm{i}}\sqrt[3]{\mathrm{Re\ Pr\ d_h/l}}$	5.10	5.19	5.20
Eq. (12): $\mathrm{Nu}_3 = \left\{\frac{2}{1+22\mathrm{Pr}}\right\}^{1/6}(\mathrm{Re\ Pr\ d_h/l})^{1/2}$	1.81	1.86	1.86
Eq. (13): $\mathrm{Nu_{m,i}} = (\mathrm{Nu}_{1,\mathrm{i}}^3 + \mathrm{Nu}_{2,\mathrm{i}}^3 + \mathrm{Nu}_{3,\mathrm{i}}^3)^{1/3}$	6.9	6.95	6.96
Eq. (11): $\mathrm{Nu_i} = \mathrm{Nu_{m,i}}(\mathrm{Pr/Pr_w})^{0.11}$	7.38	7.43	7.44
$\alpha = \mathrm{Nu_i} \cdot \lambda(T_{\mathrm{m})/\mathrm{d}}\mathrm{h}$	46.5 W/m^{2}K	46.8 W/m^{2}K	46.9 W/m^{2}K
$\dot{Q} = \alpha \cdot \pi \cdot d_\mathrm{i} \cdot l \cdot \Delta T_{\mathrm{LM}}$	4575.4 W	4374.6 W	4337.8 W
$T_{\mathrm{out}} = T_{\mathrm{in}} + \dot{Q}/(\dot{M} \cdot c_\mathrm{p}(T_\mathrm{m})$	42.1°C	40.3°C	39.9°C

Result: To heat 0.05 kg/s decane from 0°C to 40°C in the described double-pipe heat exchanger, a length of 19 m is needed.

G2. Table 3. Steps of iteration to (b)

Steps of iteration	1	2	3
Length of the annular tube	10	11.5	11.8
Eq. (14) $\mathrm{Nu_i} = \frac{(\xi_{\mathrm{ann}}/8)\mathrm{Re\ Pr}}{k_1 + 12.7\sqrt{\xi_{\mathrm{ann}}/8}\,(\mathrm{Pr}^{2/3} - 1)}\left[1 + \left(\frac{d_h}{l}\right)^{2/3}\right]F_{\mathrm{ann}}K$	239.20	238.86	238.81
$\alpha = \mathrm{Nu_i} \cdot \lambda(T_\mathrm{m})/d_\mathrm{h}$	1,506.94	1,504.84	1,504.48
$\dot{Q} = \alpha \cdot \pi \cdot d_\mathrm{i} \cdot l \cdot \Delta T_{\mathrm{LM}}$	74,137.34	85,139.42	87,339.25
$T_{\mathrm{out}} = T_{\mathrm{in}} + \dot{Q}/(\dot{M} \cdot c_\mathrm{p}(T_\mathrm{m})$	34.12	39.18	40.19

Result: To heat 1.0 kg/s decane from 0°C to 40°C in the described double pipe heat exchanger, a length of 11.8 m is needed.

Equation (25)

$$\gamma = \frac{\mathrm{Re} - 2,300}{10^4 - 2,300} = \frac{4,608 - 2,300}{10^4 - 2,300} = 0.3$$

Steps of iteration to (c)

The steps of iteration are included in Table 4

8 Parallel Plate Duct

8.1 Hydraulic Diameter; Boundary Conditions

A parallel plate duct (rectilinear gap) is formed between two plates with a constant spacing s between them. The characteristic dimension for flow through the gap, corresponding to the hydraulic diameter, is twice the gap width, that is,

$$d_\mathrm{h} = 2\,\mathrm{s} \tag{41}$$

The critical Reynolds number up to which the flow in the gap is laminar lies between 2,200 and 3,600. It depends greatly on the inlet conditions, for example, sharp or rounded edges.

There are a number of boundary conditions that apply for heat transport from the gap walls to the flowing medium, and they have been dealt with in detail in the literature for the case of laminar flow [1, 2]. Those that are considered here relate to the case of $d_\mathrm{i}/d_\mathrm{o} = 1$ in Sects. 1–7.

In the boundary condition represented by Fig. 3a, one side of the gap is maintained at a constant temperature T_{w1}, and the other side is insulated. In that represented in Fig. 3b, both walls of the gap are heated to the same temperature $T_{\mathrm{w1}} = T_{\mathrm{w2}}$. This corresponds to the boundary condition 3 illustrated in Fig. 1 for a concentric annulus.

8.2 Definition of Heat Transfer Coefficient and the Dimensionless Numbers

The definition of the average heat transfer coefficient α over a length l is the same as in pipe flow (cf. Chap. G1). The dimensionless numbers are defined by

$$\mathrm{Nu} = \frac{\alpha\, d_\mathrm{h}}{\lambda};\ \mathrm{Re} = \frac{w\, d_\mathrm{h}}{\upsilon};$$

The values for the physical properties must be referred to the main liquid temperature $T_\mathrm{m} = (T_\mathrm{in} + T_\mathrm{out})/2$.

8.3 Heat Transfer in Laminar Flow

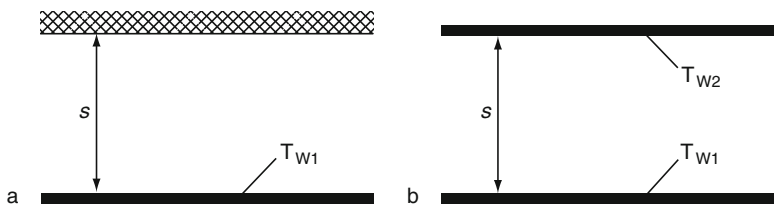
8.3.1 Hydrodynamically Developed Laminar Flow

Many authors have determined the Nusselt number for laminar flow that has been fully developed thermally and hydrodynamically.

G2. Table 4. Steps of iteration to (c)

Step of iteration	1	2	3
Length of the annular tube	14 m	13 m	13.6 m
Eq. (28) $\mathrm{Nu}_{2,2300,i} = f_{\mathrm{g,i}}(2300\ \mathrm{Pr}\ d_\mathrm{h}/l)^{1/3}$	7.23	7.41	7.30
Eq. (29) $\mathrm{Nu}_{3,2300} = \left\{\frac{2}{1+22\mathrm{Pr}}\right\}^{1/6}(2300\ \mathrm{Pr}\ d_\mathrm{h}/l)^{1/2}$	3.05	3.17	3.10
Eq. (26) $\mathrm{Nu}_{\mathrm{lam},2300,\mathrm{i}} = \left(\mathrm{Nu}_{1,\mathrm{i}}^3 + \mathrm{Nu}_{2,2300,\mathrm{i}}^3 + \mathrm{Nu}_{3,2300}^3\right)^{1/3}$	8.42	8.57	8.48
Eq. (30) $\mathrm{Nu}_{\mathrm{turb},10^4,\mathrm{i}} = \frac{(\xi_\mathrm{ann}/8)\,10^4\mathrm{Pr}}{k_1 + 12.7\sqrt{\xi_\mathrm{ann}/8}\,(\mathrm{Pr}^{2/3}-1)}\left[1+\left(\frac{d_\mathrm{h}}{l}\right)^{2/3}\right]F_{\mathrm{ann,i}}$	108.78	108.85	108.80
Eq. (24) $\mathrm{Nu}_\mathrm{m} = (1-\gamma)\,\mathrm{Nu}_{\mathrm{lam},2300} + \gamma\,\mathrm{Nu}_{\mathrm{turb},10^4}$	38.53	38.65	38.57
$\mathrm{Nu} = ((1-\gamma)\,\mathrm{Nu}_{\mathrm{lam},2300} + \gamma\,\mathrm{Nu}_{\mathrm{turb},10^4})\,K$	41.18	41.32	41.23
$\alpha = \mathrm{Nu}_\mathrm{i}\cdot\lambda(T_\mathrm{m})/d_\mathrm{h}$	259.46	260.31	259.79
$\dot{Q} = \alpha\cdot\pi\cdot d_\mathrm{i}\cdot l\cdot\Delta T_{\mathrm{LM}}$	17,870.8	16,648.4	17,382.1
$T_\mathrm{out} = T_\mathrm{in} + \dot{Q}/(\dot{M}\cdot c_\mathrm{p}(T_\mathrm{m}))$	41.1	38.3	40.0

Result: To heat 0.2 kg/s decane from 0°C to 40°C in the described double pipe heat exchanger, a length of 13.6 m is needed.



G2. Fig. 3. Boundary conditions for heat transfer in a parallel plate duct (in an annular gap for the case of $(d_\mathrm{i}/d_\mathrm{o}) = 1$). Boundary condition (a): Heat transferred from one side of the duct. Boundary condition (b): Heat transferred at both sides of the duct, each at the same wall temperature $T_{\mathrm{w1}} = T_{\mathrm{w2}}$.

The equation that applies for the boundary condition shown in Fig. 3a is

$$\mathrm{Nu}_{1,\mathrm{I}} = 4.861 \tag{42}$$

and that for the boundary condition shown in Fig. 3b is

$$\mathrm{Nu}_{1,\mathrm{II}} = 7.541 \tag{43}$$

These equations are practically the same as Eqs. (3), (4), and (5) for the case $d_\mathrm{i}/d_\mathrm{o} = 1$.

Under the boundary conditions illustrated in Fig. 3a and b, the asymptote for high values of $\mathrm{RePrd_h}/l$ in thermally developing and hydrodynamically developed flow is

$$\mathrm{Nu}_2 = 1.841\sqrt[3]{\mathrm{RePrd_h}/l}. \tag{44}$$

If laminar flow is hydrodynamically developed and thermally developing or developed, the mean Nusselt number in parallel plate ducts is given by the following equation, in which the length l is measured from the point at which heat transfer commences:

$$\mathrm{Nu_m} = (\mathrm{Nu}_1^3 + \mathrm{Nu}_2^3)^{1/3} \tag{45}$$

Nu_1 and Nu_2 for the applicable boundary conditions can be determined by solving Eqs. (42)–(44). Equation (45) which has been derived from Eq. (10) and the boundary conditions corresponding to Eqs. (3–9) when $d_\mathrm{i}/d_\mathrm{o} = 1$, yields values of $\mathrm{Nu_m}$ that agree very well with the tabulated figures [1] applicable to the same boundary conditions. The greatest difference is about 4%, and occurs for $20 < \mathrm{Re\ Pr}\ d_\mathrm{h}/l < 200$.

8.3.2 Hydrodynamic and Thermal Development of Flow

If heating commences at the inlet to the parallel plate duct, a temperature as well as a velocity profile is formed. The mean liquid temperatures and Nusselt numbers for the boundary conditions shown in Fig. 3a) have been calculated by Stephan [9]. An equation suggested by Mercer et al. [10] yields values that agree with these figures to within 7% in the $0.1 < \mathrm{Pr} < 10$ range:

$$\mathrm{Nu_{mI}} = 4.86 + \frac{0.061\{\mathrm{Re\ Pr}\ d_\mathrm{h}/l\}^{1.2}}{1 + 0.091\{\mathrm{Re\ Pr}\ d_\mathrm{h}/l\}^{0.17}} \tag{46}$$

Stephan [11] also determined mean liquid temperatures and Nusselt numbers for the boundary conditions shown in Fig. 3b) and submitted the following equation for the Nusselt numbers:

$$\mathrm{Nu_{m,II}} = 7.55 + \frac{0.024\{\mathrm{RePr}d_\mathrm{h}/l\}^{1.14}}{1 + 0.0358\{\mathrm{RePr}d_\mathrm{h}/l\}^{0.64}Pr^{0.17}} \tag{47}$$

The range quoted for the validity is $0.1 < \mathrm{Pr} < 1{,}000$.

The asymptote to the Nusselt numbers calculated for high values of $\mathrm{Re\ Pr}\ d_\mathrm{h}/l$ from the boundary theory for thermal and hydrodynamic development is the same as that applicable to concentric annuli (cf. Eq. (12)), that is,

$$\mathrm{Nu}_3 = \left\{\frac{2}{1 + 22\mathrm{Pr}}\right\}^{1/6}(\mathrm{Re\ Pr}\ d_\mathrm{h}/l)^{1/2} \tag{48}$$

The Nusselt numbers obtained from Eq. (49) represent, with only slight deviations the boundary conditions given by the Eqs. (46) and (47) and tabulated figures [1].

$$\mathrm{Nu_m} = (\mathrm{Nu}_1^3 + \mathrm{Nu}_2^3 + \mathrm{Nu}_3^3)^{1/3} \tag{49}$$

Nu_1 is obtained from Eq. (42) or (43); Nu_2, from Eq. (44); and Nu_3, from Eq. (48).

8.4 Heat Transfer in Turbulent Flow

It has been shown [2] that the equation presented for turbulent pipe flow in Chap. G2 can also be applied for the determination of Nusselt numbers in parallel plate ducts. In this case it is valid in the $0.5 < \mathrm{Pr} < 100$ range for the boundary condition illustrated in Fig. 3b and for $3 \cdot 10^4 \leq \mathrm{Re} < 10^6$; the friction factor is the same as for circular tubes, and the hydraulic diameter of the parallel plate duct should be inserted for the diameter of the tube.

G3 Heat Transfer in Helically Coiled Tubes

Volker Gnielinski
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Introduction

Centrifugal forces in a fluid flowing through a curved pipe cause secondary flows circulating outward into the core region of the pipe to form a pair of symmetric vortices. The combination of both the main and the secondary flows creates a flow pattern in which the maximum velocity is shifted outward from the center of the tube. The secondary flow produces a transverse transport of the fluid over the cross section of the pipe. This additional convective transport improves heat transfer between the fluid and the wall of the pipe but increases the pressure drop when compared to that in a straight tube. The differences are particularly apparent in laminar flows.

2 Determination of the Average Diameter of Curvature

The intensity of the secondary flow depends on the relative curvature (d/D) of the coil, where d is the inner diameter of the tube and D the diameter of the curvature. The average diameter of a spiral with n turns and a pitch h formed from a tube of the length l is

$$D_S = \frac{l}{n\,\pi} \tag{1}$$

The projected diameter of a winding D_c in the coil illustrated in Fig. 1 results from the relations of a right-angled triangle (Pythagorus).

$$D_C = \sqrt{D_S^2 - \left(\frac{h}{\pi}\right)^2} \tag{2}$$

The average diameter of the curvature D of the coil, that is, the value to be inserted in the ratio (d/D), is

$$D = D_C\left[1 + \left(\frac{h}{\pi D_C}\right)^2\right] \tag{3}$$

Appreciable differences between D and D_c result only for strongly curved tubes and large pitches. For most practical cases, the difference is negligible as h is small compared to D_c.

3 Critical Reynolds Number

The secondary flow has a stabilizing effect on the laminar flow. Any disturbances are apparently damped by the secondary flow. Therefore, the transition from laminar to turbulent flow is shifted to higher Reynolds numbers with increasing relative curvature (d/D).

The critical Reynolds number according to Schmidt [1] is

$$\mathrm{Re}_{crit} = 2300\left[1 + 8.6\left(\frac{d}{D}\right)^{0.45}\right] \tag{4}$$

This equation is based on a value for the critical Reynolds number of $\mathrm{Re}_{crit} = 2300$ for the straight tube.

4 Definition of the Heat Transfer Coefficient

The average heat transfer coefficient α is defined in terms of the heat flux $\dot{q}$ and the logarithmic mean of the temperature difference

$$\alpha = \dot{q}/\Delta T_{LM} \tag{5}$$

The logarithmic mean temperature difference $\Delta\, T_{LM}$ is given by

$$\Delta T_{LM} = \frac{(T_{w,in} - T_{in}) - (T_{w,out_w} - T_{out})}{\ln\dfrac{T_{w,in} - T_{in_i}}{T_{w,out} - T_{out}}} \tag{6}$$

where T_{in} and T_{out} are the inlet and outlet bulk fluid temperatures and $T_{w,in}$ and $T_{w,out}$ are the tube wall temperatures at the inlet and at the outlet of the coil, respectively.

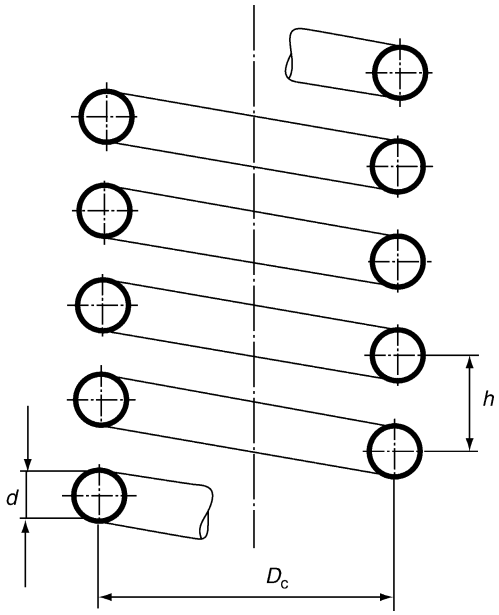
The temperature T_{out} may be calculated from

$$T_{out} = T_{in} + \frac{\dot{Q}}{\dot{M}\,c_p} \tag{7}$$

Where $\dot{Q}$ is the total rate of heat transfer to the fluid as it passes through the coil and $\dot{M}$ is the mass flow rate of the fluid. If $\dot{Q}$ is not known, the equation can be rewritten as

$$T_{out} = T_{in} + \frac{\alpha\, A\, \Delta T_{LM}}{\dot{M}\,c_p} \tag{8}$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_25,



G3. Fig. 1. Geometry of a coil.

where A is the total heat transfer area. Since T_{out} appears in ΔT_{LM}, a trial and error solution is required to obtain T_{out}.

The Nusselt number is calculated from

$$\mathrm{Nu} = \frac{\alpha d}{\lambda} \tag{9}$$

with λ the thermal conductivity of the fluid. The Reynolds number is calculated from

$$\mathrm{Re} = \frac{\dot{m} d}{\eta} \tag{10}$$

where $\dot{m}$ is the mass flow per unit area and η the dynamic viscosity of the fluid. The physical properties are evaluated at the mean temperature of the fluid:

$$T_m = (T_{in} + T_{out})/2. \tag{11}$$

5 Heat Transfer in Laminar Flow

Heat transfer coefficients in the region of thermally and/or hydrodynamically developing flow depend on the tube length l. The effect of the thermal and fluid dynamic inlet conditions on the heat transfer coefficient in laminar flow has been the subject of numerical analysis, for example, by Bauermeister and Brauer [2] and Janssen and Hoogendorn [3]. They included the factor (l/d). The figures thus calculated for the heat transfer coefficient are considerably less than those determined by experiment.

Experiments have failed to reveal any effect exerted by the relative length of flow path concerned (l/d) on the coefficient. In fact, many research workers maintain that, as a result of the secondary current in the spiral, the temperature and velocity profiles are already formed after a very short relative length (l/d).

In any case, not very many measurements have been made of the heat transfer coefficient in coils, and none is known in which the number of turns and the length of flow path have been systematically varied. Consequently, it is more reliable to adopt the Bauermeister and Brauer equations [2] to analyze the zone for which no experimental verifications exist, for example, for coils with numerous turns and long flow paths (l/d). The equations themselves are too complex to be dealt with here.

Values are quoted in the literature for measurements performed on water ($2 < \mathrm{Pr} < 5$) and oil ($100 < \mathrm{Pr} < 200$) in coils heated by condensing steam.

The geometry of the coils was as follows:

d/D	0.2	0.14	0.098	0.069	0.049	0.024	0.012
l/d	231	165	365	205	477	579	636
n	15.5	8.9	11.5	5	7.5	4.5	2.5

It has been shown [4] that, if the Schmidt equation [1] is applied, these measured values conform with a deviation of ± 15% to the following equation:

$$\mathrm{Nu} = 3.66 + 0.08\left[1 + 0.8\left(\frac{d}{D}\right)^{0.9}\right]\mathrm{Re}^{m}\mathrm{Pr}^{1/3}\left(\frac{\mathrm{Pr}}{\mathrm{Pr}_w}\right)^{0.14} \tag{12}$$

with $m = 0.5 + 0.2903\,(d/D)^{0.194}$.

The Prandtl number Pr is evaluated at the mean fluid temperature T_m and Pr_w at the wall temperature. The factor $(\mathrm{Pr}/\mathrm{Pr}_w)^{0.14}$ was introduced into the original equation by Schmidt to take into account the temperature dependence of the physical properties. Equation (12) applies for $\mathrm{Re} \le \mathrm{Re}_{crit}$, as defined by Eq. (4).

6 Heat Transfer in Turbulent Flow for $\mathrm{Re} > 2.2 \times 10^4$

Schmidt [1] found a transition region for heat transfer between the critical Reynolds number, Re_{crit}, and fully developed flow at $\mathrm{Re} > 2.2 \times 10^4$. It is described in the following paragraph. The measured values were determined on air (Pr = 0.7) and water ($2 < \mathrm{Pr} < 5$). According to Gnielinski [4] they conform to a deviation of ± 15% to the following equation if $\mathrm{Re} > 2.2 \times 10^4$:

$$\mathrm{Nu} = \frac{(\xi/8)\mathrm{RePr}}{1 + 12.7\sqrt{\xi/8}\left(\mathrm{Pr}^{2/3} - 1\right)}\left(\frac{\mathrm{Pr}}{\mathrm{Pr}_w}\right)^{0.14}. \tag{13}$$

The friction factor for turbulent flow in helically coiled tubes is given by Mishra and Gupta [5] as

$$\xi = \left[\frac{0.3164}{\mathrm{Re}^{0.25}} + 0.03\left(\frac{d}{D}\right)^{0.5}\right]\left(\frac{\eta_w}{\eta}\right)^{0.27} \tag{14}$$

The correction factor $(\eta_w/\eta)^{0.27}$ in Eq. (14), where η_w is the dynamic viscosity of the fluid at wall temperature and η that at T_m, was added by Gnielinski [6] to the original equation given by Mishra and Gupta [5] to take into account the temperature dependence of the dynamic viscosity and is based entirely on the experimental results for heating.

7 Heat Transfer in the Transition Region

Gnielinski [4] has shown that a linear interpolation of the Nusselt numbers between Re_{crit} and $Re = 2.2 \times 10^4$ suffices for the determination of the Nusselt numbers in the transition zone $Re_{crit} < Re < 2.2 \times 10^4$. The corresponding equations are

$$Nu = \gamma\, Nu_l(Re_{crit}) + (1 - \gamma)\, Nu_t(Re = 2.2 \times 10^4) \qquad (15)$$

where $Nu_1(Re_{crit})$ = Nu as in Eq. (12) if $Re = Re_{crit}$ and Nu_t ($Re = 2.2. \times 10^4$) = Nu as in Eq. (13) if $Re = 2.2 \times 10^4$ and

$$\gamma = \frac{2.2 \cdot 10^4 - Re}{2.2 \cdot 10^4 - Re_{crit}} \qquad (16)$$

G4 Heat Transfer in Flow Past a Plane Wall

Volker Gnielinski
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Introduction

Brauer and Sucker [1] dealt with the mass transfer in parallel laminar flow along a flat plate. From the numerical solutions to the complete set of differential equations for the concentration field, smoothed curves for average Sherwood numbers were derived. In view of the analogy between heat and mass transfer, these curves can also be applied to heat transfer. For Reynolds numbers Re $<$ 100, they yield higher values of the Nusselt number than those calculated by Pohlhausen [2] and Kroujiline [3] from the boundary layer theory (cf. Eq. (2)). If Re $>$ 100, the results obtained by both methods practically agree.

2 Parallel Flow Along a Flat Plate with Laminar Boundary Layer

The stream adjacent to the plate is retarded when a fluid of uniform velocity is flowing over a plate. If the leading edge of this plate is streamlined, a laminar boundary layer is formed outward from it. The thickness of the laminar boundary layer increases with increasing distance x from the leading edge. At a length x_{crit}, the forces between the streaming particles are not sufficient enough to keep them inline, and a transition to a turbulent boundary layer starts. The critical length x_{crit} is determined by the critical Reynolds number.

$Re_{x,crit} = w\, x_{crit}/\nu$, which depends on, among other factors, the degree of turbulence in the inflowing stream and the roughness of the plates surface. A figure of $Re_{x,crit} = 5 * 10^5$ is assumed. It may be higher if there is little turbulence at the inlet, or much lower if there is much turbulence.

2.1 Entire Surface at Uniform Temperature

Equations for the local and the average value of the Nusselt number were derived by Pohlhausen [2] and Kroujiline [3]. The *local value* of the Nusselt number $Nu_{x,lam}$ at a position x from the leading edge of the plate can be calculated from

$$Nu_{x,lam} = 0.332 \sqrt{Re_x}\ \sqrt[3]{Pr} \tag{1}$$

Where $Nu_{x,lam} = \frac{\alpha x}{\lambda}$ and $Re_x = \frac{wx}{\nu}$

The *average Nusselt* number $Nu_{l,lam}$ for a flat plate of the length l results from integrating Eq. (1)

$$Nu_{l,lam} = 0.664 \sqrt{Re_l}\ \sqrt[3]{Pr} \tag{2}$$

with $Nu_{l,lam} = \frac{\alpha l}{\lambda}$ and $Re_l = \frac{wl}{\nu}$.

A weak dependence of the factors 0.332 in Eq. (1) and 0.664 in Eq. (2) on Pr is ignored. According to Presser [4], the factor 0.664 increases to 0.703 for Pr = 1,000.

2.2 Uniform Heat Flux on the Surface of the Plate

According to Gauler [4], the local value of the Nusselt number at a position x from the leading edge is calculated from

$$Nu_{x,lam} = 0.460 \sqrt{Re_x}\ \sqrt[3]{Pr} \tag{3}$$

The range of validity of Eqs. (1–3) is $Re_x < 10^5$.

$Re_l < 10^5$ with the above-mentioned dependencies. Pr = 0.6 – 2000.

Physical properties are evaluated at the mean temperature $T_m = (T_{in} + T_{out})/2$ of the fluid.

3 Parallel Flow Along a Flat Plate with Turbulent Boundary Layer

If the plate has a blunt or obtuse-angled leading edge, a turbulent boundary layer will spread out from it. Presser [5] has investigated the effect exerted by the shape of the leading edge. According to Petukhov and Popov [6], the value of the Nusselt number for a flat plate at a constant wall temperature with

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_26,

physical properties evaluated at the bulk temperature T_m of the fluid can be calculated from

$$\mathrm{Nu_{turb}} = \frac{(\zeta/8)\mathrm{RePr}}{1 + 12.7\sqrt{(\zeta/8)}(\mathrm{Pr}^{2/3} - 1)} \tag{4}$$

For the *local Nusselt number*, $\mathrm{Nu}_{x,\mathrm{turb}}$, the drag coefficient ζ presented by Schlichting [7] for a plate with turbulent boundary layer, to be used in Eq. (4) is

$$(\zeta/8) = 0.296\,\mathrm{Re}_x^{-0.2} \tag{5}$$

thus resulting in

$$\mathrm{Nu}_{x,\mathrm{turb}} = \frac{0.0296\mathrm{Re}_x^{0.8}\mathrm{Pr}}{1 + 2.185\mathrm{Re}_x^{-0.1}(\mathrm{Pr} - 1)} \tag{6}$$

For the *average Nusselt number* the average friction factor given by Schlichting [7] for a plate with turbulent boundary layer to be used in Eq. (4) is

$$(\zeta/8) = 0.037\,\mathrm{Re}_l^{-0.2} \tag{7}$$

yielding

$$\mathrm{Nu}_{l,\mathrm{turb}} = \frac{0.037\mathrm{Re}_l^{0.8}\mathrm{Pr}}{1 + 2.443\mathrm{Re}_l^{-0.1}(\mathrm{Pr}^{2/3} - 1)} \tag{8}$$

The range of validity of Eqs. (6) and (8) is $5{*}10^5 < \mathrm{Re} < 10^7$ and $0.5 < \mathrm{Pr} < 2000$. The physical properties are evaluated at the mean temperature $T_m = (T_{in} + T_{out})/2$ of the fluid.

4 Combined Correlation for Average Coefficients For Both Turbulent and Laminar Flow Over a Plate

In practical applications, a blunt leading edge and higher degrees of turbulence prevent the formation of a laminar boundary layer over the entire length of the plate, even if the Reynolds number lies within the range of medium values. No sudden change of the Nusselt number given by Eq. (2) to those resulting from Eq. (8) is observed. Krischer and Kast [8] have presented a graph correlating collected data of heat transfer for air at a flat plate from $10^1 < \mathrm{Re_l} < 10^6$. As shown by Gnielinski [9], the following equation represents not only the graph of Krischer and Kast [8], but also measures the heat transfer coefficients in a wide range of Prandtl numbers.

$$\mathrm{Nu_{l,0}} = \sqrt{\mathrm{Nu_{l,lam}^2} + \mathrm{Nu_{l,turb}^2}} \tag{9}$$

where $\mathrm{Nu_{l,0}} = \alpha\, l/\lambda$ and $\mathrm{Nu_{l,lam}}$ from Eq. (2) and $\mathrm{Nu_{l,turb}}$ from Eq. (8).

Equation (9) holds for average Nusselt numbers from $10^1 < \mathrm{Re} < 10^7$ and $0.5 < \mathrm{Pr} < 2000$. Physical properties are evaluated at the mean temperature $T_m = (T_{in} + T_{out})/2$ of the fluid.

Figure 1 demonstrates the course of Eq. (9) for Pr = 0.7.

To test a computer program for Eq. (9) the result for Re = 5000 and Pr = 0.7 is $\mathrm{Nu_{l,0}} = 51.51$.

5 Dependence of the Heat Transfer on the Length of an Unheated Initial Portion of the Plate

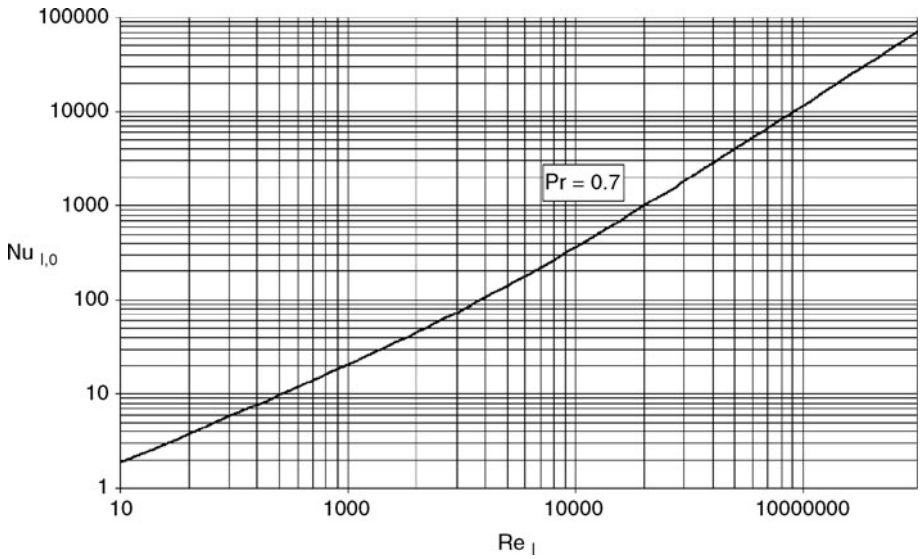
The heat transfer from a plate will be influenced by the presence of an unheated section preceding the heated section.

After Brauer [10], the effect of an unheated initial section of the plate in case of a laminar boundary layer can be taken into account by extending Eq. (2) to

$$\mathrm{Nu_{l,lam}} = 0.664\sqrt{\mathrm{Re_l}}\,\sqrt[3]{\mathrm{Pr}}\,\frac{\left[1 - (1 - l_0/l)^{3/4}\right]^{2/3}}{l_0/l} \tag{10}$$

and computing $\mathrm{Nu_{l,lam}}$ and $\mathrm{Re_l}$ with the total length l of the plate, where l_0 denotes the heated length of the plate.

According to Zukauskas and Ambrazyavichyus [11], however, this effect may be neglected in the case of a turbulent boundary layer if $\mathrm{Nu_{l,turb}}$ and $\mathrm{Re_l}$ in Eq. (8) are calculated with the length l_0 of the heated portion and if the ratio l_0/l is between 1 and 0.1.



G4. Fig. 1. Course of Eq. (9) for Pr = 0.7.

6 Effect of the Direction of Heat Flux

The direction of heat flux – that is, heating or cooling the plate – affects the heat transfer in case of temperature-dependent fluid properties. For liquids this effect can be taken into account, according to Zukauskas and Ambrazyavichyus [11], by introducing a factor

$$K = K_l = \left(\frac{\mathrm{Pr}}{\mathrm{Pr_w}}\right)^{0.25} \tag{11}$$

Pr and $\mathrm{Pr_w}$ are the Prandtl numbers of the liquid at the mean fluid temperature T_m and at the wall temperature, respectively.

For gases this effect may be allowed for, according to Churchill and Brier [12], by using the factor

$$K = K_g = \left(\frac{T_m}{T_w}\right)^{0.12} \tag{12}$$

T_m and T_w are the absolute temperatures of the gas at mean gas temperature and of the wall temperature, respectively.

As K is introduced in Eq. (9), the consideration of heat flux gives

$$\mathrm{Nu_l} = K\mathrm{Nu_{l,0}} \tag{13}$$

G5 Heat Transfer to Single Cylinders, Wires, and Fibers in Longitudinal Flow

Holger Martin[1] · *Bernhard Gampert*[2]
[1]Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany
[2]Universität Duisburg-Essen, Essen, Germany

1 Circular Cylinders in Longitudinal Flow

Heat transfer between a circular cylinder and a fluid flowing parallel to its axis is determined by the thermal and the hydrodynamic boundary layer. The following problems refer to the laminar boundary layers and single circular cylinders, that means, the flow is assumed to be not influenced by the walls or by other cylinders. Natural convection is not considered.

In principle the following cases are possible:

1.1 Longitudinal Flow over a Circular Cylinder at Rest

In order to calculate the heat transfer rates, the steady-state boundary layer equations have to be solved for the velocity and the temperature fields. For longitudinal flow over a circular cylinder at rest, the boundary conditions for the fluid dynamic layer are (see Fig. 1)

$$r = r_w = d/2\; x_A \le x \le x_E:\; u = u_w = 0,$$
$$r \to \infty\; u = u_\delta \neq 0$$
$$x_A = 0,\; x_E = L;\; x_A,\; x_E = \text{const.}$$

1.2 The Finite Circular Cylinder Axially Moving Through a Fluid at Rest

Longitudinal flow in this case is due to the motion of the cylinder. The boundary conditions for the calculation of the velocity field are (see Fig. 2)

$$r = r_w = d/2\; x_A(t) \le x \le x_E(t):\; u = u_w \neq 0,$$
$$r \to \infty\; u = u_\delta = 0$$
$$x_A(t) = u_w t,\; x_E(t) = L + u_w t$$

This case can be reduced to the previous one (Sect. 1.1) by using a coordinate system moving with the cylinder. So the heat transfer results for the cylinder at rest as given in Sect. 3 may be used as well for this case.

1.3 The Infinite Circular Cylinder Axially Moving in a Fluid at Rest

A case that is different from those in Sects. 1.1 and 1.2 is an infinitely long cylinder moving axially through a stagnant fluid. Problems of this kind arise for fibers coming from a nozzle and going out of the cooling process after a certain residence time (see Fig. 3) [1–3]. The boundary conditions for this problem are

$$r = r_w = d/2\; x_A \le x \le x_E:\; u = u_w \neq 0,$$
$$r \to \infty\; u = u_\delta = 0$$
$$x_A = 0,\; x_E = L$$

1.4 The Infinite Circular Cylinder Axially Moving in a Longitudinal Flow

A combination of cases 1.1 and 1.3 will be found if the infinite cylinder axially moves in a longitudinal fluid flow. The boundary conditions in this case are

$$r = r_w = d/2\; x_A \le x \le x_E:\; u = u_w \neq 0,$$
$$r \to \infty\; u = u_\delta \neq 0$$
$$x_A = 0,\; x_E = L$$

Heat transfer (and flow resistance) at the cylinder surface, in this case, do not only depend upon the relative velocity as used by Gampert [2, 3] $u_r = |u_\delta - u_w|$; but also upon the ratio of these two velocities, u_w/u_δ. In place of this ratio, u_w/u_δ, a parameter

G5. Fig. 3. The infinite circular cylinder axially moving in a fluid at rest.

$$w = \frac{u_w/u_\delta}{1 + u_w/u_\delta} \tag{1}$$

can be used which varies from 0 to 1 and clearly distinguishes between the three cases:

Case 1.1 (=1.2): $w = 0$, case 1.3: $w = 1$, and case 1.4: $0 < w < 1$. In place of the relative velocity u_r, the sum of the two velocities, $(u_\delta + u_w)$, seems to be a more reasonable variable to describe the dependency of heat transfer on fluid flow in this case.

$$u_{sum} = u_\delta + u_w \tag{2}$$

The reason for this choice can be easily explained by the fact that the case of vanishing relative velocity $u_r = 0$, that is, $u_\delta = u_w$ does not mean that heat transfer tends to zero. Actually, this case of vanishing relative velocity corresponds to a "frictionless" (plug flow) case of transient conduction (in a coordinate system moving with the velocity $u_\delta = u_w$) where the heat transfer coefficient α is inversely proportional to the residence time to the power of $-1/2$:

$$Nu = \frac{1}{\sqrt{\pi Fo}} \qquad Fo = \kappa t / r_w^2 \quad t = x/u \tag{3}$$

G5. Table 1. Heat transfer at the circular cylinder axially moving in a longitudinally flowing fluid [$w = 0$, $w = 0.5/1.5$, $w = 0.9/1.9$, and $w = 1/2$ (approximation of the analytical solution from Carslaw & Jaeger [4, §13.5, Eqs. (8–10)]), $w = 1$, and Pr = 0.7]

$w = u_w/(u_\delta + u_w)$	A	B	C	u_w/u_δ
0	0.547	0.951	0	0
0.3333	0.590	0.901	0	0.5
0.4737	0.620	0.863	0	0.9
0.5000	0.622	0.855	0	1
1	0.674	0.690	0.035	∞

in case of negligible curvature. The corresponding case for the infinite region bounded internally by the circular cylinder is treated in the work by Carslaw and Jaeger [4], paragraph 13.5, and it is used in an approximate form in Table 1 ($w = 0.5$, $u_w/u_\delta = 1$).

2 Definitions

Heat transfer at the cylinder in longitudinal flow is treated in the following for constant wall temperature, T_w, and constant temperature of the surroundings, T_∞.

The local heat transfer coefficient is defined as

$$\alpha_x = \frac{\dot{q}_x}{T_w - T_\infty} \tag{4}$$

The local Nusselt number is defined with the fluid conductivity, λ, measured at the wall temperature, $\lambda\,(T_w)$.

$$Nu = \frac{\alpha_x d}{\lambda} \tag{5}$$

The viscosity in the Reynolds number, $Re_d = u_r\, d/\nu$, is measured at the ambient temperature, T_∞.

3 Heat Transfer to a Circular Cylinder in Longitudinal Flow

The difference between a cylinder in longitudinal flow and a flat plate is due to the curvature of the cylinder wall. This influence depends upon the ratio of boundary layer thickness and radius of the cylinder. It can be taken into account via the length (or residence time, or curvature) parameter, X.

$$X = \frac{\nu x}{(d/2)^2\, u_{sum}} \qquad \left(= 4\frac{x/d}{Re_{sum}}\right) \tag{6}$$

In the formulae for mean Nusselt numbers, $x = L$ is to be used in X.

3.1 Heat Transfer to a Circular Cylinder for Low Values of the Curvature Parameter

If X is small enough the influence of curvature may be neglected, and the heat transfer coefficients can be calculated for a flat plate.

For the cylinder at rest ($w = 0$) in longitudinal flow (cases 1.1 and 1.2) in this limit (see also Chap. G4, and Gauler [5]) the solution is found to be

$$\mathrm{Nu} = 0.332 \frac{\mathrm{Pr}^{1/3}}{\sqrt{X/4}} (w = 0)(0.5 < \mathrm{Pr} < 500) \qquad (7)$$

for the local values (at a position x), and twice this value (0.664 in place of 0.332 in Eq. (2)) for the integral mean value, $\mathrm{Nu_m}$ (from $x = 0$ to L).

The errors to be expected (compared to the solution accounting for the curvature, as given in the Sect. 4) are about

$$2\% \text{ for } X = 0.001,$$
$$15\% \text{ for } X = 0.01,$$
$$35\% \text{ for } X = 0.1$$

The infinite circular cylinder axially moving in a fluid at rest (case 1.3, $w = 1$) in this limit (negligible curvature, flat plate) leads to [5]

$$\mathrm{Nu} = 0.4437 \frac{\mathrm{Pr}^{2/3}}{\sqrt{X/4}} (w = 1)(0.5 < \mathrm{Pr} < 5) \qquad (8)$$

The special situation $w = 1/2$ of case 1.4 ($0 < w < 1$), that is, $u_r = |u_\delta - u_w| = 0$ corresponds to plug flow (frictionless flow). In this case the local Nusselt number for negligible curvature is found from [5] as

$$\mathrm{Nu} = \frac{1}{\sqrt{\pi}} \sqrt{\frac{u_w d^2}{\kappa x}} \; (w = 1/2)(0 < \mathrm{Pr} < \infty) \qquad (9)$$

for all Prandtl numbers $\mathrm{Pr} = \nu/\kappa$.

3.2 Heat Transfer to a Circular Cylinder for Larger Values of the Curvature Parameter (Lean Cylinder, Fiber)

Gampert [2] has numerically calculated the Nusselt numbers for the cases 1.1, (=1.2), 1.3, and 1.4, using a highly accurate finite difference method. For small and large values of the curvature parameter the numerical result could be compared with analytical solutions.

The results are shown graphically in Fig. 4 for a Prandtl number of Pr = 0.7 (air). For case 1.3 ($w = 1$), Fig. 5 also shows the corresponding curves for other Prandtl numbers Pr = 0.1, 0.7, 1.0, and 10.

The local and integral mean Nusselt numbers can be correlated by the general formulae

$$\mathrm{Nu} = \frac{A}{\sqrt{X}} + \frac{B}{X^{0.1}} + C \qquad (10)$$

$$\mathrm{Nu_m} = 2\frac{A}{\sqrt{X}} + \frac{10}{9}\frac{B}{X^{0.1}} + C \qquad (11)$$

where the "constants" A, B, and C depend upon the case (i.e., on the parameter w) and the Prandtl number, Pr.

The Tables 1 and 2 give the numerical values of A, B, and C to be used in Eqs. (10) and (11).

4 Example

A thin cylindrical wire of the radius $r_w = 10^{-4}$ m moves continuously with a velocity u_w through air flowing in the same direction with a velocity u_δ. This corresponds to case 1.4, and the parameters A, B, and C for the local Nusselt number [Eq. (10)] can be found in Table 1.

Two cases shall be investigated (which have the same relative velocity $u_r = |u_\delta - u_w| = 10$ m/s).

Case 1: Air velocity $u_\delta = 100$ m/s and wire velocity $u_w = 90$ m/s.

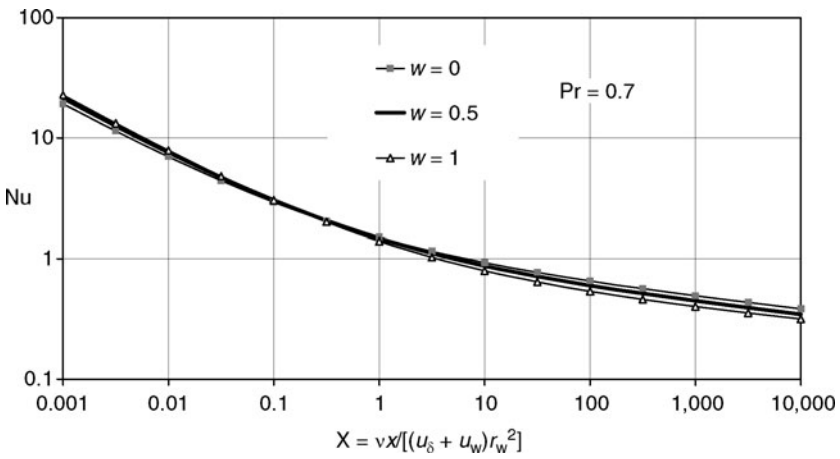
The sum of the velocities $u_s = u_\delta + u_w = 190$ m/s and the ratio $u_w/u_\delta = 0.9$.

Case 2; Air velocity $u_\delta = 20$ m/s and wire velocity $u_w = 10$ m/s.

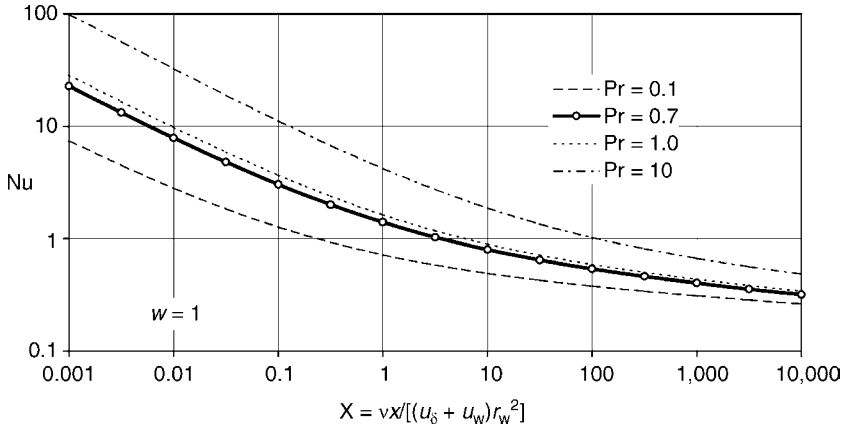
The sum of the velocities $u_s = u_\delta + u_w = 30$ m/s and the ratio $u_w/u_\delta = 0.5$.

The local Nusselt number at position $x = 0.55$ m is to be calculated.

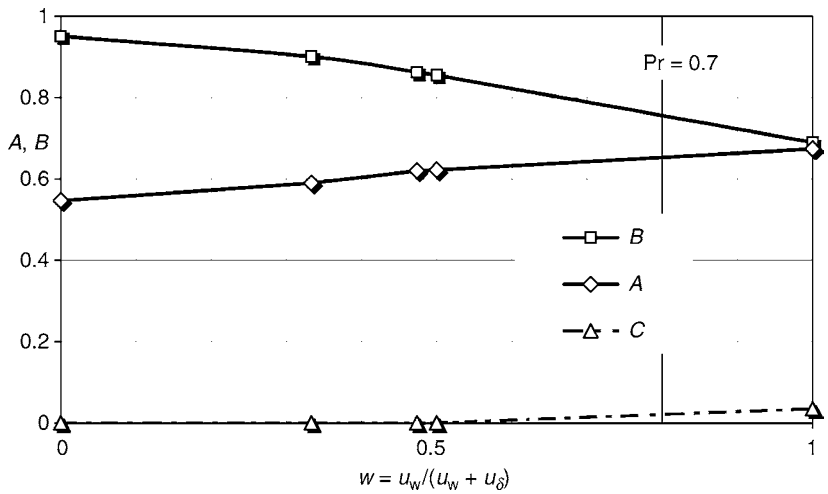
Assuming an air temperature of $T_\infty = 50°\mathrm{C}$, the kinematic viscosity, ν is found from Part D, to be $\nu = 18.2 \cdot 10^{-6} \mathrm{m^2/s}$.



G5. Fig. 4. Heat transfer at the circular cylinder in longitudinal flow. Local Nusselt number, Nu, versus the curvature parameter, X [Eq. (5)] for Pr = 0.7, parameter $w = u_w/(u_w + u_\delta)$, where u_w is the velocity of the moving cylinder and u_δ is the air velocity parallel to the axis of the cylinder.



G5. Fig. 5. Heat transfer at the continuously moving circular cylinder without forced air flow (case 1.3: $u_\delta = 0$, $w = 1$). Local Nusselt numbers, Nu, versus the curvature parameter, X [Eq. (6)] for different Prandtl numbers.



G5. Fig. 6. Heat transfer at the continuously moving circular cylinder in longitudinal air flow (Pr = 0.7). Values of the parameters A, B, and C to be used in Eqs. (10) and (11). The constants were recalculated from Gampert [3].

G5. Table 2. Heat transfer at infinite circular cylinder axially moving in a fluid at rest (case 1.3: w =1, Pr = 0.1, 0.7, 1.0, and 10)

Pr	A		B		C		Range
0.1	0.206	0.211*	0.415	0.395*	0.086	0.095*	$10^{-3} \le X \le 10^4$
0.7	0.674		0.690		0.035		$10^{-3} \le X \le 10^4$
1.0	0.857		0.732		0.040		$10^{-3} \le X \le 10^4$
10	3.075		1.135		0		$10^{-2} \le X \le 10^3$
$w = 1$	Local	Mean*	Local	Mean*	Local	Mean*	

*values of A, B, C to be used in Eq. (11)

From Eq. (6), the value of the curvature parameter, X, becomes

$$X = (18.2\,10^{-6}\,\mathrm{m^2/s} \cdot 0.55\,\mathrm{m})/(10^{-8}\,\mathrm{m^2} \cdot 190\,\mathrm{m/s}) = 5.268\ (\mathrm{Case\ 1})$$

$$X = (18.2\,10^{-6}\,\mathrm{m^2/s} \cdot 0.55\,\mathrm{m})/(10^{-8}\,\mathrm{m^2} \cdot 30\,\mathrm{m/s}) = 33.367\ (\mathrm{Case\ 2})$$

From Eq. (9) and Table 1 (for air: Pr = 0.7), one finds

$$\mathrm{Nu_d}\,(5.268,\ 0.9) = 1.00 \text{ for } (\mathrm{w} = 9/19)\ u_\mathrm{w}/u_\delta = 0.9, \text{ and}$$
$$\mathrm{Nu_d}\,(33.367,\ 0.5) = 0.74 \text{ for } (\mathrm{w} = 1/3)\ u_\mathrm{w}/u_\delta = 0.5.$$

In spite of the same relative velocity in both cases, the higher sum velocity and the higher ratio lead to a higher heat transfer coefficient. At a relative velocity of $u_\mathrm{r} = |u_\delta - u_\mathrm{w}| = 0\,\mathrm{m/s}$, and

the sum $u_s = u_\delta + u_w = 190\,\mathrm{m/s}$, the Nusselt number is very nearly the same as for Case 1 Nu (5.268, 1) = 0.995 for ($w = 1/2$) $u_w/u_\delta = 1$.

G6 Heat Transfer in Cross-flow Around Single Tubes, Wires, and Profiled Cylinders

Volker Gnielinski
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Average Nusselt Number

According to Krischer and Kast [1] the equations for determining the average Nusselt number in cross-flow over tubes, wires, and profiled cylinders are the same as those over a flat plate (Chap. G4) if the characteristic length used in the calculation of the Reynolds and Nusselt numbers is the "streamed length." This streamed length is the length of the entire path traversed by a particle in flowing over the surface presented to it by the body concerned. It is defined by Pasternak and Gauvin [2] as the total surface area A of the body divided by the maximum perimeter l_c perpendicular to the flow:

$$l = \frac{A}{l_c} \tag{1}$$

The streamed length is shown in Fig. 1. For a long tube of the diameter d and the length L according to Eq. (1), we get

$$l = \frac{\pi\, dL}{2L} = \frac{\pi}{2} d \tag{2}$$

The equation suggested by Gnielinski [3] for the average Nusselt number in cross-flow over tubes, wires, and profiled cylinders arranged as in standard engineering practice is

$$\mathrm{Nu}_{l,0} = 0.3 + \sqrt{\mathrm{Nu}_{l,\mathrm{lam}}^2 + \mathrm{Nu}_{l,\mathrm{turb}}^2} \tag{3}$$

where

$$\mathrm{Nu}_{l,\mathrm{lam}} = 0.664\sqrt{\mathrm{Re}_l}\,\sqrt[3]{\mathrm{Pr}} \tag{4}$$

and

$$\mathrm{Nu}_{l,\mathrm{turb}} = \frac{0.037\,\mathrm{Re}^{0.8}\,\mathrm{Pr}}{1 + 2.443\mathrm{Re}_l^{-0.1}\left(\mathrm{Pr}^{2/3} - 1\right)} \tag{5}$$

The minimum value of $\mathrm{Nu}_{l,0}$ in Eq. (3) results from the fact that, in practice, the length of a cylinder in cross-flow is always finite. Consequently, if the surrounding is at rest, the heat flux attains a minimum. The average Nusselt number for a cylinder thus asymptotically approaches a minimum, which is assumed to be $\mathrm{Nu}_{\min} \approx 0.3$ [3].

The relevant definitions are

$$\mathrm{Nu}_l = \alpha\, l/\lambda,$$

$$\mathrm{Re}_l = wl/\nu;\ 10 < \mathrm{Re}_l < 10^7$$

$$\mathrm{Pr} = 0.6 - 1000$$

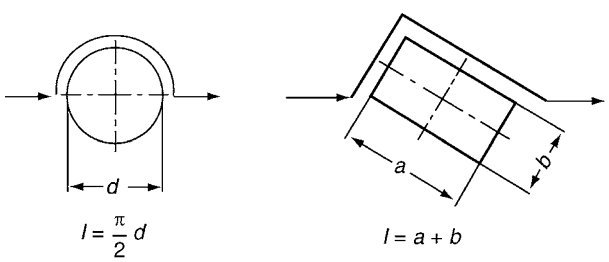
$T_m = (T_{in} + T_{out})/2$ is the mean fluid temperature to which the properties are referred.

Equation (3) is presented graphically for air (Pr = 0.7) and water at 20°C (Pr = 7) Fig. 2.

If the Reynolds number is low, for example, in cross-flow over thin wires, the relationship $\mathrm{Nu}_{\min} = 0.3$ cannot be used since the thickness of the boundary layer is not small when compared with the dimension of the object. However, the Nusselt number in this range can be determined from the Sucker and Brauer equation [4].

2 Cylinder in a Restricted Channel

It has been proved [3] that the Nusselt number for a cylinder in a narrow channel can also be determined from Eq. (3) if the velocity taken to calculate the Reynolds number is the integral mean value w along the surface of the cylinder. It is determined from the fluid velocity w_0 in the cross section of the empty channel, as is illustrated in Fig. 3, and the void fraction of the



G6. Fig. 1. Definition of the streamed length.

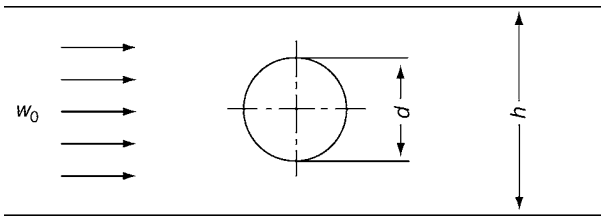
G6. Fig. 2. Course of Eq. (3) for air (Pr=0.7) and water at 20 °C (Pr=7).



G6. Fig. 3. Cylinder in a restricted channel.

flow channel over the length of the cylinder. Thus

$$w = w_0/\psi \tag{6}$$

if the height of the channel is h,

$$\psi = 1 - \frac{\pi d}{4h} \tag{7}$$

3 The Effect of Temperature-dependent Variations in Properties

The direction of heat flux (heating or cooling) affects heat transfer if the properties depend on temperature. A factor K is taken to allow for this [3], that is,

$$\mathrm{Nu}_l = \mathrm{Nu}_{l,0}\, K \tag{8}$$

For liquids, K is given by

$$K = K_\mathrm{F} = (\mathrm{Pr}/\mathrm{Pr}_\mathrm{w})^{0.25} \tag{9}$$

where Pr is the Prandtl number at T_m; and Pr_w, is that at the wall temperature at T_w.

For gases, K is given by

$$K = K_\mathrm{G} = (T_\mathrm{m}/T_\mathrm{w})^{0.12} \tag{10}$$

where T_m is the temperature of the gas, and T_w is the temperature of the wall, both in Kelvin.

4 Effect of an Inclined Flow to the Cylinder

Experiments by Vornehm [5] have shown that Nu_l decreases with the vertical angle between the direction of flow and the axis of the cylinder. The relationship is as follows:

ϕ	90°	80°	70°	60°	50°	40°	30°	20°
$\mathrm{Nu}_{l,\phi}/\mathrm{Nu}_l$	1.0	1.0	0.99	0.95	0.86	0.75	0.63	0.5

G7 Heat Transfer in Cross-flow Around Single Rows of Tubes and Through Tube Bundles

Volker Gnielinski
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Definition of the Heat Transfer Coefficient

The average coefficient of heat transfer α at the surface of a row of tubes and in a tube bundle is defined by

$$\dot{q} = \alpha \, \Delta T_{\mathrm{LM}}$$

The variable ΔT_{LM} is the logarithmic mean temperature difference and is given for a constant wall temperature boundary condition by

$$\Delta T_{\mathrm{LM}} = \frac{(T_{\mathrm{w}} - T_{\mathrm{in}}) - (T_{\mathrm{w}} - T_{\mathrm{out}})}{\ln (T_{\mathrm{w}} - T_{\mathrm{in}_{\mathrm{i}}})/(T_{\mathrm{w}} - T_{\mathrm{out}})},$$

where T_{in} and T_{out} are the inlet and outlet temperatures, respectively, of the flowing medium, and T_{w} is the wall temperature.

2 Determination of the Heat Transfer Coefficient for a Single Row of Tubes

The average Nusselt number for cross-flow over a single row of tubes can be calculated from Eq. (3) in Chap. G6 for the single tube, if the characteristic velocity in the Reynolds number in Eq. (3) is replaced by the average velocity in the void between the tubes in the row. The void fraction, which depends on the transverse pitch ratio $a = s_1/d_{\mathrm{o}}$ in the row, as is illustrated in Fig. 1, is given by

$$\psi = 1 - \frac{\pi}{4a} \tag{1}$$

Thus, the following applies for $\mathrm{Nu}_{\mathrm{O,row}}$ according to Chap. G6:

$$\mathrm{Nu}_{O,\mathrm{row}} = 0.3 + \sqrt{\mathrm{Nu}^2_{l,\mathrm{lam}} + \mathrm{Nu}^2_{l,\mathrm{turb}}} \tag{2}$$

where

$$\mathrm{Nu}_{l,\mathrm{lam}} = 0.664 \sqrt{\mathrm{Re}_{\psi,l}} \sqrt[3]{\mathrm{Pr}} \tag{3}$$

$$\mathrm{Nu}_{l,\mathrm{turb}} = \frac{0.037 \, \mathrm{Re}^{0.8}_{\psi,l} \, \mathrm{Pr}}{1 + 2.443 \mathrm{Re}^{-0.1}_{\psi,l} \, (\mathrm{Pr}^{2/3} - 1)} \tag{4}$$

$$\mathrm{Nu}_{0,\mathrm{row}} = \frac{\alpha \, l}{\lambda} \tag{5}$$

$$\mathrm{Re}_{\psi,l} = \frac{w \, l}{\psi \, \nu} \qquad 10 < \mathrm{Re}_{\psi,l} < 10^6 \tag{6}$$

$$\mathrm{Pr} = \frac{\nu}{a} \qquad 0.6 < \mathrm{Pr} < 10^3 \tag{7}$$

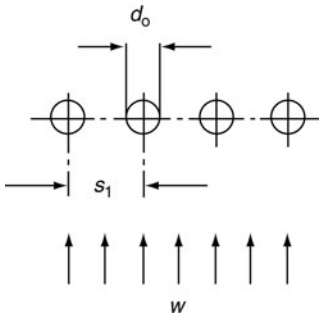
$l = (\pi/2) d_0$ is the streamed length, i.e., the length of the flow path traversed over a single tube (see Fig. 1 of Chap. G6), and w is the velocity of the flowing medium in the free cross section of the row. $T_{\mathrm{m}} = (T_{\mathrm{in}} + T_{\mathrm{out}})/2$ is the mean temperature at which the physical properties of the flowing medium are evaluated.

If the turbulence in the inflowing medium is low, e.g., if there is pronounced acceleration in the channel inlet or if diffusers have been installed to ensure steady flow, deviations in the Nusselt number of up to 40% may occur in the $10^4 < \mathrm{Re}_{\psi,l} < 10^6$ range, as has also been observed in a cross-flow over a single tube [1].

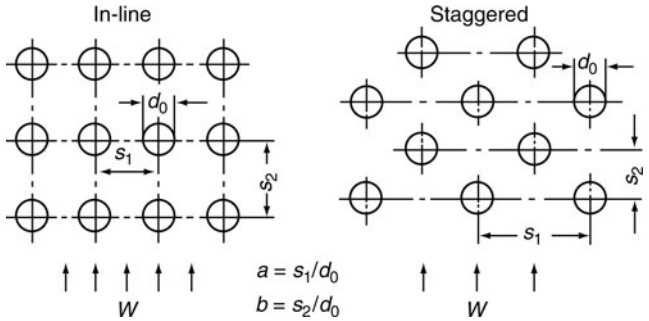
3 Determination of the Heat Transfer Coefficient in a Tube Bundle

The average Nusselt number in a cross-flow over a bundle of smooth tubes can be calculated from that in a cross-flow over a single tube [2]. However, if the flow velocity is the same in both cases, the Nusselt number for a tube in a bundle is higher than that for a single tube exposed to this velocity in free flow. The enhancement depends on the longitudinal pitch and the

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_29,



G7. Fig. 1. Lateral spacing in a row of tubes.



G7. Fig. 2. Lateral and longitudinal spacing in tube bundles.

transverse pitch of the bundle. The Nusselt number of the single tube in cross-flow can be determined from Eq. (3) in Chap. G6 if the Reynolds number is selected in the same way as that for an individual row of tubes, i.e., if the characteristic velocity for the flowing medium is the average in the void fraction of a row over a length corresponding to the tube diameter. The following applies in this case [2]:

$$\mathrm{Nu}_{0,\mathrm{bundle}} = f_\mathrm{A}\mathrm{Nu}_{l,0} \tag{8}$$

The void fraction and the arrangement factor f_A depend on the transverse pitch ratio $a = s_1/d_o$ and the longitudinal pitch ratio $b = s_2/d_o$ in the tube bundle.

The determination of a and b for various arrangements of the tube bundle is illustrated in Fig. 2. The void fraction is given by

$$\psi = 1 - \frac{\pi}{4\,a} \qquad \text{for } b \geq 1 \tag{9}$$

$$\psi = 1 - \frac{\pi}{4\,a\,b} \qquad \text{for } b < 1 \tag{10}$$

According to Eq. (3) in Chap. G6, $\mathrm{Nu}_{l,0}$ is given by

$$\mathrm{Nu}_{l,0} = 0.3 + \sqrt{\mathrm{Nu}^2_{l,\mathrm{lam}} + \mathrm{Nu}^2_{l,\mathrm{turb}}} \tag{11}$$

where

$$\mathrm{Nu}_{l,\mathrm{lam}} = 0.664\,\sqrt{\mathrm{Re}_{\psi,l}}\,\sqrt[3]{\mathrm{Pr}} \tag{12}$$

$$\mathrm{Nu}_{l,\mathrm{turb}} = \frac{0.037\;\mathrm{Re}^{0.8}_{\psi,l}\;\mathrm{Pr}}{1 + 2.443\;\mathrm{Re}^{-0.1}_{\psi,l}\;(\mathrm{Pr}^{2/3} - 1)} \tag{13}$$

$$\mathrm{Nu}_{0,\mathrm{bundle}} = \frac{\alpha\;l}{\lambda} \tag{14}$$

$$\mathrm{Re}_{\psi,l} = \frac{w\;l}{\psi\;\nu} \qquad 10 < \mathrm{Re}_{\psi,l} < 10^6 \tag{15}$$

$$\mathrm{Pr} = \frac{\nu}{a} \qquad 0.6 < \mathrm{Pr} < 10^3 \tag{16}$$

$l = (\pi/2)d_0$ is the streamed length of a single tube, w is the velocity of the flowing medium in the free cross section outside the bundle, and $T_\mathrm{m} = (T_\mathrm{i} + T_\mathrm{o})/2$ is the mean temperature of the flowing medium at which the physical properties are evaluated.

The factor f_A for in-line tube arrangement is given by

$$f_{\mathrm{A,in\text{-}line}} = 1 + \frac{0.7\;(b/a - 0.3)}{\psi^{1.5}(b/a + 0.7)^2}, \tag{17}$$

where ψ is given by Eq. (9).

Equation (17) was derived from experimental measurements with $b \geq 1.2$; the available measurements with $b < 1.2$ have a ratio $(b/a) \geq 1$.

Tube bundles with an in-line tube arrangement and a longitudinal pitch ratio $b < 1.2$ behave – according to the available data [1] for $\mathrm{Re}_{\psi,l} < 10^4$ – more like parallel channels, which are formed by the tube rows, with the tubes lying narrowly behind one another. An expected increase in the heat transfer coefficient due to the turbulence enhancement caused by the tube rows, which is expressed by Eq. (17), does not occur or is insignificant. Due to the lack of experimental data, no better information can be given.

The factor for the staggered tube arrangement is

$$f_{\mathrm{A,stag}} = 1 + \frac{2}{3\,b}. \tag{18}$$

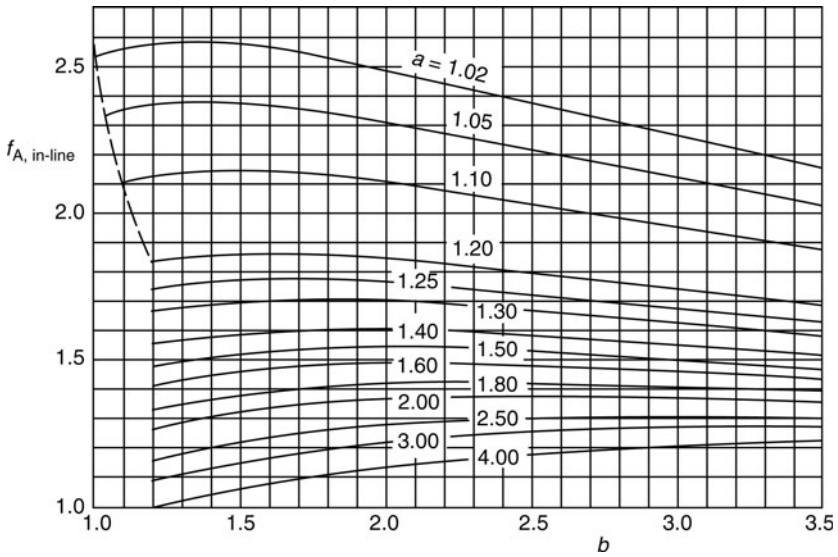
$f_{\mathrm{A,in\text{-}line}}$ is shown as a function of the transverse pitch ratio a and the longitudinal pitch ratio b in Fig. 3; and $f_{\mathrm{A,stag}}$ is shown as a function of the longitudinal pitch ratio b in Fig. 4.

An alternative calculation method, which does not need the empirical factors $f_{\mathrm{A,in\text{-}line}}$ and $f_{\mathrm{A,stag}}$ from Eqs. (17) and (18), respectively, for the enhancement of the heat transfer in a bundle, as compared to a single tube, was suggested, in 2000, by Martin and Gnielinski [3], and, in a slightly improved version, in 2002, by Martin [4]. This newer method, based on the so-called Lévêque analogy (see Martin [5]), allows to calculate heat (or mass) transfer coefficients from the frictional pressure drop. Shah and Sekulic [6] recommend this newer method [4] in their Fundamentals of Heat Exchanger Design of 2003.

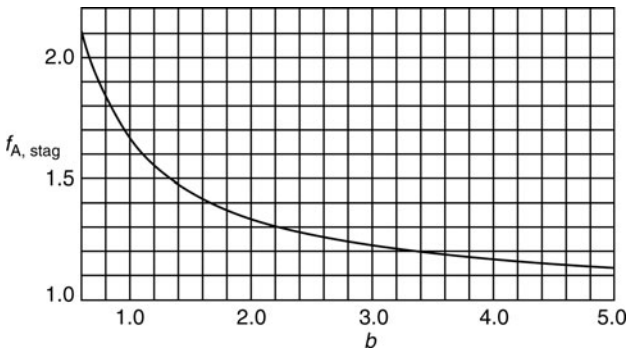
Here in Part G, the earlier empirical method is still presented in order to be consistent within all the Chaps. G6, G7, G8, and G9, which depend upon each other. The new method [4] may well be used for tube bundles in a pure cross-flow, but the application in the more complex configurations on the shell side of baffled shell-and-tube heat exchangers (Chap. G8) cannot be recommended at the present state of knowledge. A lot of additional testing and comparison will be needed before the newer method is used in the whole Part G.

4 Partly Staggered Tube Bundles

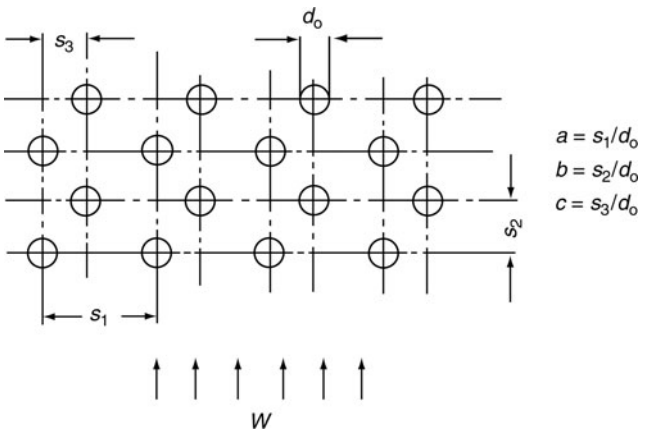
The pitch ratios a, b, and c in a partly staggered tube bundle are illustrated in Fig. 5. The average Nusselt number for these



G7. Fig. 3. Factor $f_{A,\text{in-line}}$ for tubes arranged in-line as a function of the lateral and longitudinal spacing ratios.



G7. Fig. 4. Factor $f_{A,\text{stag}}$ for staggered arrangements of tubes as a function of longitudinal spacing ratio.



G7. Fig. 5. Spacing ratios for partly staggered tube bundles.

arrangements can also be determined from Eq. (8) if those with pitch ratios $c < a/4$ are regarded as in-line; and those with $c \geq a/4$ as completely staggered. Thus,

$$f_{A,\text{part.stag}} = f_{A,\text{in-line}} \quad \text{for } c < a/4 \tag{19}$$

$$f_{A,\text{part.stag}} = f_{A,\text{stag}} \quad \text{for } c \geq a/4 \tag{20}$$

5 Effect of the Number of Rows

The value of the heat transfer coefficient measured for a tube row in a bundle depends on the number of preceding rows. It increases from the first row to about the fifth row and then remains constant. If the average Nusselt number has to be determined for bundles with ten or more rows, the effect of the first few rows needs no longer to be taken into consideration. In other words, Eq. (8) is valid for the Nusselt number in any row of a bundle with a large number of rows after the inlet effects have diminished and also for the average Nusselt number in a bundle of ten or more rows. If the number of rows is less then ten, the average Nusselt number can be approximately determined from

$$\text{Nu}_{0,\text{bundle}} = \frac{1 + (n-1)f_A}{n} \text{Nu}_{l,0} \tag{21}$$

where n is the number of rows.

6 Effect of Temperature-Dependent Variations in Properties

The direction of heat flux (heating or cooling) affects heat transfer. This can be taken into consideration by introducing a correction factor K as follows [2]:

$$\text{Nu}_{\text{row}} = \text{Nu}_{0,\text{row}}\, K \tag{22}$$

$$\text{Nu}_{\text{bundle}} = \text{Nu}_{0,\text{bundle}}\, K \tag{23}$$

The factor K for liquids with $\text{Pr}/\text{Pr}_W > 1$, i.e., liquid heating, is given by

$$K = K_L = (\text{Pr}/\text{Pr}_W)^{0.25} \tag{24}$$

where Pr is the Prandtl number for the liquid at T_m, and Pr_W is the Prandtl number at the wall temperature T_W.

If $\text{Pr}/\text{Pr}_W < 1$, i.e., liquid cooling, then

$$K = K_L = (\text{Pr}/\text{Pr}_W)^{0.11} \tag{25}$$

The effect of temperature-dependent property variations on heat transfer in gases can be described within certain limits by

$$K = K_G = (T_m/T_W)^n \tag{26}$$

where T_m is the mean gas temperature in Kelvin ($T_m = (T_m/^\circ C + 273.1\ K)$ and T_W the Kelvin temperature of the tube wall.) The index n in Eq. (26) depends on the gas.

There have been very few studies in which the T_m/T_W ratio has been systematically varied. A value of $n = 0$ has been reported for cooling of air in a cross-flow over a tube bundle [7]; and a value of $n = 0.12$ for the cooling of nitrogen in a cross-flow over a single cylinder [8].

7 Effect of Turbulence

The degree of turbulence affects the heat transfer coefficient in the first few rows of a tube bundle. It was found experimentally that the heat transfer coefficient in the first row increased by about 42% when the degree of turbulence in the air flowing through the tube bundle was increased (by installing coarse screens at inlet) from 0.008 (very smooth flow) to 0.25 [9].

The enhancement in the heat transfer coefficient decreased from one row to the other and became negligible after the fifth row. Significant improvements in heat transfer can thus be achieved by increasing artificially the degree of turbulence in front of the tube bundle; this leads, however, to an increase in the pressure drop. Therefore, it is applied only in bundles with a few number of rows.

8 Oblique Flow Over Tube Bundles

Several studies [10–12] have revealed that the coefficient of heat transfer in oblique flow over tube bundles can be determined if the effective velocity of the flowing medium is taken to be the component perpendicular to the axes of the tubes. In this case, Eq. (15) becomes $Re_{\psi,l} = (w \sin\theta)\, l/(\psi\, \nu)$, where θ is the angle between the direction of flow and the axes of the tubes. In transverse flow, $\theta = 90^\circ$ and $\sin\theta = 1$.

9 Example of a Calculation

Water flows through a tube bundle placed in a rectangular channel at a mass flow rate of $\dot{M} = 100$ kg/s and an inlet temperature of 20°C. The tube bundle has an in-line tube arrangement with a transverse pitch of 30 mm and a longitudinal pitch of 26 mm. The tube bundle has six rows; each row has ten tubes with an outside diameter of 20 mm and a tube length of 2 m. The distance between the axis of the outermost tubes of the bundle and the adjacent channel sides amounts to 15 mm. The channel cross section is thus 0.3 m wide and 2 m long. The tubes of the bundle are heated from inside; they have a wall temperature of 100°C.

It is required to calculate the water temperature at the outlet of the channel.

Because of the temperature dependence of the properties of the water, the problem can be solved only iteratively.

List of the given data:

$\dot{M} = 100$ kg/s	$n = 6$ rows of tubes
$T_{in} = 20^\circ C$	$d_O = 0.02$ m
$T_w = 100^\circ C$	$l = (\pi/2)0.02$ m
$L = 2$ m	$s_1 = 0.03$ m
$z = 10$ tubes/row	$s_2 = 0.026$ m

Calculation of the geometrical data:

$$a = s_1/d_o = 30/20 = 1.5;\ b = s_2/d_o = 26/20 = 1.3$$

Exchange area $A = \pi\, d_o\, z\, n\, L = 7.54\ m^2$;

Free cross section in front of the bundle: $S = z\, s_1\, L = 10 \cdot 0.03 \cdot 2 = 0.6\ m^2$,

$$\psi = 1 - \frac{\pi}{4 \cdot 1.5} = 0.4764 \text{ (Eq. (9))}$$

Factor for the arrangement of the tubes: in-line tubes

$$f_{A,\text{in-line}} = 1 + \frac{0.7\ (1.3/1.5 - 0.3)}{0.4764^{1.5}(1.3/1.5 + 0.7)^2} = 1.491$$

The physical properties are taken from Subchap. D2.1.

Steps of interation for the example are given in Table 1.

G7. Table 1. Steps of iteration for the example of a calculation

Step of iteration	1. Step	2. Step	3. Step
$T_{in}/^\circ C$	20	20	20
$T_{out}/^\circ C$	90	30	29.6
$T_m = (T_{in} + T_{out})/2$	55	25	24.8
$\nu(T_m)/10^{-6}\, m^2/s$	0.512	0.893	0.897
$\lambda(T_m)/W/(mK)$	0.6492	0.6072	0.6068
$\rho(T_m)/kg/m^3$	985.69	997.05	997.09
$c_p(T_m)/J/(kg\,K)$	4,182	4,179	4,179
$Pr(T_m)$	3.248	6.128	6.163
Pr_w	1.757	1.757	1.757
$w = \dot{M}/(\rho(T_m) \cdot S/m/s)$	0.169	0.167	0.167
Eq. (15): $Re_{\psi,l} = w\, l/(\psi\, \nu(T_m))$	21,767	12,332	12,277
Eq. (12): $Nu_{l,lam} = 0.664(Re_{\psi,l})^{1/2}\, Pr\,(T_m)^{1/3}$	145.1	134.9	134.9

G7. Table 1. (continued)

Step of iteration	1. Step	2. Step	3. Step
Equation (13): $Nu_{l,turb} = \frac{0.037 Re_{\psi,l}^{0.8} Pr(T_m)}{1+2.443 Re_{\psi,l}^{-0.1} (Pr(T_m)^{2/3}-1)}$	171.1	131.3	131.0
Equation (11): $Nu_{l,0} = 0.3 + (Nu_{l,lam}^2 + Nu_{L,turb}^2)^{1/2}$	224.6	188.5	188.3
Equation (21): $Nu_{0,bundle} = \frac{1+(n-1)f_{A,in-line}}{n} Nu_{l,o}$	316.5	265.6	265.3
Equation (23): $Nu_{bundle} = Nu_{0,bundle}(Pr(T_m)/Pr_w)^{0.25}$	369.1	363.0	363.1
$\alpha = Nu_{bundle}\, \lambda(T_m)/l/W/(m^2K)$	6015.4	7016.0	7013.3
$\Delta T_{LM} = \frac{(T_w-T_{in})-(T_w-T_{out})}{\ln T_w-T_{in_i}/T_w-T_{out}}$	33.66 K	74.89 K	75.10 K
$\dot{Q} = \alpha\, A\, \Delta T_{LM}/W$	1,526,686.9	3,961,728.9	3,971,309.2
$T_{out} = \frac{\dot{Q}}{\dot{M} c_p(T_m)} + T_{in}$	23.7°C	29.5°C	29.5°C

The physical properties of the water do not change at a mean temperature of $T_m = (20 + 29.5)/2 = 24.75°C$ compared with 24.8°C. Therefore, no additional step of iteration is necessary. The temperature of the water at the exit is 29.5°C.

G8 Shell-Side Heat Transfer in Baffled Shell-and-Tube Heat Exchangers

Edward S. Gaddis[1] · *Volker Gnielinski*[2]
[1]Technische Universität Clausthal, Clausthal-Zellerfeld, Germany
[2]Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Introduction

The method described in this chapter for calculating the mean heat transfer coefficient on the shell-side of a baffled shell-and-tube heat exchanger is based on the corresponding method for calculating the mean heat transfer coefficient in a tube bundle with a cross flow. However, the flow configuration on the shell-side of a baffled shell-and-tube heat exchanger leads to a number of deviations from the case of a flow across a tube bundle. The geometry of the baffles in the heat exchanger shell – as shown in Fig. 1 – generates a main stream through the heat exchanger tube bundle, which is partly across and partly parallel to the tubes. Unavoidable clearances between the outer surface of the tubes and the holes in the heat exchanger baffles, as well as between the baffles and the inside shell surface lead to leakage streams, which participate in heat transfer, but not to the same extent as the main stream. Since the tubes in the tube bundle cannot be brought uniformly and very close to the shell, bypass streams occur in the gaps between the outer tubes of the bundle and the inside surface of the heat exchanger shell; such bypass streams do not participate effectively in heat transfer. These geometrical factors dictated by the design of a shell-and-tube heat exchanger lead to deviations between the heat transfer in a tube bundle and that on the shell-side of a baffled heat exchanger; they can be taken into account by means of correction factors. The correction factors described hereafter are based on data given by Bell [1]. The presented method of calculation was checked by Gnielinski and Gaddis [2] through a large number of experimental measurements available in the open literature.

2 Required Geometrical Data

The following geometrical parameters are required for the calculation of the mean shell-side heat transfer coefficient:

D_i	Shell inside diameter
D_1	Baffle diameter
D_B	Tube bundle diameter
d_o	Outer diameter of tubes
d_B	Diameter of holes in baffles
H	Height of baffle cut
L_E	Sum of the shortest connections e and e_1 (see Fig. 3, $L_E = 2e_1 + \Sigma e$)
n_T	Total number of tubes in heat exchanger including blind and support tubes
n_W	Number of tubes in both upper and lower windows (baffle cuts)
n_S	Number of pairs of sealing strips
n_{MR}	Number of main resistances in cross flow between adjacent baffles (needed only if $n_S \neq 0$, see Fig. 6 for the determination of n_{MR})
S	Baffle spacing (assumed constant, otherwise see Sect. 4.4)
s_1	Transverse pitch
s_2	Longitudinal pitch

Tube arrangement: in-line or staggered.

3 Mean Shell-Side Heat Transfer Coefficient

3.1 Definition of Mean Shell-Side Heat Transfer Coefficient

Heat transfer between the shell-side flow and the outer surface of the tubes of a tube bundle in a baffled shell-and-tube heat exchanger is given by

$$\dot{Q} = \alpha A \Delta T_{LM}. \tag{1}$$

ΔT_{LM} in Eq. (1) is the logarithmic mean temperature difference. For a constant wall temperature boundary condition, the logarithmic mean temperature difference is calculated from the fluid inlet temperature T_{in}, the fluid outlet temperature T_{out}, and the wall temperature T_w by

$$\Delta T_{LM} = \frac{(T_{in} - T_w) - (T_{out} - T_w)}{\ln\left(\frac{T_{in} - T_w}{T_{out} - T_w}\right)} = \frac{T_{in} - T_{out}}{\ln\left(\frac{T_{in} - T_w}{T_{out} - T_w}\right)}. \tag{2}$$

Equations (1) and (2) define the mean shell-side heat transfer coefficient α.

3.2 Determination of Mean Shell-Side Heat Transfer Coefficient

The mean shell-side heat transfer coefficient α is calculated from dimensionless correlations determined experimentally. The dimensionless number that comprises the mean shell-side heat transfer coefficient is the mean shell-side Nusselt number defined by

$$Nu_{shell} = \frac{\alpha l}{\lambda}. \tag{3}$$

The characteristic length l in the mean shell-side Nusselt number in Eq. (3) is the length of a stream line over the tube surface (half tube circumference) and is given by

$$l = \frac{\pi}{2} d_o. \tag{4}$$

Equations for calculating the mean shell-side Nusselt number are presented hereafter. The mean shell-side heat transfer coefficient is thus calculated from

$$\alpha = \frac{Nu_{shell} \lambda}{l}. \tag{5}$$

4 Mean Shell-Side Nusselt Number

The mean shell-side Nusselt number Nu_{shell} of a baffled shell-and-tube heat exchanger can be calculated from the mean Nusselt number Nu_{bundle} of a tube bundle with a cross flow; its numerical value differs from that of the tube bundle because of the flow configuration on the shell-side. To allow for the deviations caused by this flow configuration, a correction factor f_W is introduced as follows:

$$Nu_{shell} = f_W Nu_{bundle}. \tag{6}$$

A procedure for calculating Nu_{bundle} is given hereafter (see also Chap. G7). Equations for calculating the correction factor f_W are presented in Sect. 4.3.3.

4.1 Mean Nusselt Number of a Tube Bundle

The mean Nusselt number Nu_{bundle} of a tube bundle under real operating conditions can be calculated from the mean Nusselt

number $Nu_{0,bundle}$ of an ideal tube bundle by introducing correction factors as follows:

$$Nu_{bundle} = f_N f_P Nu_{0,bundle}. \quad (7)$$

The correction factor f_N takes into consideration the influence of the number of tube rows in the tube bundle and the correction factor f_P the influence of the change in the physical properties of the fluid in the thermal boundary layer near the tube surface due to temperature changes during heating or cooling. A procedure for calculating $Nu_{0,bundle}$ is given hereafter. Equations for calculating f_N and f_P are given in Sects. 4.3.1 and 4.3.2 respectively.

4.2 Mean Nusselt Number of an Ideal Tube Bundle

An ideal tube bundle is defined arbitrarily as follows: Number of tube rows is $n_R \geq 10$, number of tubes per row is ≥ 10, ratio of tube length to tube diameter is ≥ 10, physical properties of fluid is independent of temperature, fluid velocity in the free cross section at the inlet of the tube bundle is uniform and perpendicular to the free cross section and smooth tube surface. Large deviations from the idealized situation can be accounted for by introducing correction factors. The Nusselt number $Nu_{0,bundle}$ of an ideal tube bundle is based on the procedure given in Chap. G7 and is calculated from

$$Nu_{0,bundle} = f_A Nu_{l,0} \quad (8)$$

with

$$Nu_{l,0} = 0.3 + \sqrt{Nu_{l,lam}^2 + Nu_{l,turb}^2}, \quad (9)$$

where

$$Nu_{l,lam} = 0.664 \sqrt{Re_{\psi,l}} \sqrt[3]{Pr} \quad (10)$$

and

$$Nu_{l,turb} = \frac{0.037 Re_{\psi,l}^{0.8} Pr}{1 + 2.443 Re_{\psi,l}^{-0.1} \left(Pr^{2/3} - 1\right)} \quad (11)$$

with

$$Re_{\psi,l} = \frac{wl}{\psi \nu} \quad \text{(Reynolds number)} \quad (12)$$

and

$$Pr = \frac{\nu}{a} \quad \text{(Prandtl number)}. \quad (13)$$

The characteristic length l in the Reynolds number in Eq. (12) is defined by Eq. (4) and the characteristic velocity w is given by

$$w = \frac{\dot{V}}{A_f}. \quad (14)$$

The cross sectional area A_f required to calculate the characteristic velocity w from the fluid flow rate $\dot{V}$ is calculated from

$$A_f = D_i S. \quad (15)$$

S is the baffle spacing assumed constant in all heat exchanger channels; if the baffle spacing of the end channels differs from that of the central channels see Sect. 4.4. According to Chap. G7, the void fraction ψ in Eq. (12) is a function of the transverse pitch ratio $a = s_1/d_o$ and the longitudinal pitch ratio $b = s_2/d_o$ and is given by

$$\psi = 1 - \frac{\pi}{4a} \quad \text{for } b \geq 1 \quad (16)$$

and

$$\psi = 1 - \frac{\pi}{4ab} \quad \text{for } b < 1 \quad (17)$$

The tube arrangement factor f_A in Eq. (8) is calculated from the following equations:
For in-line tube arrangement:

$$f_A = 1 + \frac{0.7((b/a) - 0.3)}{\psi^{1.5}((b/a) + 0.7)^2}. \quad (18)$$

For staggered tube arrangement:

$$f_A = 1 + \frac{2}{3b}. \quad (19)$$

The factor f_A for in-line and for staggered tube arrangements in dependence on a and b or on b respectively can also be evaluated from diagrams presented in Chap. G7. The ranges of the pitch ratios, which were examined for developing the above equations, are given in Chap. G7.

4.3 Correction Factors

Equations for evaluating the correction factors f_N, f_P, and f_W are given hereafter.

4.3.1 Correction Factor for Number of Tube Rows

A tube bundle in a cross flow with a number of tube rows n_R<10 has a mean Nusselt number, which differs from that for a tube bundle with $n_R \geq 10$. This is due to the fact that the fluid flow and the level of turbulence are not yet fully developed in the first few rows of the tube bundle. Equations for calculating the correction factor f_N in dependence on the number of tube rows are given in Chap. G7. However, the flow structure in the first few rows in a tube bundle between adjacent segmental baffles in a shell-and-tube heat exchanger with a large number of segmental baffles – because of the frequent change in the flow direction – differs from that in a tube bundle with a cross flow. For that reason, the correction factor f_N is ignored. Thus, in Eq. (7)

$$f_N = 1 \quad (20)$$

is substituted irrespective of the number of tube rows in the tube bundle.

4.3.2 Correction Factor for Temperature Dependence of Physical Properties

Heating or cooling the fluid through the tube bundle influences the fluid temperature in the thermal boundary layer near the

surface of the tubes. To account for the change in the physical properties of the fluid in that layer due to change of temperature a correction factor f_P is introduced as follows:
For heating of liquids $[(\mathrm{Pr}/\mathrm{Pr}_w) > 1]$:

$$f_P = \left(\frac{\mathrm{Pr}}{\mathrm{Pr}_w}\right)^{0.25}. \tag{21}$$

For cooling of liquids $[(\mathrm{Pr}/\mathrm{Pr}_w) < 1]$:

$$f_P = \left(\frac{\mathrm{Pr}}{\mathrm{Pr}_w}\right)^{0.11}. \tag{22}$$

For gases approximately:

$$f_P = \left(\frac{T_m}{T_w}\right)^{n_P}. \tag{23}$$

The exponent n_P in Eq. (23) depends on the type of gas used; very limited data about n_P are available in the literature ($n_P \approx 0$ for cooling of air and ≈ 0.12 for cooling of nitrogen; see Chap. G7).

To account for the change of the fluid temperature in the flow direction, the physical properties in the presented equations are to be evaluated at the mean fluid temperature T_m given by

$$T_m = \frac{T_{in} + T_{out}}{2}. \tag{24}$$

4.3.3 Correction Factor for Shell-Side Flow Configuration

The correction factor f_W for the shell-side flow configuration is formed as a multiplication of the geometry correction factor f_G, the leakage correction factor f_L, and the bypass correction factor f_B, or

$$f_W = f_G f_L f_B. \tag{25}$$

Equations for evaluating the correction factors f_G, f_L, and f_B are given hereafter.

Geometry Correction Factor

The geometry correction factor f_G takes in consideration the deviation of the mean Nusselt number for a baffled shell-and-tube heat exchanger from that of a real tube bundle described in Sect. 4.1. This deviation is due to the specific shell-side flow, which is partly across the tube bundle in the space between adjacent baffles and partly parallel to the tubes in the upper and lower windows (baffle cuts) of the heat exchanger. According to K. J. Bell, V. Gnielinski and E. S. Gaddis [1, 2], f_G can be calculated from

$$f_G = 1 - R_G + 0.524 R_G^{0.32}, \tag{26}$$

where

$$R_G = \frac{n_W}{n_T}. \tag{27}$$

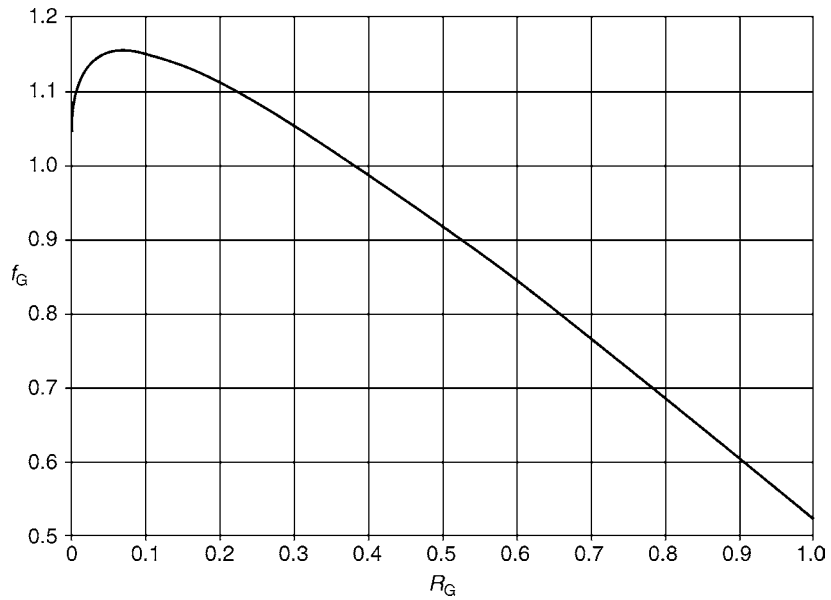
In Eq. (27), n_W is the number of tubes in both upper and lower windows; tubes that lie on the edges of the baffles and are thus partly in the cross flow between the baffles and partly in the parallel flow in the windows count as half tubes. n_T is the total number of tubes in the heat exchanger. Figure 2 may be used to calculate the geometry correction factor f_G.

Leakage Correction Factor

The leakage correction factor f_L is calculated from

$$f_L = 0.4\frac{A_{GTB}}{A_{SG}} + \left(1 - 0.4\frac{A_{GTB}}{A_{SG}}\right)\exp(-1.5R_L), \tag{28}$$

where A_{SG} is the sum of the areas of all gaps between the tubes and the holes in a baffle and between the shell and a baffle, or



G8. Fig. 2. Geometry correction factor f_G as a function of the parameter R_G.

$$A_{SG} = A_{GTB} + A_{GSB}. \tag{29}$$

The area A_{GTB} of all gaps between the tubes and the holes in a baffle is given by

$$A_{GTB} = \left(n_T - \frac{n_W}{2}\right)\frac{\pi\left(d_B^2 - d_o^2\right)}{4} \tag{30}$$

and the area A_{GSB} of the gap between the shell and a baffle is given by

$$A_{GSB} = \frac{\pi}{4}\left(D_i^2 - D_1^2\right)\frac{360 - \gamma}{360}, \tag{31}$$

where γ is the central angle of a baffle cut (see Fig. 9) measured in degrees and is given by

$$\gamma = 2\cos^{-1}\left(1 - \frac{2H}{D_1}\right). \tag{32}$$

The ratio R_L is calculated from

$$R_L = \frac{A_{SG}}{A_E}, \tag{33}$$

where A_E is the area for the cross flow between two baffles measured in the row of tubes on or near the diameter of the shell that is parallel to the edge of the windows, or

$$A_E = SL_E. \tag{34}$$

L_E is the sum of the shortest connections e between adjacent tubes and e_1 between the outermost tubes in the bundle and the shell, measured in the row of tubes on or near the diameter of the shell that is parallel to the edge of the windows ($L_E = 2e_1 + \Sigma e$). Figure 3 illustrates the meaning of L_E, e and e_1; equations for the calculation of e for different tube bundle geometries are also given in the figure. The baffle spacing S is assumed constant, otherwise see Sect. 4.4. While the leakage streams that flow through the gaps between the tubes and the holes in the baffles contribute to heat transfer, the leakage streams that flow through the gaps between the shell and the baffles do not participate in heat transfer; therefore the gap area A_{GSB} should be kept as small as possible. Figure 4 may be used to calculate the leakage correction factor f_L.

Bypass Correction Factor

Bypass streams between the inner surface of the shell and the outermost tubes of the tube bundle do not participate effectively to heat transfer. Sealing strips – as shown in Fig. 5 – can be fixed in the tube bundle to reduce the level of bypass streams. This is particularly important in shell-and-tube heat exchangers with floating-heads, where the gaps responsible for the bypass streams are relatively large. The bypass correction factor f_B is given by

$$f_B = \exp\left[-\beta R_B\left(1 - \sqrt[3]{\frac{2n_S}{n_{MR}}}\right)\right] \quad \text{for } n_S \le \frac{n_{MR}}{2} \tag{35}$$

and

$$f_B = 1 \quad \text{for } n_S > \frac{n_{MR}}{2}, \tag{36}$$

where

$$\beta = 1.5 \text{ for laminar flow } (\mathrm{Re}_{\psi,1} < 100)$$

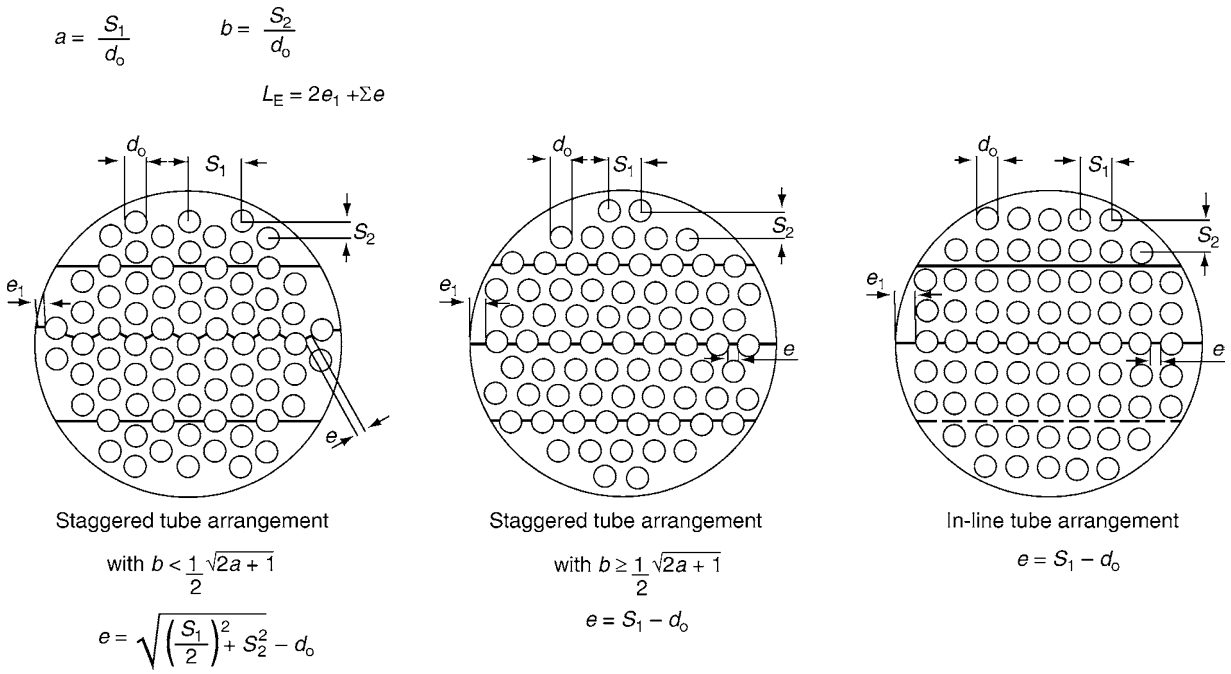
and

$$\beta = 1.35 \text{ for transition region and turbulent flow } (\mathrm{Re}_{\psi,1} \ge 100)$$

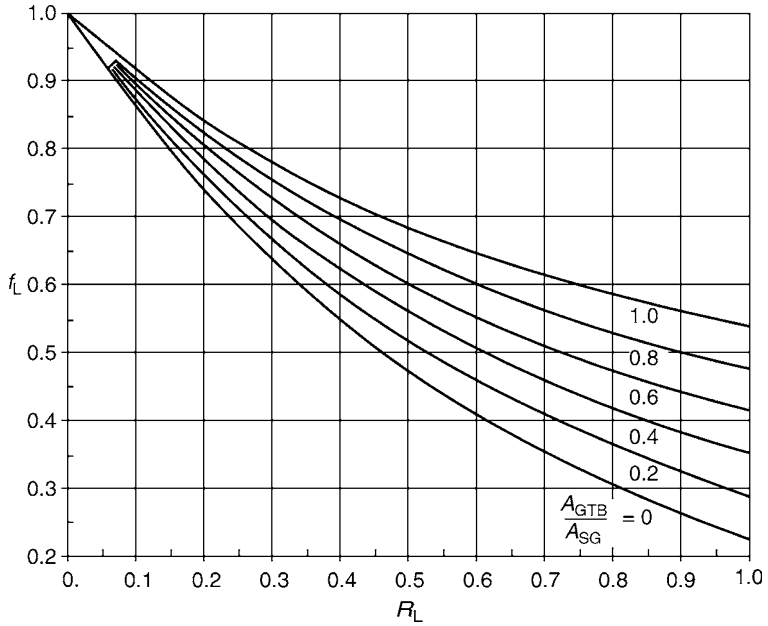
The ratio R_B is given by

$$R_B = \frac{A_B}{A_E}. \tag{37}$$

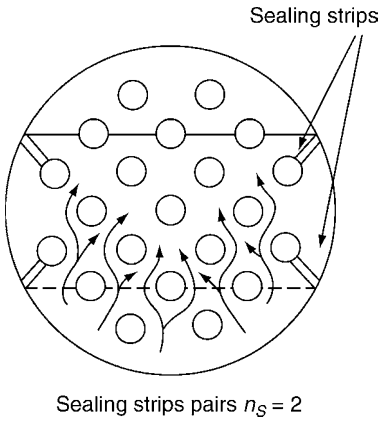
In Eq. (35), n_S is the number of pairs of sealing strips (in Fig. 5, $n_S = 2$) and n_{MR} is the number of main resistances in cross flow and thus the number of the shortest connections, which the flow



G8. Fig. 3. Illustration of the shortest connection L_E.



G8. Fig. 4. Leakage correction factor f_L as a function of R_L with the ratio A_{GTB}/A_{SG} as a parameter.



G8. Fig. 5. Reduction of bypass streams by means of sealing strips.

crosses on its way between the upper and the lower edges of adjacent baffles. Figure 6 illustrates the determination of n_{MR}. The area A_E in Eq. (37) is calculated from Eq. (34) and the area A_B is the cross sectional area that is responsible for the bypass streams and is given by

$$A_B = S(D_i - D_B - e) \text{ for } e < (D_i - D_B) \tag{38}$$

and

$$A_B = 0 \text{ for } e \geq (D_i - D_B). \tag{39}$$

The tube bundle diameter D_B is the diameter of a circle, which touches the outermost tubes in the space between the upper and lower edges of adjacent baffles (see Fig. 9). Figure 7 may be used to calculate the bypass correction factor f_B.

4.4 End Effects in Baffled Shell-and-Tube Heat Exchangers

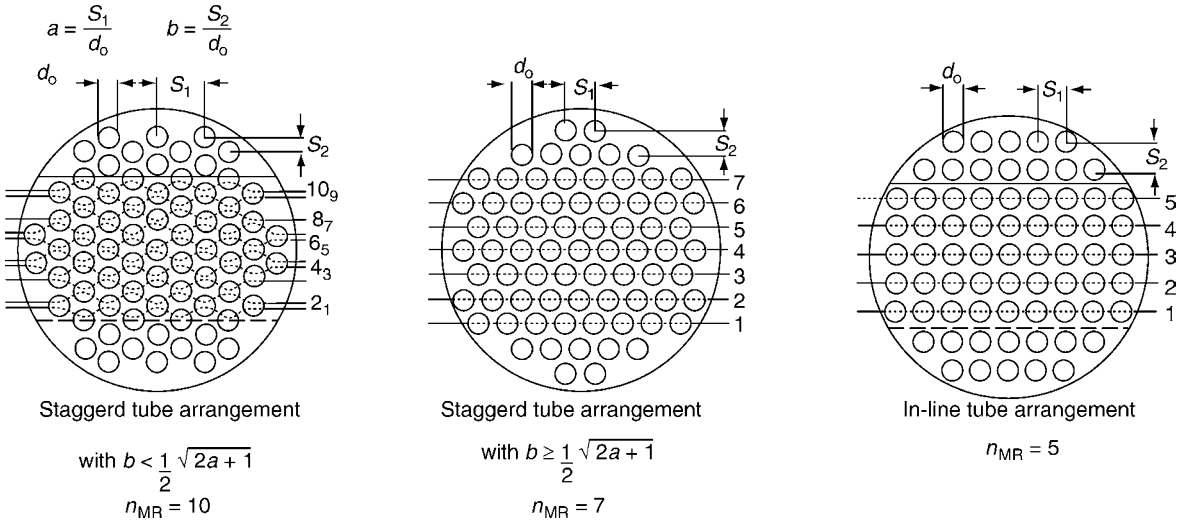
In many cases, the dimensions of the heat exchanger nozzles necessitate larger inlet and outlet baffle spacing (spacing between heat exchanger sheets and first or last baffle) compared with the central baffle spacing. This leads to a different mean heat transfer coefficient in the end channels (inlet and outlet channels) compared with the central channels. The mean heat transfer coefficient α_E in the end channels and the mean heat transfer coefficient α_C in the central channels can be calculated separately from the previous equations using the baffle spacing S_E for the end channels and the baffle spacing S_C for the central channels. The mean heat transfer coefficient α for the whole heat exchanger can be calculated from

$$\alpha = \frac{2S_E\alpha_E + (L - 2S_E)\alpha_C}{L}, \tag{40}$$

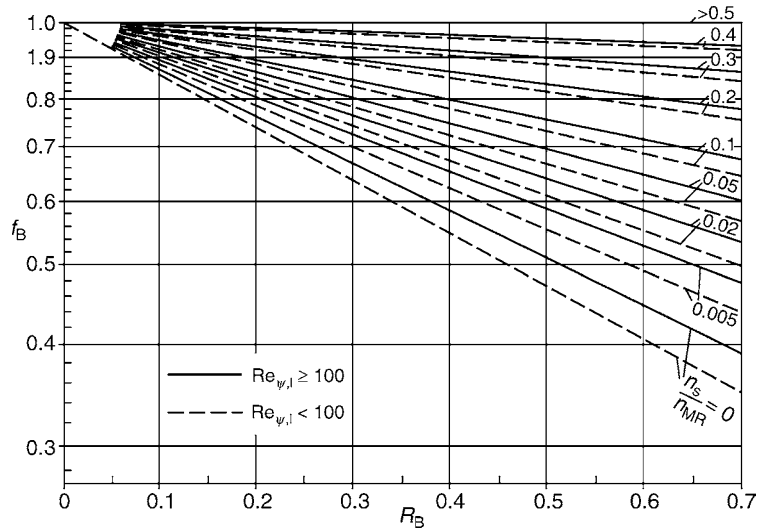
where L is the total tube length. Other factors that influence the mean heat transfer coefficient in end channels are

- Velocity distribution at inlet of inlet channel and outlet of outlet channel dictated by the construction of the nozzles particularly the inlet nozzle
- Absence of parallel flow at inlet of inlet channel and at outlet of outlet channel
- Absence of leakage streams through the heat exchanger sheets

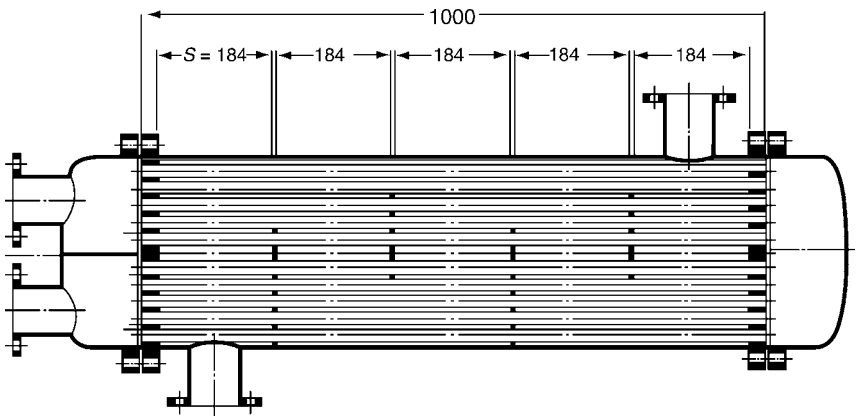
However, these deviations are relatively small in a baffled shell-and-tube heat exchanger with a large number of baffles ($L \gg 2S_E$).



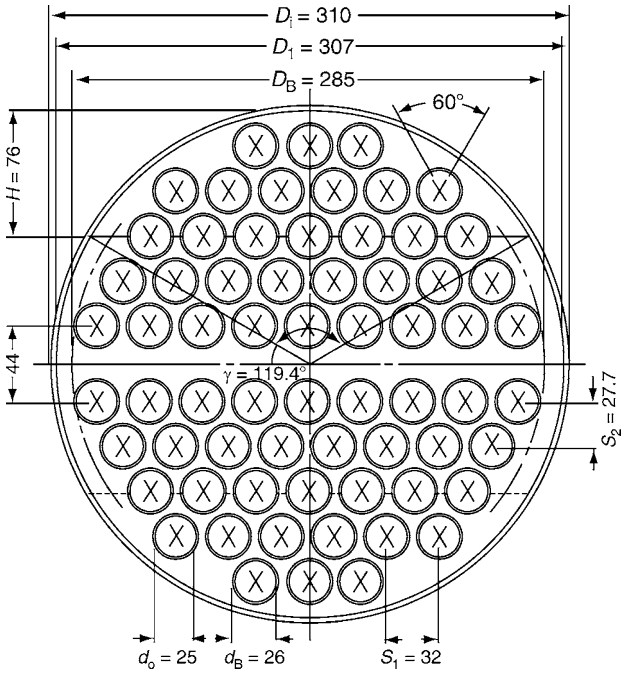
G8. Fig. 6. Determination of the number on main resistances n_{MR} in cross flow.



G8. Fig. 7. Bypass correction factor f_B in dependence on R_B and the ratio n_S/n_{MR}.



G8. Fig. 8. Longitudinal section of the heat exchanger in the example (dimensions in mm).



G8. Fig. 9. Cross-section of the heat exchanger in the example (dimensions in mm).

4.5 Limitations of the Proposed Calculation Procedure

A large number of experimental measurements obtained from shell-and-tube heat exchangers with segmental baffles and different geometries are available in the literature and were considered to check the calculation procedure presented in this chapter. The tested heat exchangers had staggered tube arrangement with different transverse and longitudinal pitch ratios as follows:

- Staggered square: with a pitch ratio $t/d_o = 1.2$, corresponding to a transverse pitch ratio $a = 1.697$ and a longitudinal pitch ratio $b = 0.849$
- Equilateral triangle: with pitch ratios in the range $1.2 \leq (t/d_o) \leq 2.2$ corresponding to transverse pitch ratios in the range $1.2 \leq a \leq 2.2$ and longitudinal pitch ratios in the range $1.039 \leq b \leq 1.905$, the ratio(b/a) is constant and is equal to 0.866

Measurements with in-line tube arrangement were not available.

The experimental measurements were made with different flow rates, different physical properties and during heating or cooling the shell-side fluid; the fluids used were water and oil with different viscosities. Measurements with gases were not available. The operating conditions during the experiments covered the following ranges:

- Reynolds number: $10 < \mathrm{Re}_{\psi,1} < 10^5$
- Prandtl number: $3 < \mathrm{Pr} < 10^3$

Measurements obtained at low Reynolds numbers ($\mathrm{Re}_{\psi,1} < 10^2$) with a high Prandtl number ($\mathrm{Pr} \approx 10^3$) showed high deviations between experimental measurements and theoretical predictions. In this range of operation, as well as with gases, care must be taken (i.e., higher factors of safety).

The above procedure of calculation is valid for heat exchangers with geometrical parameters that lie within the following ranges:

$$R_G \leq 0.8$$
$$R_L \leq 0.8$$
$$R_B \leq 0.5$$
$$0.2 \leq S/D_i \leq 1$$

Heat exchangers with geometrical ratios outside the above ranges, led to high deviations between experimental measurements and theoretical predictions. Also, heat exchanger geometries leading simultaneously to small numerical values of the correction factors f_G, f_L and f_B (i.e., a very small numerical value for f_W from Eq. (25)) showed high deviations. Thus, in addition to the above limitations, the calculation procedure should be used only for heat exchangers that have a correction factor for the shell-side flow configuration f_W, which lies within the following range:

$$f_W \geq 0.3.$$

5 Example

The shell-and-tube heat exchanger shown in Figs. 8 and 9 has two tube passes and four baffles with equal baffle spacing. Water with a volumetric flow rate of $\dot{V} = 20\ \mathrm{m^3\ h^{-1}}$ is cooled in the shell-side from an inlet temperature $T_{in} = 63.3\ ^\circ\mathrm{C}$ to an outlet temperature $T_{out} = 56.7\ ^\circ\mathrm{C}$. The wall temperature of the tubes is constant at $T_w = 50\ ^\circ\mathrm{C}$. The heat exchanger has the following geometrical data:

Shell inside diameter	$D_i = 310$ mm
Baffle diameter	$D_1 = 307$ mm
Tube bundle diameter	$D_B = 285$ mm
Outer diameter of tubes	$d_o = 25$ mm
Hole diameter in baffles to accommodate the tubes	$d_B = 26$ mm
Baffle cut	$H = 76$ mm
Total number of tubes	$n_T = 66$
Number of tubes in upper and lower windows	$n_W = 25$
(Tubes that lie on the edges of the baffles count as half tubes)	
Number of pairs of sealing strips	$n_S = 0$
Baffle spacing	$S = 184$ mm
Transverse pitch	$s_1 = 32$ mm
Longitudinal pitch	$s_2 = 27.7$ mm

Tube arrangement: staggered

Other dimensions are given in Figs. 8 and 9. It is required to calculate the mean shell-side heat transfer coefficient.

Solution:

Mean water temperature:

Equation (24): $T_m = \frac{T_{in}+T_{out}}{2} = \frac{63.3+56.7}{2} = 60\ ^\circ\mathrm{C}$

Physical properties of water:

At mean temperature $T_m = 60\ ^\circ\mathrm{C}$:

Kinematic viscosity $\nu = 0.471 \times 10^{-6}\ \mathrm{m^2\ s^{-1}}$

Thermal conductivity $\lambda = 654 \times 10^{-3}\ \mathrm{W\ m^{-1}\ K^{-1}}$

Prandtl number $\mathrm{Pr} = 2.96$

At wall temperature $T_w = 50\ ^\circ C$:

Prandtl number $Pr_w = 3.54$

Calculation of the mean Nusselt number $Nu_{0,bundle}$ for an ideal tube bundle:

$$a = \frac{s_1}{d_o} = \frac{32}{25} = 1.28$$

$$b = \frac{s_2}{d_o} = \frac{27.7}{25} = 1.11$$

Equation (16): $\psi = 1 - \frac{\pi}{4a} = 1 - \frac{\pi}{4\times 1.28} = 0.386$ (since $b > 1$)

Equation (4): $l = \frac{\pi}{2} d_o = \frac{\pi}{2} \times (25 \times 10^{-3}) = 0.03927$ m

Equation (15): $A_f = D_i S = (310 \times 10^{-3}) \times (184 \times 10^{-3}) = 0.05704\ m^2$

Equation (14): $w = \frac{\dot{V}}{A_f} = \frac{(20/3600)}{0.05704} = 0.0974\ m\ s^{-1}$

Equation (12): $Re_{\psi,l} = \frac{wl}{\psi\nu} = \frac{0.0974 \times 0.03927}{0.386 \times (0.471 \times 10^{-6})} = 21038$

Equation (10): $Nu_{l,lam} = 0.664\sqrt{Re_{\psi,l}}\sqrt[3]{Pr} = 0.664\sqrt{21038}\sqrt[3]{2.96} = 138.3$

Equation (11): $Nu_{l,turb} = \frac{0.037 Re_{\psi,l}^{0.8} Pr}{1 + 2.443 Re_{\psi,l}^{-0.1}(Pr^{2/3} - 1)} = \frac{0.037 \times 21038^{0.8} \times 2.96}{1 + 2.443 \times 21038^{-0.1}(2.96^{2/3} - 1)} = 160.7$

Equation (9): $Nu_{l,0} = 0.3 + \sqrt{Nu_{l,lam}^2 + Nu_{l,turb}^2} = 0.3 + \sqrt{138.3^2 + 160.7^2} = 212.3$

Calculation of the tube arrangement factor f_A:

Equation (19): $f_A = 1 + \frac{2}{3b} = 1 + \frac{2}{3\times 1.11} = 1.6$ (staggered tube arrangement)

Equation (8): $Nu_{0,bundle} = f_A Nu_{l,0} = 1.6 \times 212.3 = 339.7$

Calculation of the mean Nusselt number Nu_{bundle} (real tube bundle):

Calculation of the correction factor f_N for the number of tube rows:

The correction factor f_N is ignored (see Sect. 4.3.1), and therefore

Equation (20): $f_N = 1$ is used.

Calculation of the correction factor f_P for temperature dependence of physical properties:

Equation (22): $f_P = \left(\frac{Pr}{Pr_w}\right)^{0.11} = \left(\frac{2.96}{3.54}\right)^{0.11} = 0.981$ (cooling of liquid)

Equation (7): $Nu_{bundle} = f_N f_P Nu_{0,bundle} = 1.0 \times 0.981 \times 339.7 = 333.2$

Calculation of the mean shell-side Nusselt number Nu_{shell}:

Calculation of the geometry correction factor f_G:

Equation (27): $R_G = \frac{n_W}{n_T} = \frac{25}{66} = 0.379$

Equation (26): $f_G = 1 - R_G + 0.524 R_G^{0.32} = 1 - 0.379 + 0.524 \times 0.379^{0.32} = 1.005$

Calculation of the leakage correction factor f_L:

Equation (30): $A_{GTB} = \left(n_T - \frac{n_W}{2}\right)\frac{\pi\left(d_B^2 - d_o^2\right)}{4} = \left(66 - \frac{25}{2}\right)\frac{\pi(26^2 - 25^2)}{4} = 2143\ mm^2$

Equation (32): $\gamma = 2\cos^{-1}\left(1 - \frac{2H}{D_i}\right) = 2\cos^{-1}\left(1 - \frac{2\times 76}{307}\right) = 119.4^\circ$

Equation (31): $A_{GSB} = \frac{\pi}{4}\left(D_i^2 - D_l^2\right)\frac{360-\gamma}{360} = \frac{\pi}{4}(310^2 - 307^2)\frac{360-119.4}{360} = 972\ mm^2$

Equation (29): $A_{SG} = A_{GTB} + A_{GSB} = 2143 + 972 = 3115\ mm^2$

Calculation of the sum of the shortest connections L_E after Fig. 3:

Check: $b \geq \frac{1}{2}\sqrt{2a+1}$? $\rightarrow$ $1.11\text{mm} \geq \frac{1}{2}\sqrt{2\times 1.28 + 1} = 0.943\text{mm} \rightarrow$ yes

According to Fig. 3: $e = s_1 - d_o = 32 - 25 = 7$ mm

e_1 can be determined from the drawings; in this example e_1 can be calculated from the following equation:

$$e_1 = \frac{D_i - D_B}{2} = \frac{310 - 285}{2} = 12.5\ \text{mm}$$

According to Fig. 9: number of shortest connections e between the tubes in tube bundle = 8

$$L_E = 2e_1 + \Sigma e = 2 \times 12.5 + 8 \times 7 = 81\ \text{mm}$$

Equation (34): $A_E = SL_E = 184 \times 81 = 14904\ mm^2$

Equation (33): $R_L = \frac{A_{SG}}{A_E} = \frac{3115}{14904} = 0.209$

Equation (28): $f_L = 0.4\frac{A_{GTB}}{A_{SG}} + \left(1 - 0.4\frac{A_{GTB}}{A_{SG}}\right)\exp(-1.5R_L)$

$$= 0.4\frac{2143}{3115} + \left(1 - 0.4\frac{2143}{3115}\right)\exp(-1.5 \times 0.209)$$

$$= 0.805$$

Calculation of the bypass correction factor f_B:

$\frac{n_S}{n_{MR}} = 0$ (no sealing strips)

Check: $e(D_i - D_B)$? $\rightarrow$ [$e = 7$ mm, $(D_i - D_B) = (310 - 285) = 25$ mm] $\rightarrow$ yes

Equation (38): $A_B = S(D_i - D_B - e) = 184(310 - 285 - 7) = 3312\ mm^2$

Equation (37): $R_B = \frac{A_B}{A_E} = \frac{3312}{14904} = 0.222$

Check: $(Re_{\psi,1} \geq 100)$? $\rightarrow$ yes $\rightarrow \beta = 1.35$

Equation (35): $f_B = \exp\left[-\beta R_B\left(1 - \sqrt[3]{\frac{2n_S}{n_{MR}}}\right)\right] = \exp[-1.35 \times 0.222(1 - \sqrt[3]{2\times 0})] = 0.741$ (since $n_S < \frac{n_{MR}}{2}$)

Calculation of the factor f_W for shell-side flow configuration:

Equation (25): $f_W = f_G f_L f_B = 1.005 \times 0.805 \times 0.741 = 0.599$

The mean shell-side Nusselt number Nu_{shell} can be calculated from

Equation (6): $Nu_{shell} = f_W Nu_{bundle} = 0.599 \times 333.2 = 199.6$

Calculation of the mean shell-side heat transfer coefficient α:

Equation (5): $\alpha = \frac{Nu_{shell}\lambda}{l} = \frac{199.6\times 654\times 10^{-3}}{0.03927} = 3324\ W\ m^{-2}\ K^{-1}$

The procedure of evaluating the thermal performance on the shell-side of an existing shell-and-tube heat exchanger is based usually on the knowledge of the volumetric flow rate $\dot{V}$ of the shell-side fluid (or the mass flow rate), the fluid inlet temperature T_{in}, the wall temperature T_w and the total heat transfer area A as well as the other dimensions of the heat exchanger. The heat transfer calculations yield in this case the fluid outlet temperature T_{out}. On the other hand, dimensioning a new heat exchanger to fulfill the requirements of a particular process is based usually on the knowledge of $\dot{V}$, T_{in}, T_{out}, and T_w. The heat transfer calculations yield in this case the total heat transfer area A required to fulfill the process requirements on the shell-side. Moreover, in each case the wall temperature T_w can be determined only in conjunction with the thermal and fluid dynamic conditions of the fluid inside the heat exchanger tubes. In both cases (performance evaluation of an existing heat exchanger or dimensioning of a new heat exchanger for a particular job), one of the parameters used in the example (T_{out} or A) is not known a priori; it has to be assumed, checked,

and corrected if necessary. Thus, the calculations are based most probably on iteration. The given example represents only a single step in the iteration procedure.

6 Symbols

Latin Letters

A	Total surface ara of all tubes in a shell-and-tube head exchanger ($m^2(mm^2)$).
A_B	Area responsible for bypass streams (m^2 (mm^2))
A_E	Smallest area for cross flow between two baffles measured in the row of tubes on or near the diameter of the shell that is parallel to the edge of the baffles (m^2 (mm^2))
A_f	Cross sectional area defined by Eq. (15) (m^2 (mm^2))
A_{GSB}	Area of gap between the shell and a baffle (m^2 (mm^2))
A_{GTB}	Area of all gaps between the tubes and the holes in a baffle (m^2 (mm^2))
A_{SG}	sum of the areas of all gaps between the tubes and the holes in a baffle and between the shell and a baffle (m^2 (mm^2))
a	Thermal diffusivity (in the definition of Prandtl number, Eq. (13)) ($m^2\ s^{-1}$)
a	Transverse pitch ratio ($= s_1/d_o$) (l)
b	Longitudinal pitch ratio ($= s_2/d_o$) (l)
D_l	Baffle diameter (m (mm))
D_B	Tube bundle diameter (m (mm))
D_i	Shell inside diameter (m (mm))
d_B	Diameter of holes in baffles to accommodate the tubes (m (mm))
d_o	Outer diameter of tubes (m (mm))
e	Shortest connection between adjacent tubes in the same tube row or in adjacent tube rows (see Fig. 3) (m (mm))
e_1	Shortest connection between the outermost tube in the bundle and the shell measured in the tube row on or near the diameter of the shell that is parallel to the edge of the baffles (see Fig. 3) (m (mm))
f_A	Tube arrangement factor (l)
f_B	Bypass correction factor (l)
f_G	Geometry correction factor (l)
f_L	Leakage correction factor (l)
f_N	Correction factor for number of tube rows (l)
f_P	Correction factor for change in physical properties in the thermal boundary layer near the surface of the tubes (l)
f_W	Correction factor for shell-side flow configuration (l)
H	Height of baffle cut (m (mm))
L	Total length of heat exchanger tubes (m (mm))
L_E	Sum of the shortest connections e and e_1 measured in the row of tubes on or near the diameter of the shell that is parallel to the edge of the baffles (see Fig. 3) (m (mm))
l	Half circumference of tube (m (mm))
$Nu_{0,bundle}$	Mean Nusselt number of an ideal tube bundle (see Eq. (8)) (l)
Nu_{bundle}	Mean Nusselt number of a tube bundle under real operating conditions (see Eq. (7)) (l)
$Nu_{l,0}$	Mean Nusselt number for a single tube (l)
$Nu_{l,lam}$	Mean Nusselt number for a single tube with laminar flow (l)
$Nu_{l,turb}$	Mean Nusselt number for a single tube with turbulent flow (l)
Nu_{shell}	Mean shell-side Nusselt number ($= \alpha l/\lambda$) (l)
n_{MR}	Number of main resistances in cross flow between adjacent baffles (see Fig. 6) (l)
n_P	Exponent of temperature ratio in Eq. (23) (l)
n_R	Number of tube rows in cross flow in a tube bundle between adjacent baffles (l)
n_S	Number of pairs of sealing strips (l)
n_T	Total number of tubes in heat exchanger including blind and support tubes (l)
n_W	Number of tubes in both upper and lower windows (baffle cuts) (l)
Pr	Prandtl number ($= \nu/a$) (l)
Pr_w	Prandtl number at wall temperature T_w (l)
$\dot{Q}$	Heat flow rate between the shell-side fluid and the outer surface of the tubes (W)
R_B	Ratio A_B/A_E (see Eq. (37)) (l)
R_G	Ratio n_W/n_T (see Eq. (27)) (l)
R_L	Ratio A_{SG}/A_E (see Eq. (33)) (l)
$Re_{\psi,l}$	Reynolds number for a tube bundle ($= wl/\psi\nu$) (l)
S	Baffle spacing (in the case of same baffle spacing in all channels) (m (mm))
S_B	Bypass stream (see Fig. 1)
S_C	Baffle spacing in central channels (m (mm))
S_E	Baffle spacing in end channels (inlet and outlet channels) (m (mm))
S_L	Leakage stream (see Fig. 1)
S_M	Main stream (see Fig. 1)
s_1	Transverse pitch (m (mm))
s_2	Longitudinal pitch (m (mm))
T	Absolute temperature ($T = T + 273.1$) (K)
T_w	Absolute wall temperature ($T_w = T_w + 273.1$) (K)
t	Pitch for an equilateral triangle or a staggered square tube arrangement (m (mm))
w	Characteristic velocity in the definition of the Reynolds number ($m\ s^{-1}$)
$\dot{V}$	Fluid flow rate ($m^3\ s^{-1}$ ($m^3\ h^{-1}$))

Greek Letters

α	Mean shell-side heat transfer coefficient in heat exchanger ($W\ m^{-2}\ K^{-1}$)
α_C	Mean shell-side heat transfer coefficient in central channels ($W\ m^{-2}\ K^{-1}$)
α_E	Mean shell-side heat transfer coefficient in end channels (inlet and outlet channels) ($W\ m^{-2}\ K^{-1}$)
β	Constant in Eq. (35) (l)
γ	Central angle of a baffle cut (◦)
T	Fluid temperature (°C)

T_w	Wall temperature of tubes (°C)
ΔT_{LM}	Logarithmic mean temperature difference (°C)
λ	Thermal conductivity ($W\,m^{-1}\,K^{-1}$)
v	Kinematic viscosity ($m^2 s^{-1}$)
ψ	Void fraction (see Eqs.(16) and (17))(1)

Subscripts

in	At inlet
m	Mean value
out	At outlet

Notice: The units between brackets (mm, mm^2, and $m^3\,h^{-1}$) are not consistent with the M.K.S. units system; they are used in the example for convenience.

G9 Fluid-Particle Heat Transfer in Flow Through Packed Beds of Solids

Volker Gnielinski
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Introduction

Heat transfer coefficients between particles and fluid in packed beds are one of the basic pieces of information needed for unit operations and chemical reactor design. Heat transfer is of interest, for example, in chemical reactors with fixed beds of catalysts in which large amounts of heat are absorbed or released, or in fixed beds used as regenerative heat exchangers. Particles of very different shapes, such as spheres, cylinders, Raschig rings or Berl saddles are used as packing material. Chap. G9 deals with the calculation of heat transfer coefficients between a fluid flowing through a packed bed and the particles of the packed bed.

2 Definition of the Heat Transfer Coefficient

The average coefficient of heat transfer between the solid particles in a bed and a fluid flowing through the bed is defined by

$$\dot{q} = \alpha \, \Delta T_{\mathrm{LM}}$$

The logarithmic mean temperature difference is given by

$$\Delta T_{\mathrm{LM}} = \frac{(T_{\mathrm{w}} - T_{\mathrm{in}}) - (T_{\mathrm{w}} - T_{\mathrm{out}})}{\ln \dfrac{T_{\mathrm{w}} - T_{\mathrm{in_i}}}{T_{\mathrm{w}} - T_{\mathrm{out}}}}$$

where T_{in} and T_{out} are respectively, the inlet and the outlet temperatures of the fluid and T_{w} is the wall temperature.

3 Determination of the Heat Transfer Coefficient

The coefficient of heat transfer between a fluid and the particles in a bed of solids through which it flows is greater than that for flow over individual particles of the same shape.

According to Gnielinski [1, 2], it can be predicted by means of a form factor f_{a} and a Nusselt number equation that applies for flow over a single sphere. Thus,

$$\mathrm{Nu} = f_{\mathrm{a}} \, \mathrm{Nu}_{\mathrm{sphere}} \tag{1}$$

where

$$\mathrm{Nu}_{\mathrm{sphere}} = 2 + \sqrt{\mathrm{Nu}_{\mathrm{lam}}^2 + \mathrm{Nu}_{\mathrm{turb}}^2} \tag{2}$$

$$\mathrm{Nu}_{\mathrm{lam}} = 0.664 \sqrt{\mathrm{Re}_\psi} \sqrt[3]{\mathrm{Pr}} \tag{3}$$

$$\mathrm{Nu}_{\mathrm{turb}} = \frac{0.037 \, \mathrm{Re}_\psi^{0.8} \, \mathrm{Pr}}{1 \times 2.443 \mathrm{Re}_\psi^{-0.1} (\mathrm{Pr}^{2/3} - 1)} \tag{4}$$

$$\mathrm{Nu} = \frac{\alpha \, d_{\mathrm{S}}}{\lambda} \tag{5}$$

$$\mathrm{Re}_\psi = \frac{w_{\mathrm{free}} \, d_{\mathrm{S}}}{\nu \, \psi} \tag{6}$$

$$\mathrm{Pr} = \frac{\nu}{a} \tag{7}$$

and

$$d_{\mathrm{S}} = \sqrt{\frac{A_{\mathrm{P}}}{\pi}} \tag{8}$$

The diameter of a sphere of the same area as that of a particle in the bed is determined from the geometrical area A_{P} of an individual particle with the aid of Eq. (8). The area A_{P} is calculated from the area per unit volume of the bed and the number of particles per unit volume. If the bed consists of spheres of the same diameter d, then $d_{\mathrm{S}} = d$.

w_{free} is the superficial velocity above the bed. The void fraction ψ is obtained from the volume V of the vessel containing the bed and the volume V_{F} of all particles in the bed, i.e.,

$$\psi = \frac{V - V_{\mathrm{F}}}{V} \tag{9}$$

The following numerical values can be inserted for the form factor f_{a}:

For a bed consisting of spheres of the same size,

$$f_{\mathrm{a}} = 1 + 1.5(1 - \psi) \tag{10}$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_31,

for cylindrical particles with a length l to diameter d ratio of $0.24 < l/d < 1.2$,

$$f_a = 1.6 \tag{11}$$

for cubes,

$$f_a = 1.6 \tag{12}$$

for Raschig rings,

$$f_a = 2.1 \tag{13}$$

and for Berl saddles,

$$f_a = 2.3 \tag{14}$$

The values to be inserted for the physical properties of the fluid in Eqs. (5–7) must be referred to the mean temperature of the fluid, i.e., $T_m = (T_{in} + T_{out})/2$.

4 Validity and Other Methods for Calculation

The validity of Eq. (1) has been checked by heat and mass transfer measurements in the following ranges:

For beds of spherical particles,
$10^{-1} < \mathrm{Re}_\psi < 10^4$, and Pr or $Sc = 0.6 - 1000$;
for cylinders,
$10^2 < \mathrm{Re}_\psi < 10^4$, and Pr or $Sc = 0.6 - 1300$;
for cubes,
$10^2 < \mathrm{Re}_\psi < 10^4$, and $\mathrm{Pr} = 0.7$; and
for Berl saddles and Raschig rings,
$10^2 < \mathrm{Re}_\psi < 10^4$, and $Sc = 0.6$ and $Sc = 2.5$.

In the literature, the Nusselt numbers cited for packed beds and for Peclet numbers in the $\mathrm{Pe} = \mathrm{Re}_\psi \mathrm{Pr}$ range below 500–1000 are much less than the corresponding values obtained from Eq. (1): Many of these values have been collated by Kunii and Suzuki [3]. A mathematical model that has been suggested by Schlünder [4] was taken as a basis by Martin [5] to explain the difference between the experimental and calculated values in the light of flow irregularities that result from different void fractions in the packed bed.

The model is based on a packed bed that consists of particles of equal size and has an average void fraction of ψ. A larger void fraction is assumed for part of the cross section. Since both parts give rise to the same pressure drop, the fluid velocity is greater in the part of the bed with the larger void fraction. Hence the two parts of the bed have different NTUs. These differences are particularly pronounced if the Péclet numbers are small.

Equation (1) is valid for the coefficients of heat transfer between the particles and the fluid in both parts of the bed. However, the values that it yields are much higher than those obtained by combining the various values of NTU for the two components of the flow. The apparent Nusselt numbers thus determined are related in the same way as the measured values given in the list [3] to the Péclet number and the ratio of the particle diameter to the height of the bed.

Boiling

Despite the large number of studies on boiling heat transfer, the prediction of heat transfer coefficients is still based on empirical or semiempirical methods. The reason is the lack of a coherent theory of the complex interactions of the various heat and mass transport processes on the various characteristic length scales involved in boiling heat transfer. The aim of Part H "Boiling" is to present and explain the state of the art of the empirical or semiempirical methods for pool boiling and flow boiling situation in Chaps. H2 and H3, respectively. The specific theoretical background which helps understanding and applying the methods is included in these sections, too. Any boiling process, pool or flow boiling, starts with the formation of individual bubbles. Important empirical parameters, e.g., active nucleation site density, are controlled by this basic process. Therefore, an introductory Chap. H1 on fundamentals of bubble formation is put infront.

Peter Stephan

H1 Fundamentals of Bubble Formation

Karl Stephan
Universität Stuttgart, Stuttgart, Germany

Heat transfer in boiling is more easily understood when we know how the vapor bubbles form on the hot surface.

The following considerations hold for the equilibrium of a vapor bubble, assumed to be spherical, Fig. 1, with the liquid surrounding it. Between the gaseous bubble (gas = index G) and the surrounding liquid (liquid = index L), *thermal equilibrium* exists

$$\vartheta_G = \vartheta_L = \vartheta\,. \tag{1}$$

If a surface element of the spherical shell is cut out of the vapor bubble, as depicted in the right side of Fig. 1, with side lengths $r\,\mathrm{d}\varphi$, the forces $\sigma r\,\mathrm{d}\varphi$ exerted by the surface tension σ (σ is force per unit length) act upon the edges. The resultant F_R of these forces is given by

$$\mathrm{d}^2F_R = 2\sigma r\,\mathrm{d}\varphi^2\,.$$

The forces resulting from the gas and liquid pressure are also of influence

$$p_L(r\,\mathrm{d}\varphi)^2 + \mathrm{d}^2F_R = p_G(r\,\mathrm{d}\varphi)^2\,.$$

From this, the condition of *mechanical equilibrium* follows

$$p_G = p_L + 2\sigma/r\,. \tag{2}$$

Finally, the condition for *equilibrium with respect to mass exchange* between the gaseous and liquid phase also holds. This leads, as illustrated, for instance, in [1], to

$$p_L = p_0 - \frac{\varrho'}{\varrho' - \varrho''}\,\frac{2\sigma}{r} \tag{3}$$

or with to

$$p_G = p_0 - \frac{\varrho'}{\varrho' - \varrho''}\,\frac{2\sigma}{r}\,. \tag{4}$$

Equation (3) or (4) is known as *Thomson's equation*. It produces a relationship between the vapor pressure $p_0(\vartheta)$ at a flat phase interface, the liquid pressure $p_L(\vartheta, r)$ and the vapor pressure $p_G(\vartheta, r)$ at the surface of a vapor bubble of radius r. These relationships are illustrated in Fig. 2. At a given temperature ϑ, the vapor pressure p_G, corresponding to (Subchap. H1.4), is smaller by

$$p_0 - p_G = \Delta p_G = \frac{\varrho''}{\Delta\varrho}\,\frac{2\sigma}{r} = \frac{\varrho''}{\varrho' - \varrho''}\,\frac{2\sigma}{r}\,,$$

than the vapor pressure p_0 at the flat phase boundary. As the surface tension σ is temperature dependent, the curves for the vapor pressure p_G and the liquid pressure p_L do not run exactly but only approximately parallel to the vapor pressure curve p_0 at the phase interface.

If, instead of stipulating the boiling temperature ϑ, the pressure p_0 of a liquid–vapor bubble system is given, then the liquid has to be superheated by $\Delta\vartheta = \vartheta - \vartheta_S$ in comparison to the system with a flat phase boundary, so that a vapor bubble of radius r is in equilibrium with the liquid, as shown in Fig. 2. In addition, it is clear that the required degree of superheating $\Delta\vartheta = \vartheta - \vartheta_S$ is larger, if the radius r of the vapor bubble is the smaller, therefore, for small radii $r^* < r$ the curves for the vapor pressure $p_G(\vartheta, r^*)$ and the liquid pressure $p_L(\vartheta, r^*)$ in Fig. 2 are shifted further to the right. Conversely, for a given degree of superheating $\Delta\vartheta$, a vapor bubble of definite radius r is in equilibrium with the superheated liquid. For the approximate calculation of the required superheating, we assume that the curves $p_0(\vartheta)$ and $p_L(\vartheta, r)$ in Fig. 2 run parallel. This gives

$$\frac{\mathrm{d}p_L}{\mathrm{d}\vartheta} = \frac{\mathrm{d}p_0}{\mathrm{d}\vartheta}\,. \tag{5}$$

The differential $dp_0/d\vartheta$ is the slope of the vapor pressure curve $p_0(\vartheta)$. It can be calculated from the Clausius-Clapeyron equation

$$\frac{\mathrm{d}p_0}{\mathrm{d}\vartheta} = \frac{\Delta h_v \varrho'' \varrho'}{T_s\,(\varrho' - \varrho'')}\,. \tag{6}$$

On the other hand, with (3)

$$\frac{\mathrm{d}p_L}{\mathrm{d}\vartheta} \cong \frac{p_0 - p_L}{\Delta\vartheta} \cong \frac{1}{\Delta\vartheta}\,\frac{\varrho'}{\varrho' - \varrho''}\,\frac{2\sigma}{r}\,. \tag{7}$$

From these equations, the bubble radius r is calculated as a function of the superheating $\Delta\vartheta = \vartheta - \vartheta_S$, to be approximately

$$r \cong \frac{2\sigma T_S}{\varrho'' \Delta h_v \Delta\vartheta}\,. \tag{8}$$

According to this, for a particular degree of liquid superheating $\Delta\vartheta$ a definite bubble radius exists, at which the bubble is in equilibrium with the liquid. Bubbles whose radii are $r^* < r$ are in equilibrium with the liquid only if the superheating is $\Delta\vartheta^* > \Delta\vartheta$, as shown in Fig. 2. A liquid superheated by $\Delta\vartheta$ is too cold. Therefore, bubbles that are too small will condense again. Bubbles of radius $r^* > r$ are in liquid that is superheated, and they can continue to grow. However, in reality the residence time of bubbles, in particular those close to the wall, is so small that equilibrium is never reached and the actual superheating of the fluid is many times greater than $\Delta\vartheta$. A particular critical bubble radius also belongs to this actual superheating. In boiling water at 1 bar, according to Eq. (8), the bubble diameter is $2r \cong 0.155$ mm, based on superheating in the core of the liquid by 0.4 K. A bubble of this size is then able to form and can grow. A bubble of this type contains around $3{\cdot}10^{20}$ water molecules. However, it is difficult for so many molecules with the high energy of vapor molecules to collect coincidentally at a certain position inside the liquid, form a bubble and then grow. This raises the question of how vapor bubbles are actually formed.

Observations have taught us that no bubbles form in a completely pure, carefully degassed liquid, unless the liquid is

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_33,

H1. Fig. 2. Vapor and liquid pressure between a liquid and a spherical vapor bubble.

extremely superheated or, for example, ionising beams are sent through it. Furthermore, over a long time, the bubbles reappear at the same place on the heated surface, with a varying frequency that can be approximated to an error function. Obviously, this has something to do with highly active centers that catalyze the transformation from unstable superheated liquid to stable vapor. These centres are the remains of gas or vapor in depressions in the surface that have not been driven out by the liquid, because even with good wetting ability it cannot completely fill the fine depressions on the surface. When heated, the gas or vapor remnants expand until a critical size is reached that corresponds to the size of a viable bubble. Then a vapor bubble can grow further as a result of the superheating of the fluid, until finally the adhesion force becomes smaller than the buoyancy and dynamic forces and the bubble detaches itself from the heated surface. After the bubble breaks off, further gas or vapor remains enclosed in the depression. This will be cooled by cold liquid flowing from the centre of the fluid to the wall, and then subsequently, by additionally heating from the wall. A new nucleus for the growth of a vapor bubble forms. These considerations explain why the surface structure is an influential quantity for heat transfer.

Vapor bubbles almost always develop at favourable positions on solid surfaces or on suspended particles. Therefore, it is generally *heterogeneous nuclei formation* that prevails. The *homogeneous nuclei formation*, with bubbles formed by "themselves" as a result of the natural fluctuations of the molecules, plays a very minor role.

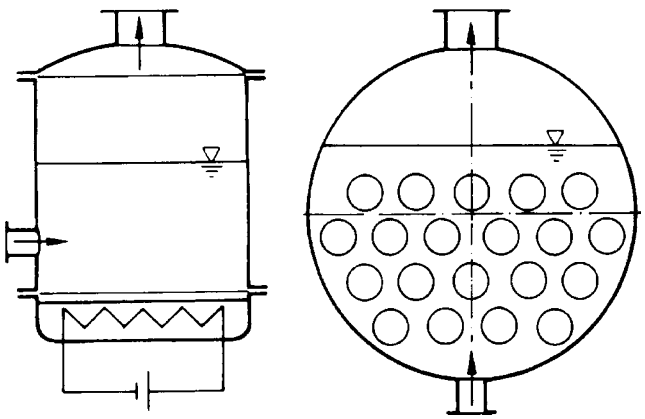
[2]Brunel and Oxford Universities, UK

1 Pool Boiling Regimes

In industrial applications, heat is transferred to a boiling liquid from heated walls or tube bundles in a boiler, as shown schematically in Fig. 1. The heat source may be a fluid, chemical, electric, or nuclear energy. The geometry of the heating elements varies widely. Much of the former data and all of the new material for the update of this chapter were derived from experiments with single, horizontal, copper cylinders with embedded electrical heating elements and thermocouples, immersed in a large pool of saturated liquid.

If the temperature T_w of such an element is raised to a value above the saturation temperature T_{sat} corresponding to the system pressure p, the relationship between the heat flux $q = Q/A$ and the temperature difference $\Delta T = T_w - T_{sat}$ will be similar to that shown in Fig. 2 [1–3].



H2. Fig. 1. Evaporator in which the heated surfaces are flat walls, tube bundles, or assemblies of metal rods.

The diagram (Fig. 2a) on the left applies to an intermediate reduced pressure $p^* = p/p_c$ and (Fig. 2b) on the right to a reduced pressure close to the critical point. Both logarithmic diagrams include grids of straight lines corresponding to constant values of the surface coefficient of heat transfer α, which is defined by

$$q = \alpha \Delta T \tag{1}$$

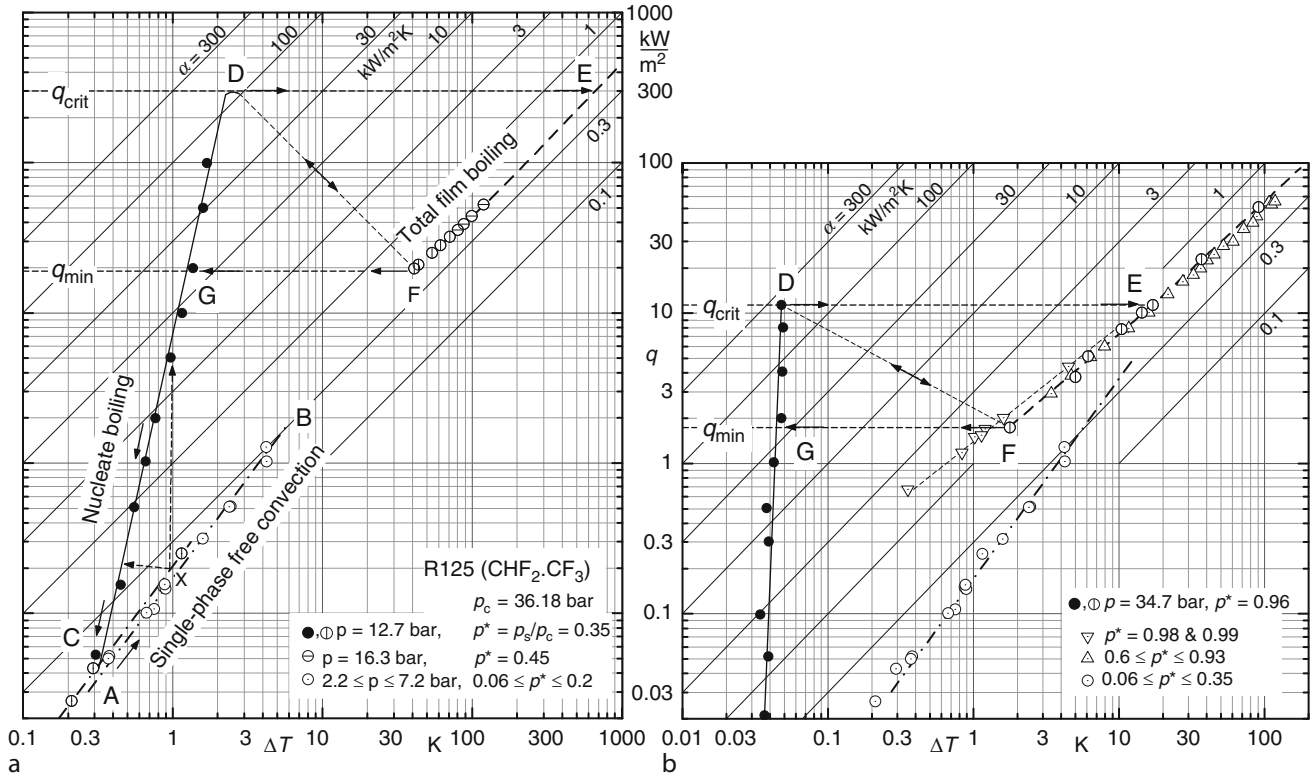
It can be seen in Fig. 2a that for small increases in the temperature difference in free convection without bubble formation (line A–B), the increase in heat flux q is somewhat more than directly proportional to ΔT, that is, α increases with ΔT. At a certain temperature difference (point C), which depends on the pressure and the characteristics of the heating surface, vapor bubbles start to form at the heated surface, causing q to increase with increasing ΔT much more rapidly than in free convection, shown by the interpolation lines drawn between the data points indicated by solid dots in Fig. 2a and b. These lines are nearly straight in many cases, indicating a power-law relationship between q and ΔT (and α).

The pronounced nonlinear increase in q with ΔT is characteristic of heat transfer during nucleate boiling. Vapor bubbles are formed at gas or vapor filled cavities on technically rough heating surfaces, with radii r of a few microns, similar to the sizes of the cavities. Because of surface tension σ, the pressure inside a vapor nucleus of radius r must be higher than the pressure in the adjacent liquid by an amount given approximately by

$$\Delta p \sim 2\sigma / r. \tag{2}$$

This requires the liquid to be superheated by an amount that can be estimated from the slope of the equilibrium vapor pressure curve $(dp/dT)_{sat}$. When this superheat is exceeded, the vapor nucleus becomes unstable and grows by evaporation, with heat supplied from the superheated liquid and wall by several mechanisms that are discussed in [4] and in Chap. H1.

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_34,



H2. Fig. 2. Heat flux q as a function of the temperature difference ΔT in nucleate and film boiling and in single-phase free convection. Fluid: Refrigerant R125 (CHF_2CF_3); heated surface: horizontal copper tube with 25 mm OD and sandblasted surface (according to [3], extended).

An increase in wall superheat activates an increasing number of smaller nucleation sites, leading to the nonlinear increase in q.

The number of active nucleation sites at a given ΔT also increases with a rise in the saturation pressure, because the surface tension σ decreases and the slope $(dp/dT)_{sat}$ increases. An example is given by comparing the continuous lines with solid dots in Fig. 2a and b, which present numerical values that are typical for many organic liquids. It can thus be seen that if the pressure is raised from 35% to 96% of the critical value, the temperature difference required to effect a given heat flux is reduced by an order of magnitude.

The activation of increasing numbers of nucleation sites by increases in wall superheat and/or system pressure can only occur if appropriate sizes of cavities are present on the heating surface. This depends on its microgeometry (roughness) and cleanliness. The examples in Fig. 2 are for a clean refrigerant boiling on a clean copper surface that had been sandblasted with fine corundum powder. The very steep increase of q with ΔT at near-critical pressure is caused by the activation of many tiny cavities of similar size and shape that release extremely small bubbles, as seen in the photographs in [3].

Nucleate boiling allows heat to be transferred at comparatively high rates by applying small temperature differences. However, there is a limit to the extent that the heat flux can thus be increased. The temperature difference ΔT at which this maximum (or critical) heat flux q_{crit} (point D in Fig. 2) occurs depends on the saturation pressure. In this regime of very intense nucleate boiling, a coherent film of vapor starts to form on parts of the heated surface, leading to a new regime of total film boiling when the surface is completely covered. There, the heat flux increases again with ΔT, at first with slightly decreasing heat transfer coefficient and then at a rate corresponding to a gradual increase in α, as in Fig. 2a at very high superheats, mainly as a result of growing turbulence in the film of vapor and the gradual increase in heat transfer by radiation. The absence of contact between the liquid and the heating surface reduces the influence of the surface properties, compared to nucleate boiling.

It is worth noting that the heat transfer coefficient and the maximum heat flux in nucleate boiling and the minimum heat flux in film boiling depend considerably on pressure, whereas heat transfer in total film boiling and in single-phase free convection is only slightly influenced by the pressure (and thus the temperature) in the saturated state. The only exception arises in the vicinity of the critical point, owing to the large changes in some properties with very small changes in temperature and pressure, illustrated by the fine dashed line for $p^* = 0.98$ and 0.99 in Fig. 2b with higher heat transfer coefficients than the bold dashed line for $p^* = 0.96$ and lower pressures.

The above is a somewhat simplified description of pool boiling that sets out some of the problems that have to be addressed in providing information for industrial design: nonlinearity between heat flux and temperature difference, dependence on fluid properties and pressure, dependence on surface properties that are difficult to define, and transitions between regimes with entirely different heat transfer characteristics.

These transitions are of potential importance in industrial applications because “hysteresis” occurs, dependent on whether the heat flux is increasing or decreasing and on the nature of the

heat source. Heating by the rapid flow of a fluid at a controlled inlet temperature approximates to controlling the temperature of the heating surface; heating by electrical or nuclear energy approximates to controlling the heat flux.

At first, the onset of nucleate boiling from single-phase free convection at a certain superheat is discussed that depends on the size of nucleation cavities available on the surface. With fluid heating, an attempt to increase the wall temperature activates more of the available sites, leading to an increase in the heat flux following the nearly vertical dashed line from point X in Fig. 2a. With electrical or nuclear heating, an attempt to increase the heat flux requires the activation of more sites, and this may result in a reduction in the wall temperature that in the limit follows the nearly horizontal dashed line starting from the same point X.

The particular path in both cases depends on hysteresis operating at the level of individual cavities, some of which may depend on "seeding" by vapor from bubbles formed at adjacent cavities, or may remain active at lower superheats than are required initially. Once the heat flux has been increased to a high value ("fully developed nucleate boiling"), all the available nucleation sites have been activated, and subsequent changes in q move up and down the line A–D in a repeatable manner. For this reason, data in the nucleate boiling region are conventionally reported for experimental conditions in which the heat flux is gradually reduced from a high value.

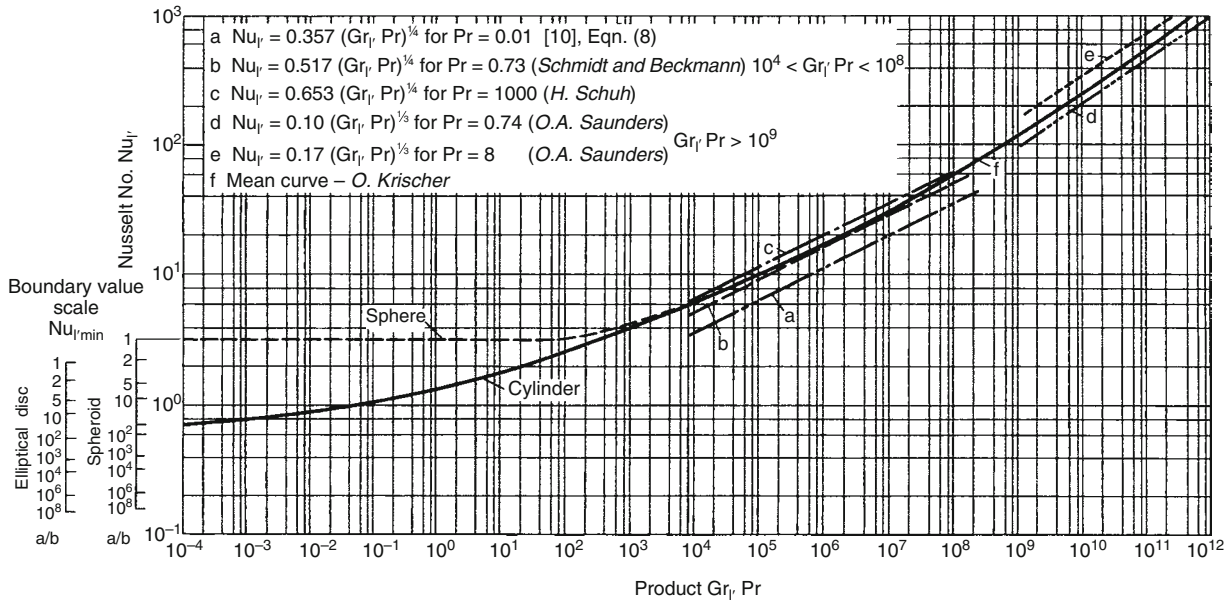
A different sort of hysteresis occurs in the transition between nucleate and film boiling. For fluid heating with a progressive change in wall temperature, there is a broad transition region D–F with patches of nucleate and film boiling on the heated surface. The point F of minimum heat flux and minimum wall temperature in total film boiling is called the Leidenfrost point. This transition is important during the cooldown of cryogenic systems, and during the metallurgical quenching of components with a large thermal capacity. For electrical or nuclear heating of systems with a low thermal capacity, the transition from nucleate boiling (point D) to film boiling (point E) following a small increase in heat flux (above q_{crit}) occurs rapidly, with the next stable equilibrium between heating element and boiling liquid occurring at very high superheat ("burnout"), if reduced pressures are not too high (Fig. 2a).

Transition back from film boiling to nucleate boiling with decreasing heat flux, however, occurs at a much lower minimum heat flux starting from the Leidenfrost point F and ending at G. Industrial systems employing electrical or nuclear heating are designed to avoid the hysteresis loop D–E–F–G. (More details on interactions between the characteristics of the heating element and the boiling liquid are given in fundamental studies by Stephan [5, 6] and in more recent publications [7, 8].)

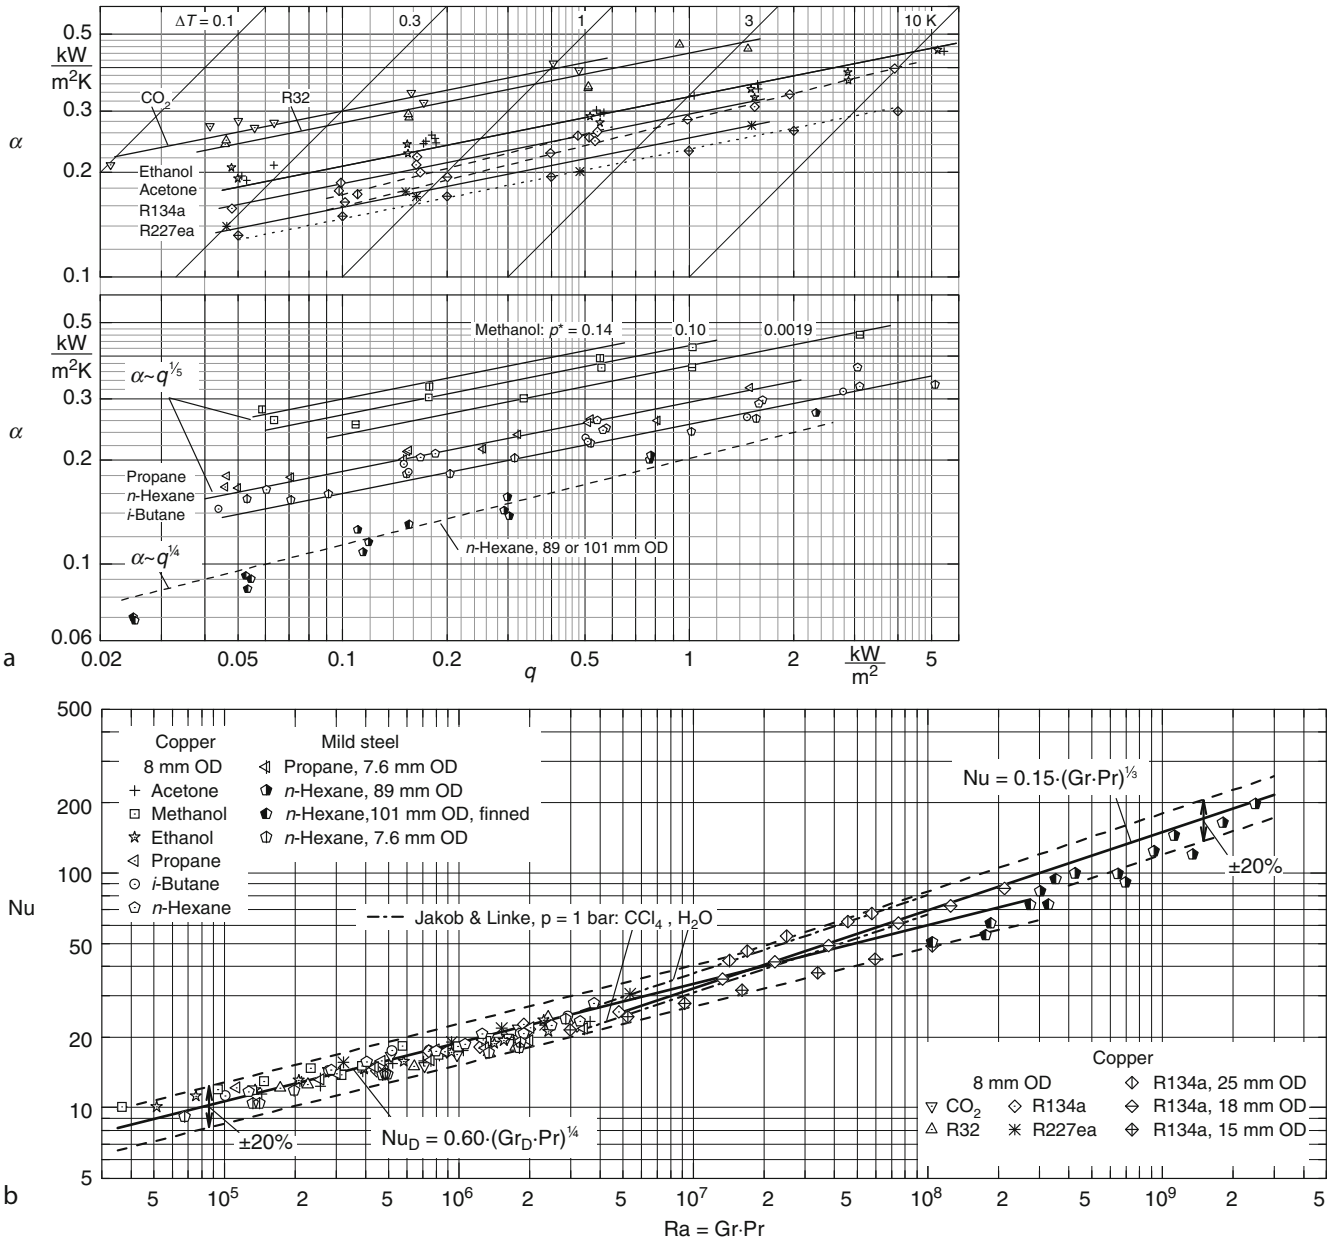
So far, it has been assumed that the liquid pool is at the saturation temperature corresponding to the system pressure. This is a necessary condition at the free surface of the pool. The increased hydrostatic pressure below the free surface leads to slight subcooling ($T < T_{sat}$) of the liquid near the heater, which may have significant effects at pressures close to p_c. Substantial subcooling occurs at the start of heating a cold pool (without a free surface, or in contact with a gas) but is difficult to maintain unless there is a continuous supply of cold liquid to the vessel. For this reason, the effects of subcooling are discussed in Chap. H3 on "Flow Boiling."

2 Single-Phase Free Convection

Single-phase free convection without bubble formation may occur in regions of evaporators where the heating surface operates at small wall superheats or low heat fluxes below the onset of nucleate boiling, for example, in refrigeration, line A–B in Fig. 2a. The predictive equations are then those that are used generally for free convection (Fig. 3), with the heat transfer



H2. Fig. 3. Experimental and theoretical results in free convection heat transfer around bodies of various geometries and Prandtl numbers [10]. (Taken from 3rd German ed. of VDI-Heat Atlas, 1977.)



H2. Fig. 4. Single-phase free convective heat transfer without bubble formation from horizontal tubes with different diameters to various fluids (from [11–13, 15–20]). (**a**) Heat transfer coefficient as a function of the heat flux with the superheat ΔT as parameter; (**b**) Nusselt number as a function of the Rayleigh number. Dashed lines: error limits. Dot-dashed lines for water and tetrachloromethane according to Jakob and Linke [13].

coefficient α averaged over the surface, and the fluid properties evaluated for the saturated liquid state. These are for laminar or turbulent flow in the boundary

$$\mathrm{Nu_D} = 0.60(\mathrm{Gr_D\,Pr})^{1/4} \quad \text{(laminar)} \tag{3}$$

$$\mathrm{Nu} = 0.15(\mathrm{Gr\,Pr})^{1/3} \quad \text{(turbulent)}, \tag{4}$$

valid in both cases for Prandtl numbers lying in the range 2–100. The two equations predict the same Nusselt number Nu when the Rayleigh number Ra = product of Grashof number Gr and Prandtl number Pr is slightly less than 2×10^7, so the transition from turbulent to laminar flow probably occurs in the range $10^7 < \mathrm{GrPr} < 10^8$. The transition from laminar to turbulent flow may be shifted toward much higher values of GrPr in special cases in which laminar flow is favored by the geometry and finish of the heating surface.

In turbulent flow, the heat transfer coefficient is unaffected by the characteristic length scale, which has a weak effect in laminar flow. For horizontal cylinders, the diameter D is used for this length. It may also be the *Krischer* length of flow path [9] for other simple geometries, Fig. 3, which also shows the limiting values of Nu for small values of $\mathrm{GrPr} < 10^4$. The variation of ±20% between data is typical of the combined effect of experimental scatter and of accuracy to be expected from simple correlations for free convection. The relations between heat transfer coefficient α, heat flux q, and length scale D

corresponding to Eqs.(3) and (4) are laminar $\alpha \sim (q/D)^{1/5}$ (3a), turbulent $\alpha \sim q^{1/4}$ (4a).

The relationships are illustrated in Fig. 4a for ten saturated liquids at pressures ranging from less than 0.2% to more than 30% of the critical pressure, obtained during studies of pool boiling on horizontal cylinders with different diameters and of different materials since 1993 [11, 12, 15–20]. Lines of constant temperature difference ΔT have been plotted in Fig. 4a to indicate its magnitude in relation to q. The nondimensional plot of Nu vs. Ra = (GrPr) in Fig. 4b with D as characteristic length confirms that the data agree with Fig. 3 and Eqs.(3) and (4) to ±20%, ranging from laminar flow to above the laminar-turbulent transition.

In the laminar flow regime, it can be seen from the solid lines in Fig. 4a and b that the values of α for all the liquids vary only by a factor of 2 at a given q and $D = 8$ mm. For a particular fluid, for example, methanol (with by far the biggest variation in pressure), α decreases by only 20% as the pressure is reduced by a factor of 70.

The influence of diameter is illustrated in Fig. 4a for R134a, see key in Fig. 4b, on copper cylinders of diameter 8 mm (solid line), 15 mm with gold-plated surface [11] (dotted line), 18 and 25 mm (dashed lines). The 8 and 15 mm data follow the smaller slope characteristic of laminar flow, although the 15 mm data lie in the transition region. The values differ by a ratio slightly greater than predicted by Eq. (3), and the 15 mm data lie on the lower limit of the laminar correlation in Fig. 4b. The data for 18 and 25 mm follow the larger slope characteristic of turbulent flow, although they too lie in the broad transition region. The values of α are similar to those for the 8 mm cylinder in laminar flow.

The effect of much larger changes in D is illustrated in Fig. 4a by data for *n*-hexane on cylinders of diameter 7.6 mm (solid line, laminar flow) and 89 mm (dashed line, turbulent flow), showing that it is possible for α to be lower in turbulent flow on a large cylinder than in laminar flow on a small cylinder at the same heat flux. This example also includes data for a *finned* tube of external diameter 101 mm (root diameter 89 mm; fin spacing 5 mm), using the wetted area of the fins to calculate q. The data for the smooth and finned cylinders are then the same within experimental uncertainty. This confirms earlier findings for low-fin copper tubes of various geometries with fin heights of 1.5–3.5 mm, spacing 1.3–3.8 mm [2, 14], but may not hold for fin spacing below 1 mm.

From the above evidence, Eqs.3 and 4 may be used to predict to ±20% the heat transfer coefficients in single-phase free convection on horizontal cylinders with smooth and low-fin surfaces (including operation in the transition zone between laminar and turbulent flow), which frequently precedes (or follows) pool boiling. They may also be used to estimate heat transfer coefficients for other simple geometries.

3 Nucleate Boiling of Pure Substances

3.1 Summary of Calculation Method for α

Despite the large number of treatises that have appeared on the subject in the literature (see, e.g., recent review articles [4, 21–23]) no coherent theory yet exists that would allow heat transfer coefficients during nucleate boiling to be predicted from first principles to the accuracy required in engineering.

Thus, in the light of the current state of the art, only empirical or semiempirical correlations can be applied in practice. Their development has proved that it is expedient to treat separately the influence on α of the main groups of variables, that is, the properties of the liquids, the nature of the heated surfaces, and the operating parameters (namely, the heat flux q and pressure p). This concept has been applied to establish a reduced heat transfer coefficient α/α_0 of the form

$$\alpha/\alpha_0 = F_q F_{p^*} F_w \tag{5}$$

where α_0 is the heat transfer coefficient for a *specific* fluid at a reference state that is the same for *all* fluids, and the functins F are independent nondimensional functions applicable to *all* fluids (with a very small number of exceptions), representing the *relative* influences on α of the heat flux q, the reduced pressure p^* (caused by the change in fluid properties with p^*, see [17, 24, 25]), and wall properties. In previous editions of the *Heat Atlas*, it has been shown that experimental data for a large number of fluids are correlated successfully by this concept. The reference conditions are chosen to be typical mid-range values for fully developed nucleate boiling in industrial applications: $q_0 = 20$ kW/m^2 and $p_0^* = 0.1$. The reference state for the heater is defined as a copper cylinder with an intermediate value $R_{a0} = 0.4$ µm of the arithmetic mean roughness height of the surface (as defined in ISO 4287/1:1984), which lies within the range common for heater surfaces manufactured in practice.

The concept with respect to the variation of heat flux and pressure (in terms of reduced pressure) from the reference state is illustrated in Fig. 5 for *i*-butane boiling on a copper tube. The influences of the four independent parameters in Eq. (5) will be discussed in detail in Sects. 3.2, 3.3, and 3.4.

In this edition of the *Heat Atlas*, the functions F_q and F_{p*} have been updated using new experimental data. A new simple method for determining α_0 is presented and a more rational form of Eq. (5) is proposed, using the new concept of a reference fluid.

3.2 Effect of Heat Flux and Pressure

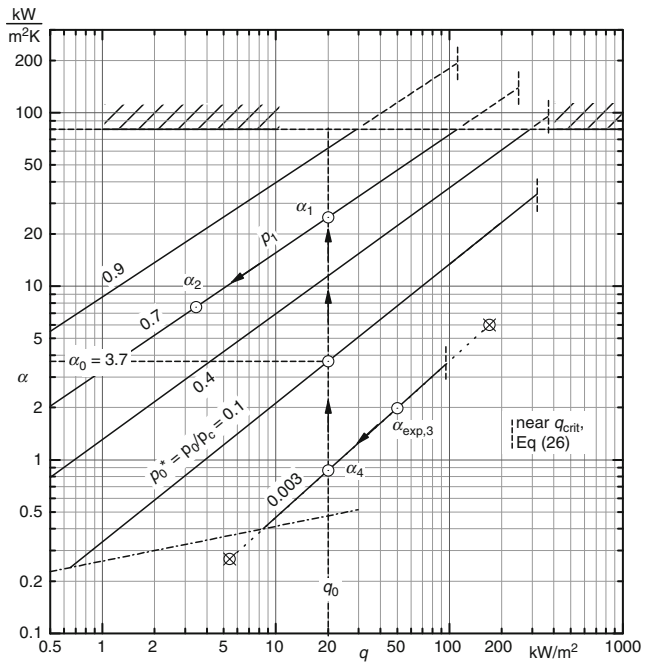
In Eq. (5), the terms

$$F(q) = (q/q_0)^n \tag{6}$$

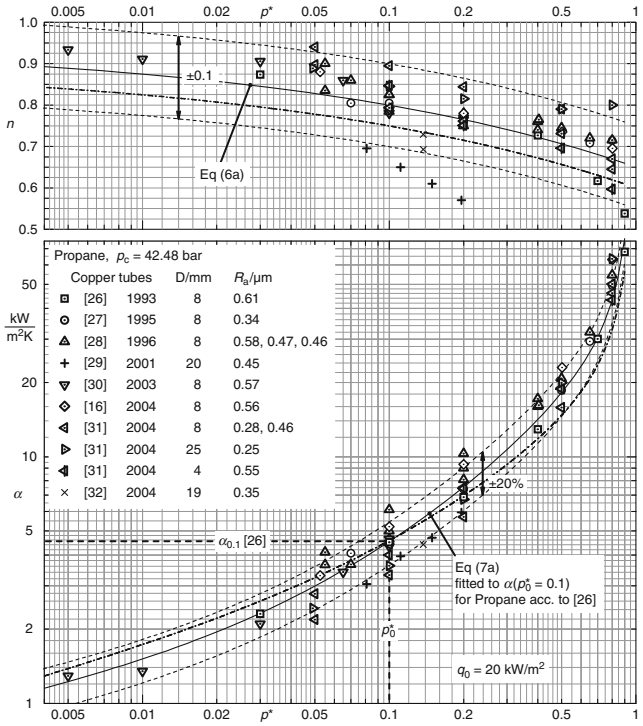
and

$$F(p) = F(p^*) \tag{7}$$

express the relationships between the heat transfer coefficient α and the heat flux q at constant reduced pressure (see, e.g., α_1, α_2 or α_3, α_4 in Fig. 5) and between α and reduced pressure p^* at constant q (see, e.g., α_1 and α_4 in Fig. 5). The relations $\alpha(q)$ and $\alpha(p^*)$ in the fourth German edition of the *VDI-Heat Atlas* (1984) were adopted for the first English edition (1993), and had been established empirically from experiments for many fluids. The updated forms of the two relations have been developed using also the new experimental results of the past 20 years.



H2. Fig. 5. Conversion of measured or calculated heat transfer coefficients into the corresponding values at other pressures and heat fluxes taking *i*-butane boiling on a copper tube as an example. Dot-dashed line: single-phase free convection; vertical dashed lines: maximum heat flux q_{crit} in nucleate boiling; arrows indicating how α_2 can be calculated from α_0 or from $\alpha_{exp,3}$.



H2. Fig. 6. Heat transfer coefficient α and exponent n as functions of the reduced pressure p^* for propane. Example for the determination of the reference value, $\alpha_{0.1}$ for each individual source in Fig. 7, from measured values.

In Fig. 6, the update procedure is demonstrated for measurements of propane boiling on horizontal copper tubes with different diameters D and mean roughness heights R_a. Corresponding new data for other organic fluids are shown in Fig. 7 where the values $\alpha_{0.1}$ at $p_0^* = 0.1$, q_0, but $R_a = R_{a,exp}$ (to treat the sources as authentically as possible) had been interpolated for each fluid and roughness of the heated wall (e.g., $\alpha_{0.1}$ for [26] in Fig. 6) and were used to determine the *relative* pressure dependence of α in the lower diagrams, and the exponent n in the upper represents the slopes of the straight lines in loglog-plots of α over q as in Fig. 5.

The update results in somewhat steeper increases of α with q or p^*, respectively, as follows from comparing the dot-dashed lines for the former with the full lines for the new relations according to

$$n(p^*) = 0.95 - 0.3p^{*0.3} \tag{6a}$$

and

$$F(p^*) = 0.7p^{*0.2} + 4p^* + (1.4p^*)/(1 - p^*). \tag{7a}$$

As can be seen from Fig. 7, the dot-dashed lines from the former versions of Eqs. (6a) and (7a) remain within the experimental scatter of the new data and approach the upper border of the scatter for very small reduced pressures in the lower diagrams, while passing slightly beyond the lower border at very high reduced pressures.

No reliable new measurements have been found in the literature for cryogenic fluids so the former experimental results are shown in Figs. 8 and 9. The experimental scatter for these fluids is very high, as can be seen particularly from the big differences in α for nitrogen and helium at atmospheric pressure (N_2: circles at $p^* = 0.03$ in Fig. 8; He: all symbols at $p^* = 0.44$ in Fig. 9). On the one hand, this will be caused by the much greater difficulties for measurements at very low saturation temperatures; on the other, it is caused by using different heating elements (tubes, plates, wires) and wall materials (the question on whether it is permissible to apply results of measurements on thin wires is dealt with in the discussion of Fig. 12 in Sect. 3.5).

For these fluids, no update of the calculation method (Eqs. (6) and (7)) is given and the former equations shown in the diagrams should be applied. In the case of helium, the reference heat flux is $q_0 = 1$ kW/m^2 (lower diagram of Fig. 9) because nucleate boiling no longer exists at $q = 20$ kW/m^2 for this fluid, and furthermore, it cannot be decided if Eq. (6a) may be used, due to the very high experimental scatter in the upper diagram of Fig. 9.

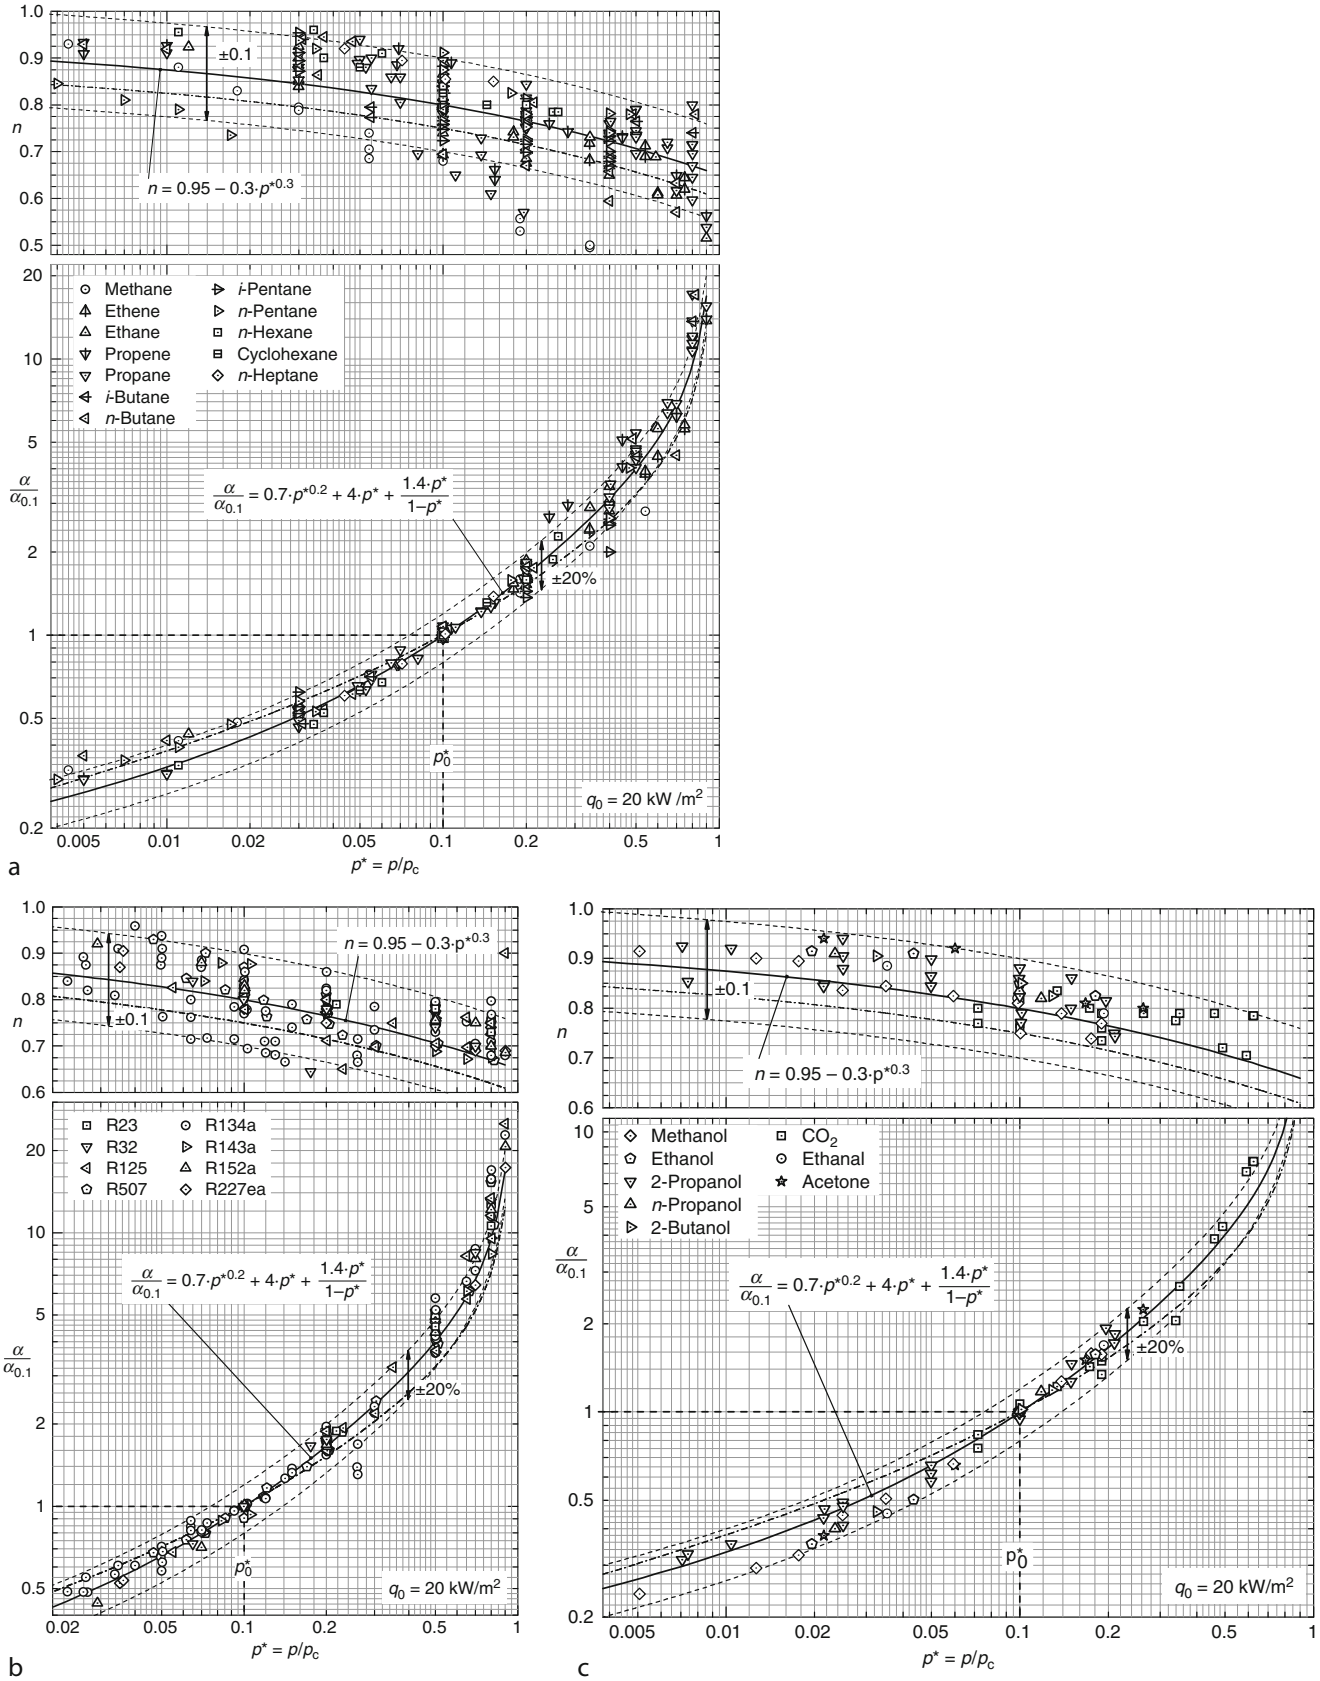
For water, relationships $n(p^*)$ and $F(p^*)$ according to

$$n(p^*) = 0.9 - 0.3p^{*0.15} \tag{6b}$$

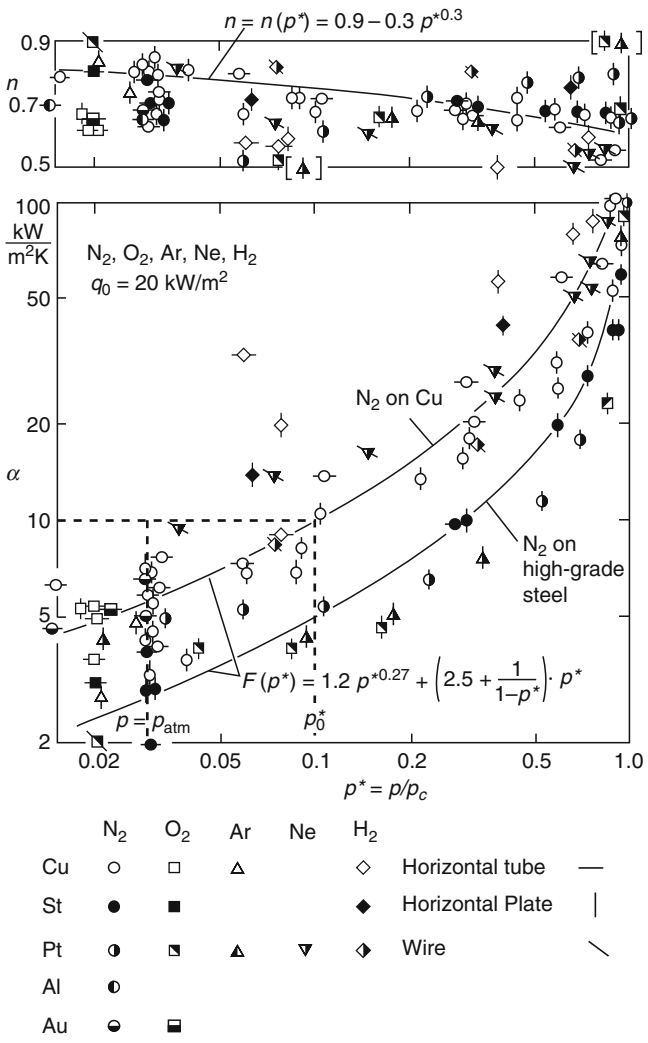
and

$$F(p^*) = 1.73p^{*0.27} + 6.1p^{*2} + \left(0.68p^{*2}\right)/\left(1 - p^{*2}\right) \tag{7b}$$

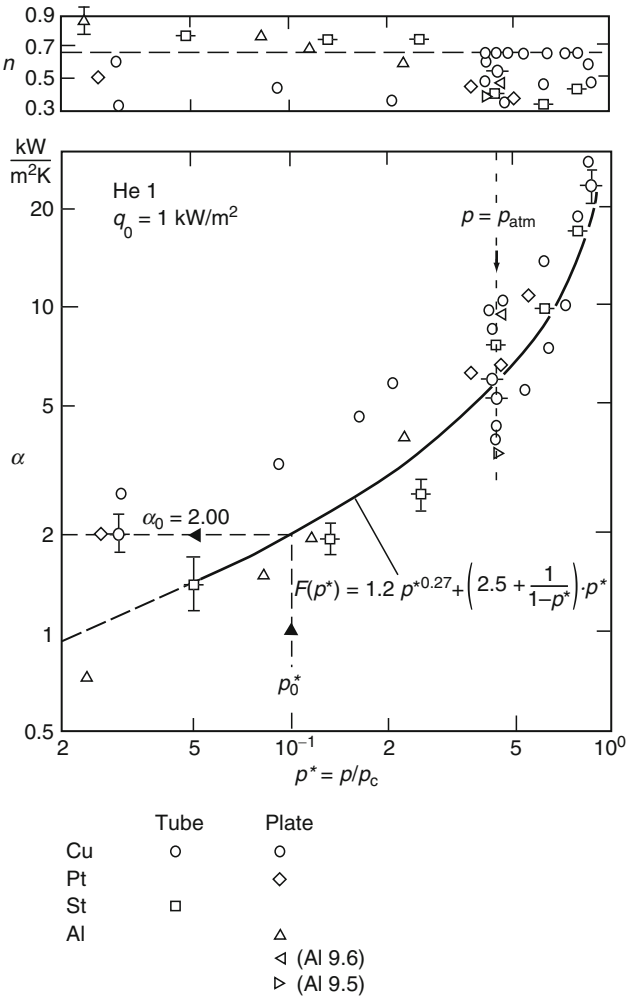
had been established from the former measurements (Fig. 10) that differed somewhat from those for the other fluids. As no new experimental results have been found to support an update for water, Eqs. (6b) and (7b) should continue to be applied. Suggestions of *Fritz* in the *VDI-Heat Atlas* of 1963 (dot-dashed lines in the upper and lower parts of Fig. 10) for both



H2. Fig. 7. Pressure dependence of the exponent n and of α for nucleate boiling of three groups of fluids on single horizontal copper cylinders. Full curves according to Eqs. (6a) and (7a), dot-dashed curves from calculation method before the update. (**a**) (top, left): Hydrocarbons (from [17, 18, 26–39]). (**b**) (bottom, left): Partly fluorinated hydrocarbons = HFC-refrigerants (from [11, 15–18, 20, 31, 40–45]). (**c**) (bottom, right): Alcohols and other organic fluids (from [17–20, 31, 33, 46–49]).



H2. Fig. 8. Heat transfer coefficient α and exponent *n* as functions of the reduced pressure *p** for cryogenic fluids taken from the former edition of the *Heat Atlas* (from [50–72]). The curves in both diagrams represent the former calculation method.

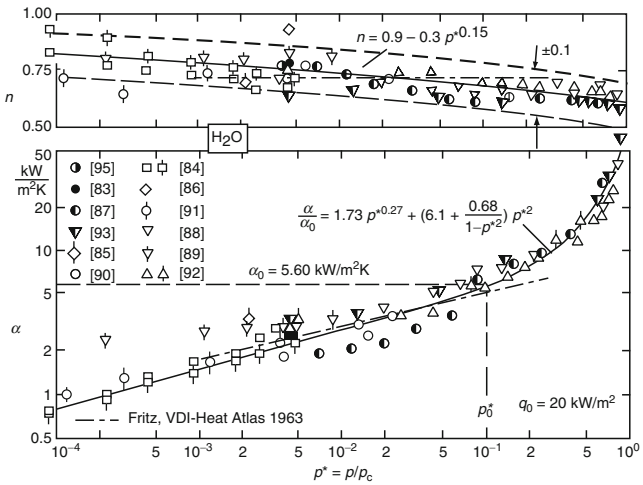


H2. Fig. 9. Heat transfer coefficient α and exponent *n* as functions of the reduced pressure *p** for helium taken from the former edition of the *Heat Atlas* (from [60, 63, 73–82]). The curve in the lower diagram represents the former calculation method.

relationships practically agree with Eqs. (6b) and (7b) within the limited pressure range previously investigated ($0.001 < p^* < 0.1$ or $0.22 < p < 22$ bar, respectively).

Comments on Eqs. (6) and (7):

A. The *upper limit* for the validity of Eqs. (6) and (7) is given by $p^* = 0.9$, because measured values for $p^* > 0.9$ are scanty and are also unreliable owing to the very small superheat of the wall surfaces at these pressures (cf. Fig. 2b). Another reason is that pressures of $p^* > 0.9$ are of little interest in practice at present. The *lower limit* recommended is an absolute pressure of $p = 0.1$ bar (the lowest line in Fig. 5 almost corresponds to this pressure), because nucleation at even lower pressures differs drastically from that at higher pressures; for instance, bubbles with diameters larger than 10 mm at the instant of detachment are often formed. An alternative update of Eq. (6) was proposed by Ribatski and Saiz Jabardo in 2003 [96] (see also [45]), based on their own measurements, by modifying the exponent of p^* from 0.3 to 0.2, instead of modifying the first term from 0.9 to 0.95 as



H2. Fig. 10. Heat transfer coefficient α and exponent *n* as functions of the reduced pressure *p** for water taken from the former edition of the *Heat Atlas* (from [83–95]). The curves in both diagrams represent the former (and new) calculation method for water according to Eqs. (6b) and (7b).

done in Eq. (6a). This results in almost the same n-values as in the former Eq. (6a) at the upper limit of $p^* = 0.9$ (with $n = 0.606$ updated from 0.609) and a somewhat larger change at the lower limit of approximately $p^* = 0.003$ ($n = 0.806$ updated from 0.847).

B. Straight lines for α at $p^* = \text{const.}$ as in Fig. 5 end in free convection without bubble formation (dot-dashed line) or at the maximum heat flux q_{crit} of nucleate boiling (dashed vertical lines in Fig. 5). Unlike the straight extrapolations to q_{crit} in Fig. 5, the slope n may decrease during the approach to q_{crit}. Evaporators are usually designed to operate at a heat flux well below q_{crit}. For operating conditions close to this limit, it would be advisable to verify the calculations by experiment.

C. The steep increase of α with p^* according to Eq. (7) also follows from Eq. (2) and the pressure dependencies of surface tension and slope of the vapor pressure cuve in a calculation model given in [17, 24, 25], which also implies that the exponent n is incorporated in F_p of Eq. (5), if this function is determined using properties of the fluid instead of the empirical function $F(p^*)$ given in Eq. (7). Furthermore, the $\alpha(q)$-increase according to Eq. (6) also depends on the distributions in size and spatial arrangement of the active nucleation sites, that is, on the roughness pattern of the heated surfaces [20, 45, 96, 97]. These interrelations between the $\alpha(q)$, $\alpha(p)$, and $\alpha(R_a)$ dependencies show that the assumption of *separate* influences of the various groups of parameters on α in Eq. (5) is only a first order approach.

3.3 Effect of the Properties of the Fluid

In the concept Eq. (5) is based upon, the influence of the properties of the fluid are (arbitrarily) separated in two parts, the one related to the variation of pressure is represented within F_{p*} or Eq. (7), respectively, and the other at the constant reduced reference pressure p_0^* is expressed by α_0 (Fig. 11). This latter part is presented in Table 1 in the form of the column for the updated experimental values $\alpha_{0,exp}$ from Figs. 6 and 7 (and pertaining references). When the experimental surface roughness $R_{a,exp}$ differed from the reference roughness R_{a0}, $\alpha_{0,1}$ of the figures was adjusted by means of Eq. (9), as discussed in Sect. 3.4. Superscript *d* denotes fluids for which experimental data are sparse; *f* denotes fluids without update. The experimental values from the *Heat Atlas* 1991/1993 are also tabulated, to show the effect of the update. While all new data are for copper tubes as heating elements, the data preceding the update were predominantly for tubes (and for copper as wall material) and a few other geometries (and materials).

In the two upper diagrams of Fig. 11, the updated and former values of $\alpha_{0,exp}$ are shown by large shaded and open circles respectively and the experimental results from the various new sources are shown by small open circles, plotted in logarithmic scales against the property ratio P_f. As can be seen, the data are correlated well by the power law

$$\alpha_{0,calc} = 3.58 P_f^{0.6}, \text{ with } P_f = (dp/dT)_{sat}/\sigma \qquad (8)$$

where $(dp/dT)_{sat}$ is the slope of the vapor pressure curve and σ is the surface tension, both at the reference pressure $p_0^* = 0.1$.

This representation, used first in [18], results from considerations in [24] (also discussed in [2, 17, 25]) and from former plots employing P_f in its reciprocal form [33, 97]). As can be seen from comparing the new averaged experimental heat transfer coefficients $\alpha_{0,exp}$ for each of the 28 updated fluids in the upper two diagrams of Fig. 11 and the pertaining values in Table 1 with $\alpha_{0,calc}$ determined from Eq. (8), the maximum deviation of the calculated, from any of the experimental values, is less than $\pm 9\%$ (except for ethene), with a mean deviation below $\pm 4\%$.

In Fig. 11 (third from the top), Eq. (8) is compared with the updated values for the 28 fluids above (closed symbols) and 26 not yet updated fluids of Table 1, together with water and ammonia, but without helium (open symbols). It follows that the mean deviation for all the fluids of Table 1, again excluding helium, rises to slightly below $\pm 10\%$, because the mean deviation of the 26 not updated fluids (excluding helium) is significantly higher, (below $\pm 15\%$, open circles).

As before the update, it is recommended that $\alpha_{0,exp}$ be used instead of $\alpha_{0,calc}$ for all fluids with reliable experimental values in Table 1 (without superscript *d* or *f*), particularly in those cases where the values calculated with Eq. (8) are higher than the experimental ones.

Because of the extended principle of corresponding states, the success of this correlation with a dimensional constant does not imply that $(dp/dT)_{sat}$ and σ are the only properties that would appear in a mechanistic model for α_0.

A further development of the correlation is to employ a reference fluid, together with the reference wall material, so that Eq. (8) may be written in the dimensionless form (see the diagram at the bottom of Fig. 11)

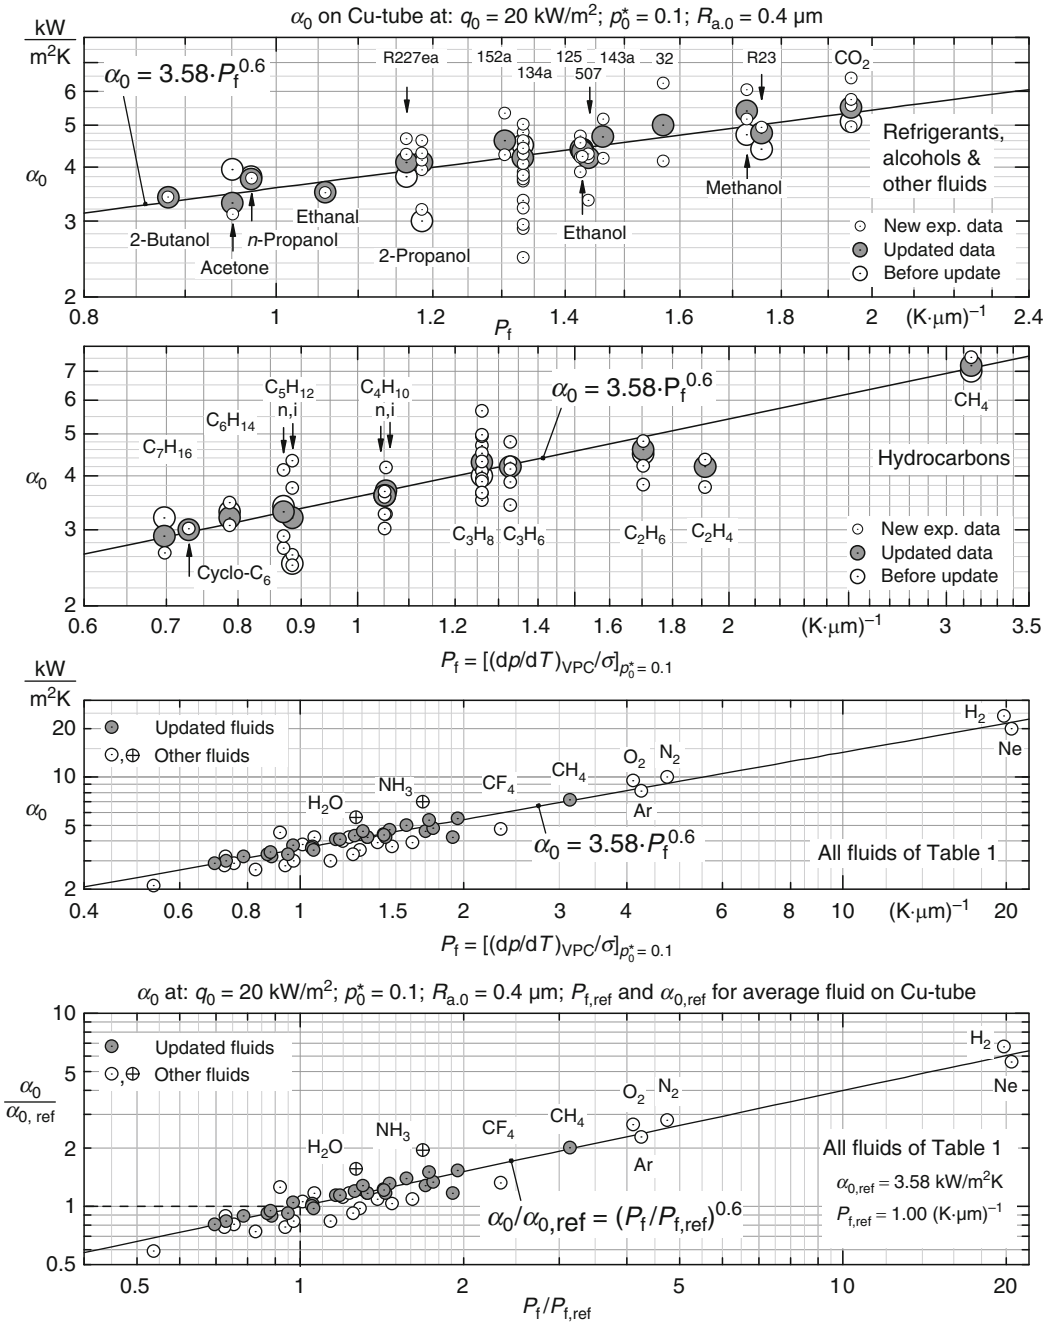
$$\alpha_0/\alpha_{0,ref} = \left(P_f/P_{f,ref}\right)^{0.6} \qquad (8a)$$

A suitable reference is a fictitious fluid with the intermediate experimental $\alpha_0(P_f)$-relation of Eq. (8) and the fluid parameter $P_f = 1\ (\mu m\ K)^{-1}$, which lies in the middle of the P_f-variation for the fluids important in practice ($0.5 < P_f < 2$) except for the cryogenics and liquid metals. Thus for this fluid boiling on a copper surface with the reference roughness, the fluid reference values are $\alpha_{0,ref}$ ($= \alpha_{0,exp}$) $= 3.58$ kW/m^{2}K, $P_{f,ref} = 1.000\ (\mu m\ K)^{-1}$. As can be seen from Table 1, also the three fluids *i*-butane, *n*-pentane, and R12 could be used as reference fluids because the calculated and experimental α_0-values for each of them are the same (and their P_f being in the intermediate range).

In a separate column of Table 1, values of $\alpha_{0,calc}$ have been determined using the former calculation method in which the Stephan/Preusser correlation [83] at $p^* = 0.03$ (near p_{atm}) and Eq. (7) are applied (using the new form of Eq. (7) and recent sources for the many properties of the fluids incorporated in the correlation). Also for this calculation method, the mean deviation from the experimental data is only slightly higher, but the new method in Eqs. (8) and (8a) has the advantage that it contains only two thermophysical properties of the fluids. It is up to the user to determine which of the two Eqs. (8) or (8a) to apply because the calculations result in the same values. Equation (8a) allows now to rewrite Eq. (5) in a more consistent way

$$\alpha/\alpha_{0,ref} = F_q F_{p*} F_f F_w \qquad (5a)$$

with $\alpha_{0,ref}$ being the fixed value given above (and included in Eq. (8)), and the influence of the fluid properties at p_0^*



H2. Fig. 11. Heat transfer coefficient α_0 at the reference conditions as function of the property ratio P_f. Upper two diagrams: Comparison of Eq. (8) with the data for 28 fluids before and after the update (open or shaded big circles), together with the experimental data from the various new sources (small open circles). Lower two diagrams: Comparison of Eqs. (8) and (8a) with the updated values for the 28 fluids above (shaded circles) and the 28 other fluids of Table 1 (open circles), excluding helium.

being represented by F_f (or the right-hand side of Eq. (8a), respectively), in *relative* form as for the other three groups of parameters.

3.4 Effect of the Properties of the Heater

The quantitative effect exerted by the material of the heated wall and the texture of its surface on the heat transfer coefficient over a wide range of pressures in nucleate boiling is far less well understood than the three groups of effects discussed in Sects. 3.2 and 3.3 above (see, e.g.,[19, 20, 28, 45, 49, 98]. Consequently a method of general validity for the determination of the function F_W in Eq. (5) cannot be submitted.

In the following, the limited experimental evidence available at present is used to develop a preliminary method of representing separately the influences of the material of the heated wall and the roughness texture of its surface, thus

$$F_W = F_{WR} \cdot F_{WM}. \quad (9)$$

For this separation, it is essential to have an appropriate quantitative specification of the surface texture. It cannot be

assumed that the same texture will be represented by the same value of a single roughness parameter, or that a particular surface treatment will result in the same texture for different wall materials. The influence of unknown differences in the roughness may be interpreted erroneously as part of the influence of the material.

Stephan [95] in 1963 found that $\alpha \propto R_a^{2/15}$, expressed here in terms of the reference roughness R_{a0}:

$$F_{WR} = (R_a/R_{a0})^{2/15}. \quad (9a)$$

Originally, a different parameter in the former German standard DIN 4762/1:1960 was chosen by Stephan because it could be related to the volume of vapor trapped in the roughness cavities of the heating surface. This relationship is not implied, however, in any of the parameters defined in the new standard ISO 4287/1:1984.

From comparative measurements on metal surfaces that had been finished in a variety of ways (drawn, turned, milled, emeried, and sandblasted), see [99] and former editions of the *VDI-Heat Atlas*, it was shown that a power law relationship exists between the former parameter and R_a that is valid over a large range of R_a-values $0.1 < R_a < 10$ µm, and that $R_{a,0} = 0.4$ µm is a representative value for metal surfaces, for which R_a generally lies in the range $0.2 < R_{a,m} < 0.6$ µm. Therefore, Eq. (9a) can be written in terms of R_a as has been done here, and the reference value chosen is $R_{a,0} = 0.4$ µm.

Subsequently, other correlations have been developed for $\alpha(R_a)$, either with a slight influence of the reduced pressure [100,101] but about the same *average* $\alpha(R_a)$-dependency as in Eq. (9a), or without the influence of p^* [45] but with a somewhat more pronounced increase of α with R_a. For the sake of simplicity and a "conservative" approach (because roughness will mostly be higher in industrial applications than for laboratory specimens), Eq. (9a) is recommended for use until the influences of surface texture are better understood.

Among the properties of the *wall material*, the effusivity $b = (\lambda\rho c)^{0.5}$, the square root of the product of thermal conductivity λ, density ρ, and specific heat capacity c is particularly important for the transient conduction of heat in the wall to the active nucleation sites on its surface. In Table 2, heat transfer coefficients are compared for five heaters with defined surface roughness and made of four different materials. From the data it can be concluded that the influence of the wall material may be represented very approximately by

$$\alpha \propto (\lambda\rho c)^{0.25} = b^{0.5} \text{ or } F_{WM} = (b/b_{Cu})^{0.5}, \quad (9b)$$

if the influence of the surface roughness has been eliminated by Eq. (9a) (in a similar approximation). The heaters are four tubes with different diameters and a thin wire, the wall materials are copper, mild steel St35.8, high-grade steel, and platinum. The fluids are propane and the refrigerant R134a boiling at $p_0{}^* = 0.1$, and the results for three heat fluxes are given (50, 20, and 5 kW/m^2).

All the experimental values in Table 2 were first converted to the same arithmetic mean roughness height $R_{a,0} = 0.4$ µm by

H2. Table 2. Approximate representation of the influence of the wall material (and surface roughness) on the heat transfer coefficient in Eq. (9) shown for experiments with horizontal heaters of different diameters and wall material as examples. Boiling liquids: Propane and R134a at $p^*_0 = 0.1$

[a]Some of the values interpolated from experimental data for other heat fluxes, but uncertainty for this within experimental limits of error.

means of Eq. (9a) and then the α-values for the different metals were calculated using Eq. (9b) and the $\alpha_{0.4}$-data of the copper tube. As can be seen, the α-values calculated at the reference heat flux $q_0 = 20$ kW/m^2 are conservatively lower than the measured values by 0–20% and the same holds approximately for the two other heat fluxes – but only for *conversion* in the above direction, that is, *starting from copper*. Equation (9b) has been included in the German editions of the *Heat Atlas* since 1994.

In preceding editions of the *Heat Atlas*, average experimental α_0-values for stainless steel and platinum besides those for copper were also listed in Table 1 for the three cryogenic fluids oxygen, nitrogen, and argon boiling at $p_0^* = 0.1$ and $q_0 = 20$ kW/m^2. As no information about surface roughness was found at that time, the data were assigned to $R_{a,0} = 0.4$ µm. Also for these fluids, Eq. (9b) was used to convert the data for copper to the other metals, and the deviations remained within the limits given above, despite the additional uncertainty about the roughness (Table 3).

From the above, the function F_W in Eqs. (5) and (10) can be written as

$$F_W = (R_a/R_{a0})^{2/15}\left[(\lambda\rho c)/(\lambda\rho c)_{Cu}\right]^{0.25}. \qquad (9c)$$

The reference conditions are $R_{a,ref} = R_{a,0} = 0.4$ µm and $(\lambda\rho c)_{ref} = (\lambda\rho c)_{Cu}$. It is convenient to use copper as reference wall material because most of the data in the literature were measured with copper heaters. The geometrical characteristics of the wall, such as the diameter of horizontal tubes, do not appear in F_W. The data of Table 2, corrected for the influences of roughness and wall material by Eq. (9), verify the outcome of other recent investigations [20, 103, 107] that the diameter of the tubes, within a wide range of variation, has little influence on α at intermediate heat fluxes, if the average superheat of the circumference is used in the definition of α (Eq. (1)). This may also be seen already from the experimental values for the two tubes with $D = 7.6$ or 88.4 mm, with the same wall material and almost the same surface roughness (Table 2).

As follows from detailed examinations in [20], the effect of different heater diameters on nucleate boiling heat transfer mainly consists of convective influences of the bubbles, which slide along the heated surface and improve heat transfer with increasing heater diameter, particularly at small to intermediate heat fluxes and not too elevated reduced pressures, by providing additional vapor–liquid interface for evaporation near the heated surface. This may be incorporated in Eq. (6) in the future as more systematic evidence becomes available.

Comments (A, B) on Eq. (9a) and (C, D) on Eq. (9b):

A. There is experimental evidence that the single *mean* roughness parameter used in Eq. (9a) is not sufficient to determine the influence of surface roughness on the heat transfer coefficient in nucleate boiling. For instance, a few cavities with reentrant internal shapes that are particularly suited for trapping small amounts of vapor during bubble detachment will increase heat transfer at small heat fluxes (and not too elevated reduced pressures) without affecting the R_a-value of an otherwise very smooth surface. On the other hand, the great number of tiny cavities produced by sandblasting with fine grain will improve heat transfer at high heat fluxes and reduced pressures in comparison with a smooth emery-ground surface with the same small R_a-value.

B. For very rough surfaces (e.g., $R_a > 3$ to 5 µm), the increase of α with R_a according to Eq. (9a) may be found up to very high R_a-values of about 10 µm at high heat fluxes and is even more pronounced at lower fluxes [28] on surfaces that have been sandblasted with coarse steel particles of irregular shape, because tiny cavities are produced along with the large cavities that dominate R_a. By contrast, blasting with coarse glass beds, as in [45], will also result in large cavities and high R_a-values, but only a few small cavities with reentrant characteristics will be formed. Thus, the increase according to Eq. (9a) will exist only at the lowest q-values but vanish or change in the opposite direction at high heat fluxes [45].

It follows from (A) and (B) that more roughness parameters should enter Eq. (9a) to characterize the shape and size distribution of the cavities within the roughness texture, as Stephan has pointed out already in his pioneering work of 1963. Applying R_a with more fitting parameters (e.g., as in [28]) will not predict the behavior of surfaces differing from those fitted.

C. Equation (9b) should only be applied to convert heat transfer coefficients from copper to metals with lower effusivity

H2. Table 3. Equation (9b) applied to experimental data in former editions of the Heat Atlas for cryogenic liquids boiling on heaters made of different metals at $p^*_0 = 0.1$, $q_0 = 20$ kW/m^2

Material of heater		Copper			Platinum			Stainless steel

$\frac{\alpha_{exp} - \alpha_{calc}}{\alpha_{exp}}$	in %	0	0	0	11.3	4.1	17.8	6.5

[a] Material properties of copper assumed as included in Table 2.
[b] $R_a = R_{a,0} = 0.4$ µm assumed as no data on roughness available.
[c] Properties of high-grade steel as in Table 2 applied. Using properties of two common qualities of high-grade steel, as given in Part D of the *Heat Atlas*, would reduce deviation from 6.5 to 4.2% or −1.5%.

because the positive deviations in Tables 2 and 3 indicate that its influence may be overestimated somewhat. Its use for conversion in the opposite direction would result in nonconservative overprediction of the heat transfer coefficient on a copper surface.

D. Special care has to be taken when using Eq. (9b) for metal alloys. The examples in Tables 2 and 3 indicate that the prediction is no worse than for pure metals. However, it should not be used without experimental verification for alloys that contain components with highly different thermal conductivity (or effusivity), as is the case for CuNi10 or different grades of brass (Cu with 20–40% Zn). For all these copper alloys, heat transfer coefficients no smaller than for copper have been found in some reliable measurements [31, 35, 37, 45]. Variations in properties on a crystalline microscale may influence transient conduction processes between closely spaced nucleation sites. Another weakness of Eq. (9b) is that at present it does not consider the wetting properties of the system metal – fluid at the fluid-solid boundary.

3.5 Effect of Industrial Scale Evaporators

Including the effects discussed above, Eq. (5) can be rearranged to give

$$\alpha/\alpha_{0,\mathrm{ref}} = (q/q_0)^{n(p^*)} F(p^*) \left(P_f/P_{f,\mathrm{ref}}\right)^{0.6} (R_a/R_{a0})^{2/15} \left[(\lambda\rho c)/(\lambda\rho c)_{\mathrm{Cu}}\right]^{1/4}. \quad (10)$$

Examples of parameters, other than those embraced by Eq. (10), that may affect the performance of industrial-scale free-convection evaporators are

- The geometry of the individual heating elements (e.g., finned tubes and tubes with surfaces to augment boiling) and the entire layout of the evaporator (tube bundles; horizontal and inclined flat walls; etc.);
- Additives and adulterants in the boiling liquid (e.g., wetting agents, oils, or dissolved substances that are deposited on the heated surfaces);
- The operation of the plant (e.g., the admission of subcooled liquid and intermittent operation with on–off control.

Calculating the heat transfer coefficient α_{10} from Eq. (10) for fully developed nucleate boiling *on a single horizontal copper tube*, allowance for these effects can be made by introducing an average heat transfer coefficient $\bar{\alpha}$ and appending appropriate corrections, that is,

$$\bar{\alpha}/\alpha_{10} = C_{\mathrm{G}} C_{\mathrm{Ad}} C_{\mathrm{Op}} \quad (11)$$

where C_{G} is the correction for the geometry; C_{Ad}, for the adulterants in the boiling liquid; and C_{Op}, for the particular mode of operation.

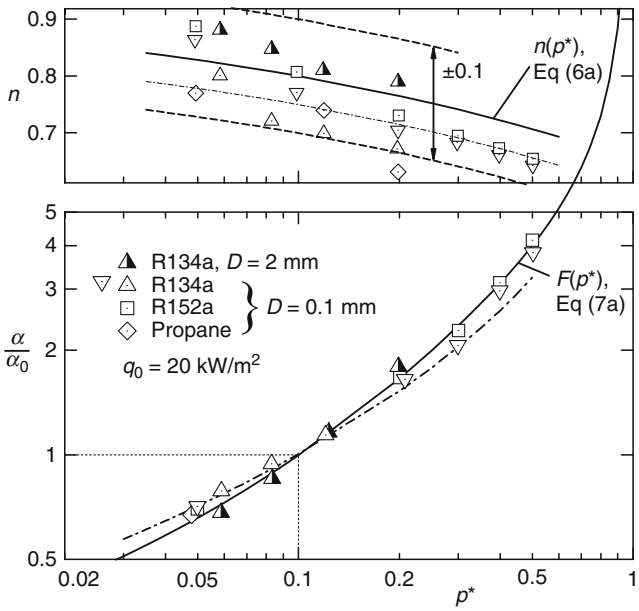
The design of large shell-and-tube evaporators is hampered by the lack of reliable information in the literature. One reason for the scantiness of reliable data is the factor of uncertainty involved in scaling up the results obtained in research setups. Another reason is that the three parameters for which corrections are allowed usually occur simultaneously in large pilot plants and cannot be separated. Hence, the results obtained on individual items or equipment or their assemblies cannot be presented, even to a limited extent, in a generalized form.

Thus very approximate correlations will be proposed in the sections that follow only for the first factor in Eq. (11), while the others will be discussed in the form of hints for making rough estimates. (Priority in the near future must be devoted to the improvement of Eq. (9c), while the factors in Eq. (11) should be verified by experiment in each case for the individual items of equipment or assemblies.)

3.5.1 Geometry

With respect to their geometry, there are no significant differences *in the relative increases* of the heat transfer coefficient α with the heat flux q or reduced pressure p^* between horizontal tubes and horizontal flat plates or wires. For plates, this has been shown in former editions of the *Heat Atlas* (and is evident also from Fig. 14); for thin tubes (D = 2 mm) and wires, it is demonstrated in Fig. 12 by comparing new experimental results with Eq. (6a) or (7a), respectively.

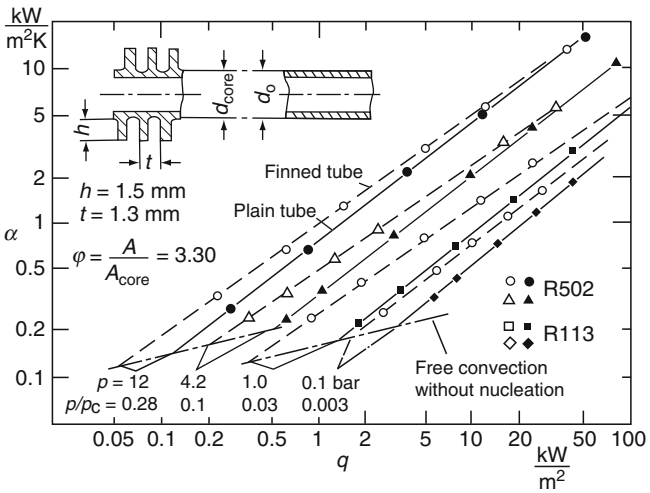
On the other hand, differences may occur *in the absolute values of* α for horizontal tubes and those for flat plates or thin wires. In the case of flat plates, flow development and edge effects exert influences that are absent for horizontal tubes. In the case of thin horizontal wires, the differences may be caused by the entirely different ratio between the diameters of the heating element and the detaching bubbles, in comparison with tubes. This ratio becomes similar to the normal conditions



H2. Fig. 12. Relative pressure dependence of α and the exponent n for various fluids boiling on a thin tube and wires ([104–106]) in comparison to Eqs. (6a) and (7a), shown as solid lines, or the calculation method in previous editions of the *Heat Atlas* (dot-dashed lines).

for tubes at lower reduced pressures only at very high reduced pressures $p^* > 0.9$ with bubble radii < 50 µm [3].

Roughly, the same applies to vertical heated surfaces, because an improvement in heat transfer brought about by additional convection at the lower end is accompanied by an impairment at the upper end due to the restriction imposed by the rising cloud of bubbles on the liquid inflow. In some cases, the flow velocity at the lower end of vertical heated surfaces or through horizontal tube bundles may greatly exceed the upward velocity of the free-flowing bubbles. Under these circumstances, heat transfer must be determined by the methods described in Chap. H3 (Flow Boiling) for forced-circulation evaporators.



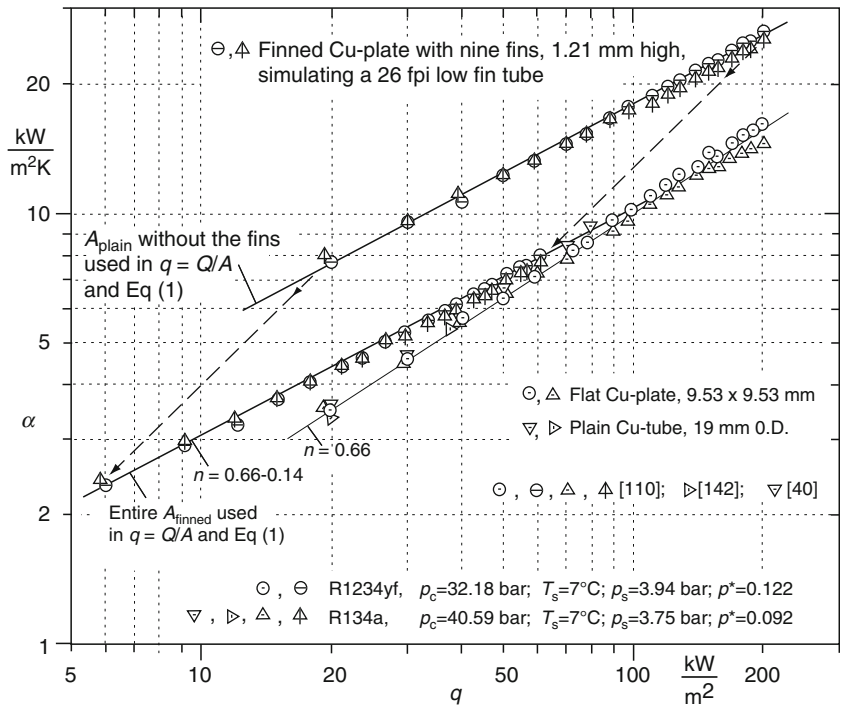
H2. Fig. 13. α as a function of q for a finned and a plain tube of the same core diameter. Parameter: Pressure p or reduced pressure p^*. Both α and q expressed in terms of the total outer area of the respective tube.

3.5.2 Finned Tubes and Tubes with Artificial Cavities

Within the range of initial nucleate boiling where the heat flux is low, horizontal evaporator tubes with external fins (as sketched in Fig. 13) transfer heat more efficiently than plain tubes. This is illustrated in Fig. 13 for the range of pressures extending from 0.3 to 30% of the value at the critical point and in Fig. 14 for a flat plate with similar fins at p^* near 0.1.

Throughout almost the entire range of heat flux concerned, the finned tube has a higher heat transfer coefficient, expressed in terms of the external area, than the plain tube. (In Fig. 13 and in all further general considerations on finned tubes, the heat transfer coefficient defined by Eq. (1) was not derived from the temperature at the actual surface but from that at the base of the fins. It is thus referred to as the "apparent heat transfer coefficient.")

The increase in α can be ascribed to the great roughness at the crests of the fins and the additional convection caused by the bubbles that rise along the flanks of the fins. Both kinds of influences increase heat transfer at low heat fluxes more than at higher, so the effect of the heat flux on α is weaker for finned tubes than for plain. And the same holds for the (relative) effect of pressure because the augmentation of α by convection is (almost) independent of pressure.



H2. Fig. 14. $\alpha(q)$-dependency for R134a and the new refrigerant R1234yf boiling on flat plain or finned copper plates ([110], extended).

As a consequence, the exponent n will be less than that for a plain tube, and the pressure dependence of $F(p^*)$ will be weaker. A rough estimate for the *effect of the heat flux on finned tubes* can be obtained from

$$n_f(p^*) = n(p^*) - 0.1\, h/t_l \tag{6c}$$

where n_f and n are the indices in the terms for the heat flux ratio – in Eq. (5) or (10) – for the finned and plain tubes respectively and $n(p^*)$ can be obtained from Eqs. (6a) and (6b); h is the height of the fins; and t_l is the free spacing between fins. Approximate allowance can be made for the *effect of the reduced pressure* by substituting the term $(p^*/\sqrt{\varphi})$ for (p^*) in $F(p^*/\sqrt{\varphi})$ or $F(p^*)$ of Eqs. (7a) and (7b), that is,

$$F_{f,p^*} = F(p^*/\sqrt{\varphi}) \tag{7c}$$

where φ is the ratio of the surface area of the finned tube to that of a plain tube of the same core diameter.

If no experimental data are available for verification, Eqs. (6c) and (7c) should not be used except for copper tubes of conventional dimensions (trapezoid-shaped – also called K-shaped – fins as sketched in Fig. 13 and t_l not much smaller than 1 mm), and unless the pressure is within the range $0.02 > p^* < 0.3$ (or from somewhat below 1 bar to not much above 10 bar).

Allowance for the roughness of finned tubes should not be in the form of Eq. (9), because the great dissimilarities in the surface structure of the fin crests and the other parts of the tubes produce conditions completely different to those encountered for plain tubes. However, a great allowance has already been introduced by the modifications made in the relationship between the heat transfer coefficient, the heat flux, and the pressure.

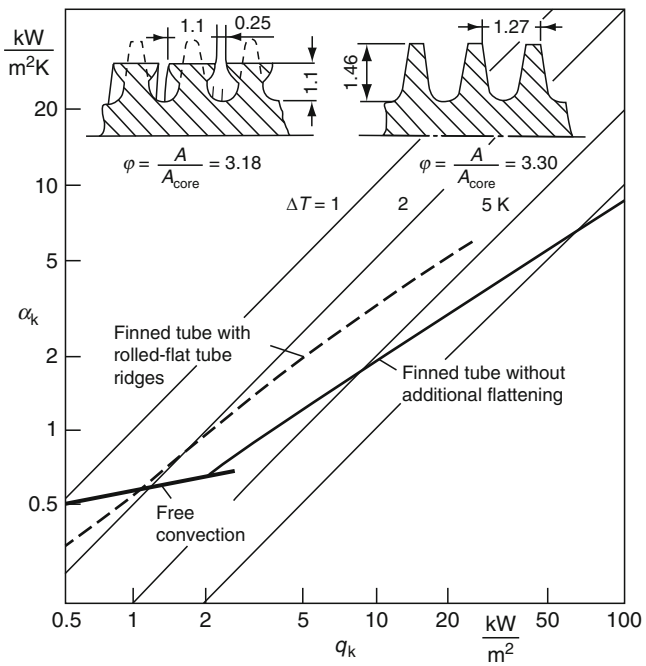
A fact that can be exploited in estimating the *reference value* $\alpha_{0,f}$ *for finned tubes* is that the heat transfer coefficients for both finned and plain copper tubes, are approximately the same at a heat flux of about 100 kW/m^2 and reduced pressures near $p^* = 0.1$:

$$\alpha_{100,\text{finned}} = \alpha_{100,\text{plain}} \text{ at } q = 100 \text{ kW/m}^2 \text{ and } p_0^* = 0.1. \tag{8c}$$

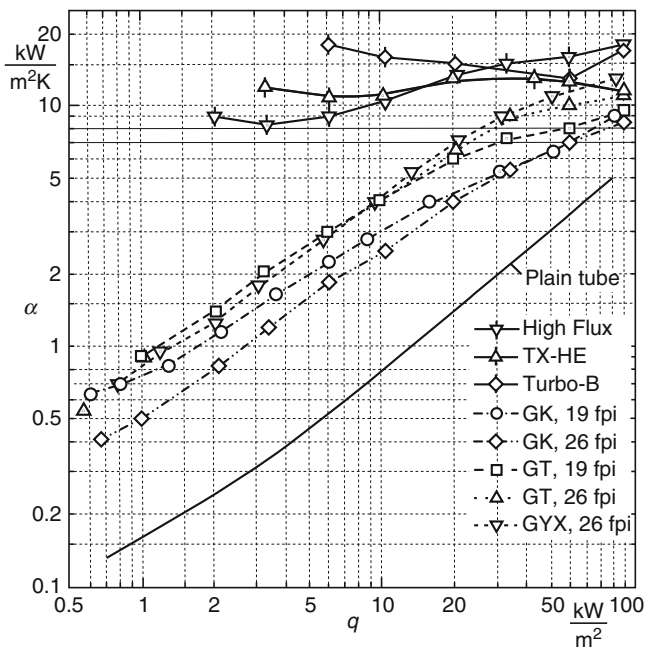
This is evident from Figs. 13 and 14. Thus, the first step will be to calculate the heat transfer coefficient $\alpha_{100,\text{plain}}$ that applies for both tubes from α_0 using Eq. (8) or Table 1 and from $n(p^*)$ applying Eq. (6). $\alpha_{0,f}$ can then be derived from $\alpha_{100,\text{finned}}$ using Eq. (6c), see Example 2 and Fig. 20.

The method suggested here yields results that agree well with measured values (cf. Figs. 17b, c and 20). Equally good agreement is achieved by a calculation method devised by Slipcevic [108] (also discussed in [109]).

The differences in n and α that exist between plain and integral-fin (K-shaped) tubes and are used in the method discussed above have also been verified in very recent experiments [110] with R134a and the new refrigerant R1234yf (see Table 1) boiling on small flat plain or finned copper plates that can be applied in the cooling of electronic chips (Fig. 14). As in the method, the (somewhat extrapolated) line for the finned plate and the interpolation line for the plain intersect near 100 kW/m^2 and the difference of 0.14 in n corresponds to 0.1 h/t_l in good approximation. The absolute values of α measured in [110] lie at the lower limit of the experimental scatter, as shown in [39] also for other fluids investigated by this group.



H2. Fig. 15. Heat transfer coefficient as a function of the heat flux in nucleate boiling of Refrigerant R11 at a pressure of 1.3 bar for two tubes with fins of the same basic structure, but one with the ridges of the fins flattened by rolling (α_k and q_k expressed in terms of the area A_{core}).



H2. Fig. 16. Heat transfer coefficient as a function of the heat flux for Refrigerant R114 boiling at 1 bar on different structured and porous surfaces (from [115], modified in [111]).

In the past decades, a great variety of evaporator tubes with enhanced surfaces containing artificial nucleation sites have been developed (see, e.g., the reviews in [111–114] and Figs. 15 and 16), that can be divided into two main groups, one based on integral-fin tubes with modified fins to form reentrant grooves or tunnels ("structured surfaces," e.g., the T-type in Fig. 15 or the four types with broken interpolation lines in Fig. 16), and another based on plain tubes with sintered porous metallic matrix bonded to the tube surface ("porous surfaces," e.g., the three types with solid interpolation lines in Fig. 16).

The examples in Figs. 15 and 16 demonstrate the typical improvement of heat transfer from *structured* surfaces over plain tubes for pressures near atmospheric. The improvement by the porous surfaces is much better, but their α, q-behavior is entirely different (also for higher pressures [116]), thus ending up with basically the same heat transfer coefficients for all kinds of surfaces at high heat fluxes near 100 kW/m^2.

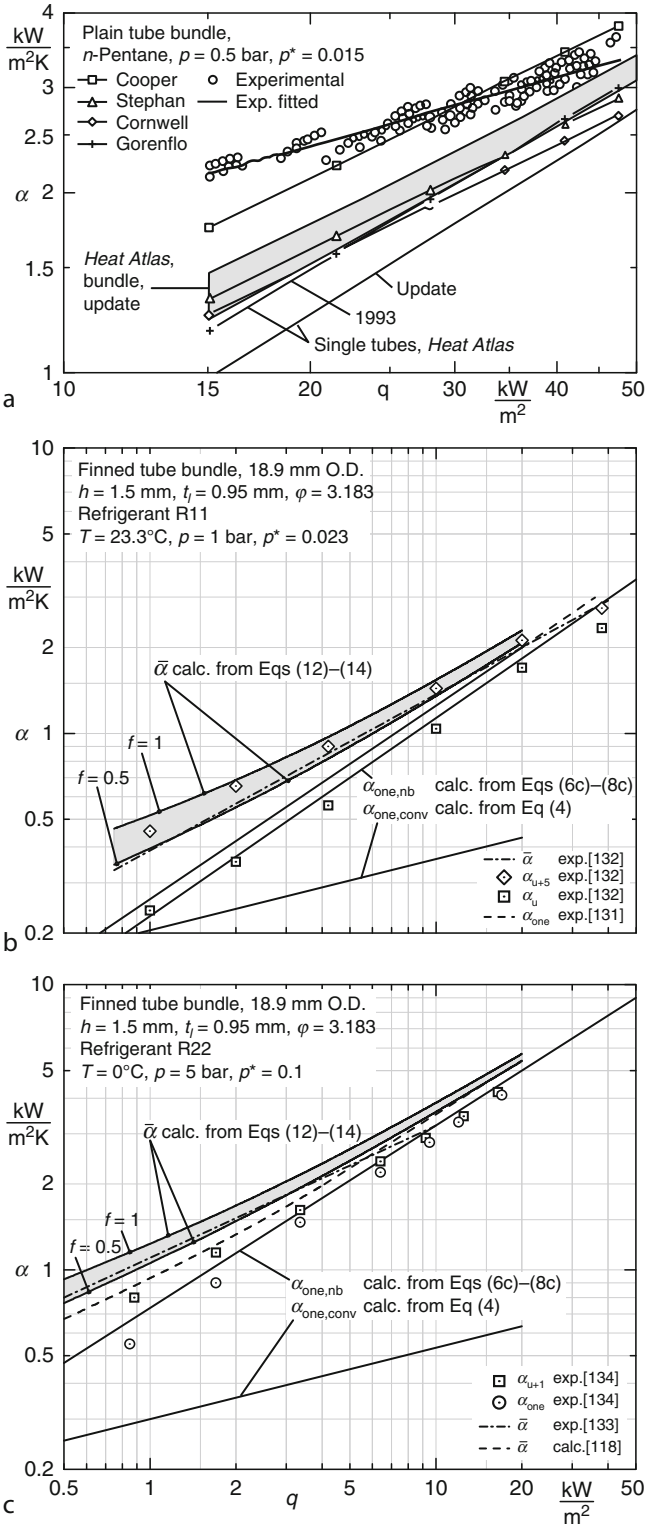
The few examples of nucleate boiling heat transfer from tubes with artificial reentrant cavities shown in Figs. 15 and 16 give an impression of the difficulties in the development of calculation methods for enhanced boiling heat transfer from the many complex commercially used surface configurations. In the reviews cited above, a great number of correlations are discussed, but their application without experimental verification is not yet safe, if extrapolation to configurations other than the particular one used in the development of the method is required.

3.5.3 Horizontal Tube Bundles

If the heat flux is low or moderate, the average heat transfer coefficient in nucleate boiling on the outer surfaces of horizontal tubes in a bundle is higher than that for a single tube. One reason for this is that the liquid inlet is designed to cope with the requirements for the entire bundle, with the result that the flow rate over the lowermost bank of tubes is higher than that over a single tube. Another reason is the rising cloud of bubbles within the bundle.

A significant number of proposals have appeared in the literature for the calculation of the contributions thus made toward heat transfer [117–125]. In the discussion on Eq. (11), attention was drawn to the problems involved in the interpretation of experimental results and to their application in the design of tube-bundle evaporators. In view of these remarks, there would be no justification for a complicated mathematical outlay; for this reason, the following simple method, analogous to those described elsewhere [117, 118], is recommended for horizontal tube bundles operating under the restricted condition that the flow velocity of the cloud of bubbles within the bundle is similar to that for the swarm of bubbles leaving a single horizontal tube. If it is much higher, the calculation methods of two-phase flow should be employed [126–130] (see also the remarks at the end of Sect. 4 on the effect of bubbles coming from lower tube banks).

First, the average heat transfer coefficient $\bar{\alpha}$ for the tube bundle is separated in a purely formal manner into the



H2. Fig. 17. Calculated and measured values of the heat transfer coefficient as functions of the heat flux for tube bundles. (**a**) *n*-Pentane boiling on a plain tube bundle at $p = 0.5$ bar (according to [120], extended). (**b**), (**c**) Refrigerants R11 or R22 boiling on finned tube bundles. The indices $u + 1$ and $u + 5$ denote the bank of tubes as counted from the undermost (see specimen calculation in Example 2 and Fig. 20).

coefficient α_u for the undermost row and the relative improvement $(\bar{\alpha}/\alpha_u)$ within the bundle. Thus,

$$\bar{\alpha} = \alpha_u(\bar{\alpha}/\alpha_u). \tag{12}$$

α_u is calculated by additive superposition of the heat transfer coefficient $\alpha_{one,nb}$ and the convective contribution $\alpha_{one,conv}$, both for a single tube, that is,

$$\alpha_u = \alpha_{one,nb} + f\alpha_{one,conv} \tag{13}$$

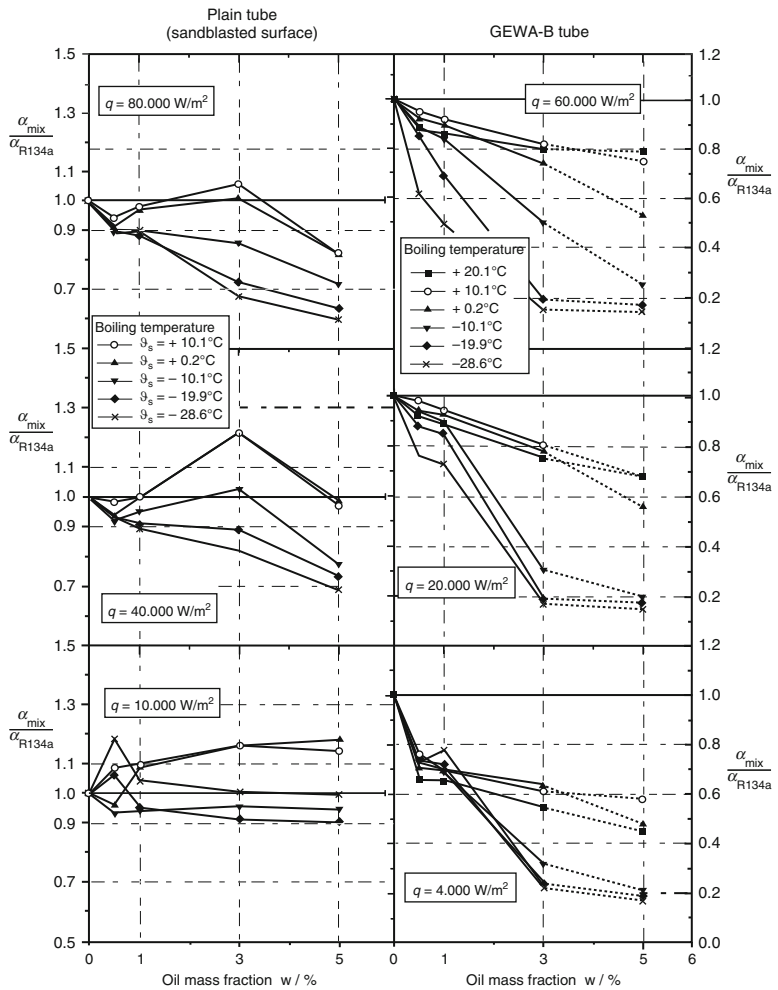
where the factor f depends on the size of the tube bundle and the anticipated inlet flow velocity, where $0.5 \leq f \leq 1$.

The evaluation of data extracted from the literature gives the following approximate *dimensional* expression for $(\bar{\alpha}/\alpha_u)$:

$$(\bar{\alpha}/\alpha_u) = 1 + (2 + q\varphi)^{-1} \tag{14}$$

where q is the heat flux in kW/m^2 on the *total outer surface area* of the tubes, and φ is the area ratio (φ = 1 for plain tubes). Equation (14) applies for $(q\varphi)$ between ca. 1 and 20 kW/m^2 and for near-atmospheric pressure, that is, about 0.5–10 bar. The evaluation of Eqs. (12)–(14) for bundles of plain and finned tubes is illustrated in Fig. 17 and, in connection with Example 2, in Fig. 20. For the sake of simplicity and in the light of the restriction mentioned above, $\alpha_{one,conv}$ is calculated there for natural convection from Eqs. (3) and (4). A better approximation would be to estimate the rising velocity of the cloud of bubbles within the bundle from the vapor volume varying with heat flux and pressure.

A condition that has been assumed in the derivation of these equations is that q = constant for the entire tube bundle. This is certainly not satisfied if the bundles are heated by a liquid. In this case, the heat flux for the individual segments or rows in the bundle must be estimated from the difference between the temperature of the heating medium and that of the boiling liquid at the inlet to each segment of the bundle [132, 135].



H2. Fig. 18. Relative variation of the heat transfer coefficient for R134a/SE55 oil mixtures boiling on a plain tube with fine sandblasted surface (*left*) or an enhanced (GEWA-B) tube (*right*) versus oil mass fraction at different pressures and heat fluxes (according to [140], modified).

3.5.4 Impurities

As a rule, adulteration of the boiling liquid by another impairs heat transfer (cf. Sect. 4). The only impurities that can increase the transfer of heat above that of the pure liquid are surface active agents, if they are added in low concentrations, but the improvement is usually slight [134, 136–139]. The increase can be ascribed to the decrease in surface tension and the associated reduction in the energy required to produce viable bubbles. Typical new results obtained by Spindler and Hahne [140] on adding oil to refrigerants boiling on plain or enhanced tubes are shown in Fig. 18. It is evident that the oil may augment (by surface active ingredients) or reduce heat transfer in the case of the plain tube as has been found for many refrigerants mixed with different lubricating oils in the literature (various new sources are given in [140]); on the other hand, only degradation of heat transfer occurs in Fig. 18 for the enhanced tube.

Impurities in the form of dissolved or suspended additives that are deposited on the heated surface usually give rise to heat transfer coefficients that are lower than those for nucleate boiling of the pure liquid.

Apart from the presentation of results of individual measurements, no method yet exists for estimating the effect of impurities on the heat transfer coefficient in nucleate boiling.

3.5.5 Evaporator Operation

All the experimental results that have been described up to now in Sect. 3 and the calculation methods developed from them apply to the case in which the potential nucleation sites are fully activated at the wall superheat and the liquid is in the saturated state associated with the reigning pressure at some distance from the heated surface. If the operation of the evaporator does not allow these conditions to be adhered to, the heat transfer coefficients in the range of initial nucleate boiling are lower than those that would be expected from Eqs. (5) to (10).

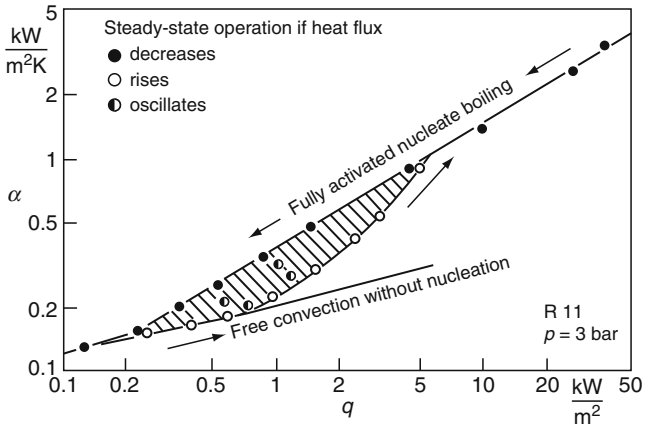
On–off controllers or gradual increments in heat flux increase the likelihood that nucleation is not completely activated. As a consequence, an operating point is reached between fully activated nucleation and free convection without bubble formation, as is illustrated by the hatched zone in Fig. 19.

A corresponding effect is brought about by the entry of subcooled liquid. In this case, therefore, Eq. (3) or (4) should be used instead of Eq. (5) in order to allow a safeguard, even if the heat flux or superheat is somewhat higher than that corresponding to the commencement of nucleate boiling.

3.5.6 Examples

Example 1

Calculate the length of a single cylindrical rod of 10 mm outer diameter required to transfer 1 kW for the evaporation of water at $p = 100$ bar. The superheat is $\Delta T = 3$ K.



H2. Fig. 19. Effect of the mode of operation on the heat transfer coefficient at initial nucleate boiling of Refrigerant R11 on a finned tube at $p = 3$ bar [141] (similar results in [135, 136]).

$Q = 1$ kW $= \pi\ D\ L\ \alpha\ \Delta T$. The desired length is $L = Q/\pi\ D\ \alpha\ \Delta T$.

The heat transfer coefficient is calculated in the following steps:

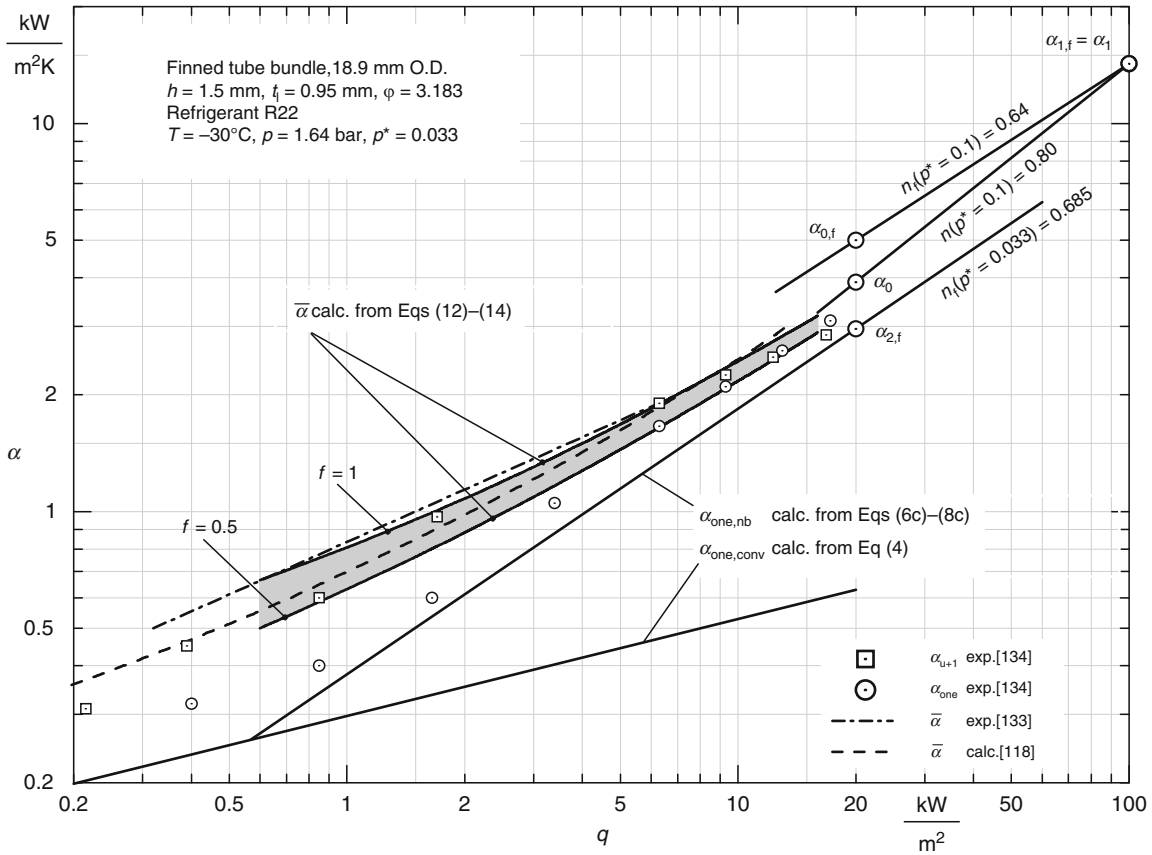
a. According to Table 1, the reference value is $\alpha_{0,\mathrm{exp}} = 5.60$ kW/m^{2}K at $q_0 = 20$ kW/m^2 and $p_0^* = 0.1$. A value of 4.13 kW/m^{2}K, that is, ca. 26% lower, is obtained from Eq. (8). For the highly associating fluid water, the experimental value is preferred to the principle of corresponding states.
b. Conversion into the value at $p_1 = 100$ bar: Since $p_c = 220.64$ bar (Table 1), $p_1^* = 0.453$. Equation (7b) then gives $\alpha_1/\alpha_0 = F(p_1^*) = 2.186$ or $\alpha_1 = 2.186\alpha_0 = 15.77$ kW/m^{2}K (at $p_1 = 100$ bar and $q_1 = 20$ kW/m^2).
c. $\alpha(q)$ at p_1: Equation (6b) gives $n(p_1^*) = 0.634$; thus, $\alpha \sim q^{0.634}$ at p_1.
d. $\alpha(\Delta T)$ at p_1: $\alpha \sim q^{0.634} = (\alpha\Delta T)^{0.634}$ according to Eq. (1); therefore, $\alpha \sim \Delta T^{1.73}$.
e. α_2 at $\Delta T_2 = 3$ K and $p_2 = p_1$: $\alpha_2/\alpha_1 = (\Delta T_2/\Delta T_1)^{1.73} = 4.442$, as $\Delta T_1 = q_1/\alpha_1 = 1.267$ K. Thus $\alpha_2 = 4.442\ \alpha_1 = 70.0$ kW/m^{2}K and $q_2 = 210$ kW/m^2.

Since α_2 is near 100 kW/m^{2}K, it should be checked how close the heat flux q_2 is to the maximum in nucleate boiling (Fig. 5). It follows from Sect. 5 that $q_{\mathrm{crit}} > 1000$ kW/m^2 $>> q_2$. (The values of the maximum heat flux that can be obtained for water are much higher than those for most organic liquids.)

The length of rod required is thus $L = (1/0.01 \times 70 \times 3 \times \pi)$ m $= 15.1$ cm.

Example 2

An evaporator has to be designed in which Refrigerant R22 boils at −30°C (Fig. 20). The tubes have fins of $h = 1.5$ mm height spaced at $t_l = t - b = 0.95$ mm. The area ratio is $\varphi = 3.18$. Determine $\alpha(q)$ for the tube bundle; that is, $\alpha_f(q)$ has to be developed for the saturation pressure of R22 at −30°C,



H2. Fig. 20. α as a function of q, as calculated from Eqs. (4) to (14) (see Example 2). Comparison with experimental data [133, 134] and with a calculation method [118]. $u + 1$ denotes the bank of tubes immediately above the undermost.

p = 1.64 bar or $p/p_c = p^* = 0.0329$ (with p_c = 49.9 bar from Table 1).

The calculation proceeds in the following steps:

a. α_0 for a single plain tube:
According to Table 1, the reference value is $\alpha_{0,\text{exp}} = 3.90$ kW/m^{2}K at $q_0 = 20$ kW/m^2 and $p_0^* = 0.1$. A value of 4.37 kW/m^{2}K, that is, 12% higher, is obtained from Eq. (8). For a safe design, $\alpha_{0,\text{exp}}$ is preferred.

b. $\alpha_{0,f}$ for a single finned tube:
According to Eq. (8c), $\alpha_{1,\text{finned}} = \alpha_{1,\text{plain}}$ at $q_1 = 100$ kW/m^2 and $p_0^* = 0.1$.
$\alpha_{1,\text{plain}}$ follows from Eq. (10) and $\alpha_{0,\text{exp}}$ at $p_0^* = 0.1$:
$\alpha_1/\alpha_0 = (q_1/q_0)^n = (100/20)^n = 3.624$, with $n(p^* = 0.1) = 0.800$ from Eq. (6a).
So $\alpha_1 = 3.624\ \alpha_0 = 14.13$ kW/m^{2}K $= \alpha_{1,f}$. $\alpha_{0,f}$ for the finned tube is obtained in the same way backward:
$\alpha_{0,f}/\alpha_{1,f} = (20/100)^{n_f} = 0.3558$, with n_f $(p^* = 0.1) = 0.642$ from Eq. (6c), and $\alpha_{0,f} = 0.3558\ \alpha_{1,f} = 5.03$ kW/m^{2}K.

c. $\alpha_{2,f}$ at $p_2 = 1.64$ bar or $p_2^* = 0.0329$:
According to Eq. (7c), $\alpha_{2,f}/\alpha_{0,f} = F_{2,f,p^*}(p*/\sqrt{\varphi})/F_{0,f,p^*}(p*/\sqrt{\varphi}) = 0.5922$.
Hence $\alpha_{2,f} = 0.5922\ \alpha_{0,f} = 2.98$ kW/m^{2}K, with $n_{2,f} = 0.684$ from Eq. (6c).

Thus, the following applies for a single tube at $p_2^* = 0.0329$:
$\alpha_{\text{one,nb}} = C_{\text{nb}}\, q^{0.684}$, where $C_{\text{nb}} = \alpha_{2,f}/q^{n_{2,f}} = 0.384$ and $\alpha_{\text{one,conv}} = C_{\text{conv}}\, q^{0.25}$ with $C_{\text{conv}} = 0.30$ from Eq. (4) and the properties listed for R22 in Part D.

d. Determination of $\alpha(q)$ for the tube bundle from Eqs. (12) to (14):

$$\bar{\alpha} = \alpha_u(\bar{\alpha}/\alpha_u) = \left(\alpha_{\text{one,nb}} + f\alpha_{\text{one,conv}}\right)\left[1 + (2 + q\varphi)^{-1}\right],$$
$$\bar{\alpha} = \left(0.384\, q^{0.684} + 0.30 f q^{0.25}\right)\left[1 + (2 + q\varphi)^{-1}\right].$$

If the upper and lower limits for the estimate are taken to be $f = 1$ and $f = 0.5$ respectively, the hatched zone in Fig. 20 will be obtained. The unit to which the numerical values for α pertain throughout the entire calculation is kW/m^{2}K; and for q, kW/m^2.

4 Nucleate Boiling of Mixtures

4.1 Experimental Evidence

It is found experimentally that the heat transfer coefficient α_{mix} in nucleate boiling of zeotropic binary mixtures is less than an

"ideal" heat transfer coefficient $\alpha_{id,m}$, defined by the molar average of the heat transfer coefficients α_1 and α_2 for the pure components, Eq. (15):

$$\alpha_{id,m} = x_1\alpha_1 + x_2\alpha_2 = x_1\alpha_1 + (1 - x_1)\alpha_2 \qquad (15)$$

where x_1 and x_2 are the molar fractions of components 1 and 2. This was established by Bonilla and Perry for a great number of zeotropic mixtures [143] and has since been confirmed in many other studies that have been reviewed (cf., e.g., [41, 144]. It is also demonstrated by the lowest diagrams of Figs. 21–24 (α_{id} may be defined for constant saturation pressure (Fig. 21d) or constant *reduced* pressure (Figs. 23–25); the latter will be used in Sect. 4 because it is more appropriate for a unified discussion of the results (see also [41, 147]).

Alternatively, the "ideal" heat transfer coefficient α_{id} for mixtures can be defined by using the molar average ΔT_{id} in Eq. (1):

$$\Delta T_{id} = q/\alpha_{id,T} = x_1\Delta T_1 + x_2\Delta T_2 \qquad (15a)$$

where ΔT_1 and ΔT_2 are the temperature differences required to transfer q to the pure components 1 and 2 respectively. Thus,

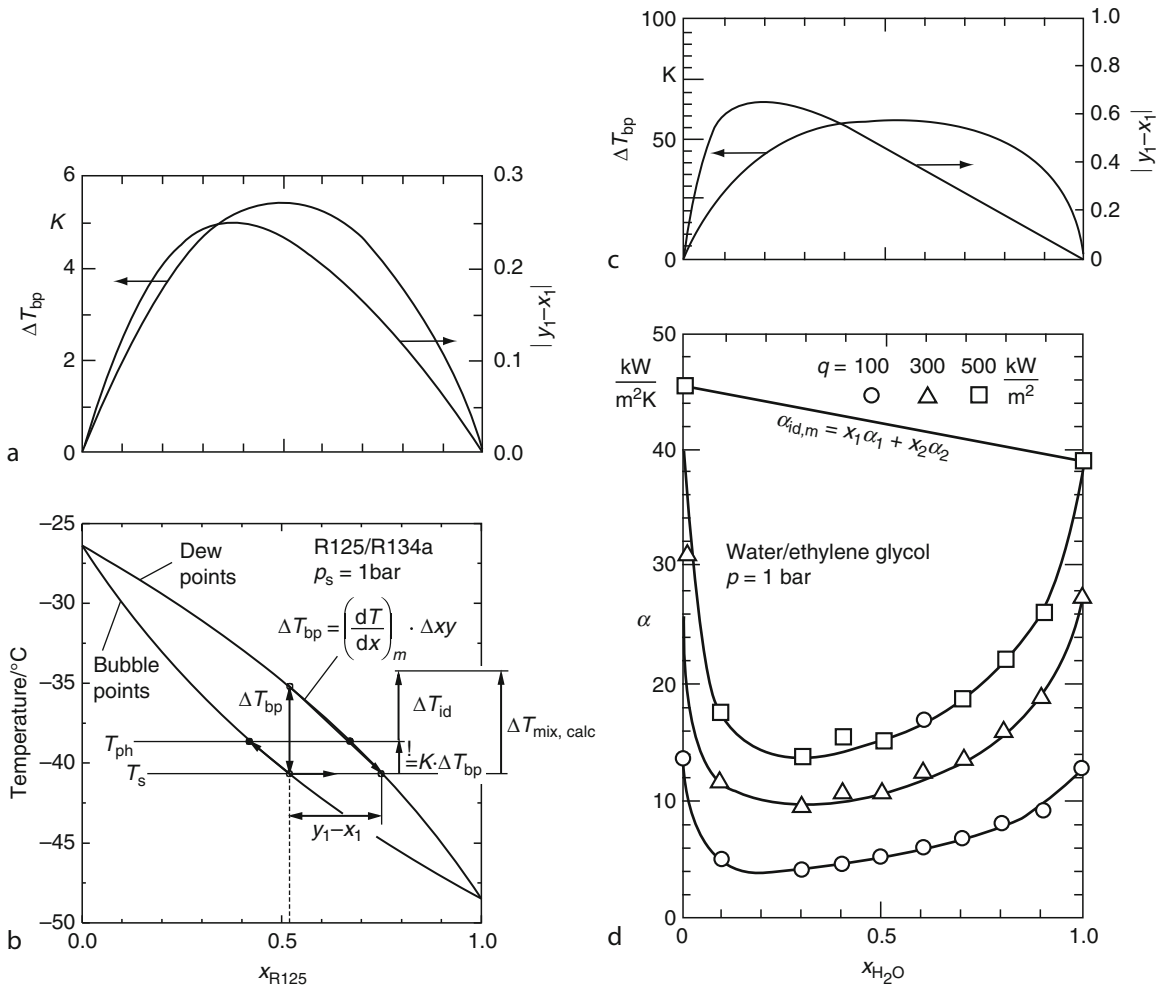
$$q/\alpha_{id,T} = x_1(q/\alpha_1) + x_2(q/\alpha_2) \text{ or } 1/\alpha_{id,T} = (x_1 + \alpha_1) + (x_2/\alpha_2). \qquad (15b)$$

As can easily be verified, $\alpha_{id,T} = \alpha_{id,m}$, if $\alpha_1 = \alpha_2$, and the maximum difference between the ideal coefficients is only about ±5% if α_1 and α_2 vary by about a factor of two, as for the updated list of substances other than cryogens for Eq. (8), in the range $0.7 < P_f < 2$, or $2.89 < \alpha < 5.43$ kW/m^{2}K (Table 1).

By analogy with pure fluids, the actual heat transfer coefficient α_{mix} defined by Eq. (1a) is

$$\alpha_{mix} = q/\Delta T = q/[T_W - T_{sat}(p, x_1)] \qquad (1a)$$

where $T_{sat}(p, x_1)$ is the bubble temperature corresponding to the bulk liquid composition and the system pressure p. In a zeotropic mixture, the equilibrium composition of the vapor differs from that of the liquid, $y_1 \neq x_1$, which is illustrated in Figs. 21–24. Consequently, during evaporation at a finite rate, the *lower* boiling component evaporates preferentially to provide



H2. Fig. 21. Diagrams on the left: (**a**) Nearly symmetrical dependence of the two characteristic features of the vapor/liquid equilibrium, Δxy and ΔT_{bp}, on the composition x of the liquid and (**b**) relationship of these features to the superheat ΔT of the heated wall for the binary refrigerant system R125/R134a (modified from [41]). Diagrams on the right: (**c**) Markedly asymmetrical x-dependence of Δxy and ΔT_{bp} compared with (**d**) the asymmetrical x-dependence of α_{mix} for the binary system water/ethylene glycol (from [145], according to [41]).

the enrichment of this component in the bubbles growing on the heated wall, with an accompanying enrichment of the *higher* boiling component in the liquid within the boundary layer near the wall.

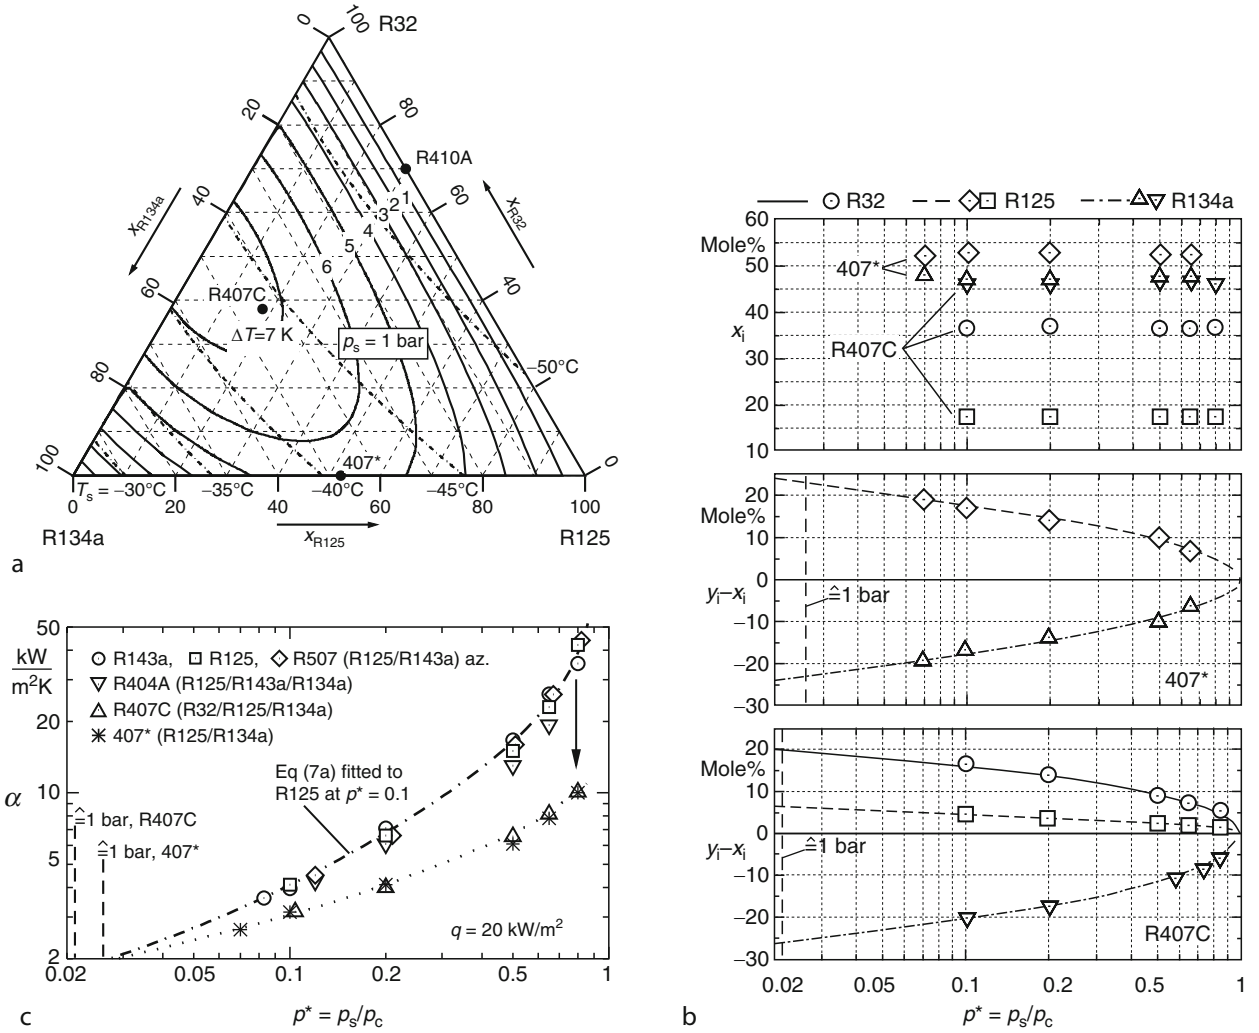
Thus, the temperature T_{ph} of the liquid–vapor interface is elevated over the saturation temperature $T_{sat}(p, x_l)$ (Fig. 21b), and the effective temperature difference ΔT for heat transfer from the surface of the wall through the adjacent liquid to the bubbles is diminished. This causes the reduction in α_{mix} below $\alpha_{id,m}$. The value of T_{ph} depends on processes of mass transfer in the liquid boundary layer, which oppose the local enrichment of the higher boiling component. Simple estimates for T_{ph} form the basis of the calculation methods for the heat transfer coefficients of boiling mixtures discussed in Sect. 4.2.

It follows that the heat transfer coefficient α_{mix} should not fall below the molar average α_{id} if the composition of the vapor (y) in the growing vapor bubbles is the same as that of the undisturbed liquid (x), as in *azeotropic* mixtures. This premise has been confirmed to a good approximation by measurements on such systems. This can also be seen in Fig. 24 for the mixtures of R22/R115 along the azeotropic line [148, 149] and in Fig. 22c, where the α-values for the azeotropic refrigerant R507 are the same as for its components R125 and R143a within the whole pressure range investigated [41, 144].

In the case of binary systems that form an azeotrope, the azeotropic mixture can be regarded as a new pure component, and the system can be divided into two separate binary subsystems. For ternary or multicomponent systems, the definitions of ΔT_{id}, $\alpha_{id,m}$, and $\alpha_{id,T}$ have to be extended to

$$\Delta T_{id} = \sum_i x_i \Delta T_i, \qquad \alpha_{id,m} = \sum_i x_i \alpha_i$$
$$\text{and} \quad 1/\alpha_{id,T} = \sum_i x_i/\alpha_i. \tag{15c}$$

The two binary systems in Figs. 23 and 24 have been taken as examples to illustrate the dependencies of the heat transfer coefficient α on the heat flux q (through the exponent n), reduced pressure p^* (obtained from the experimental value

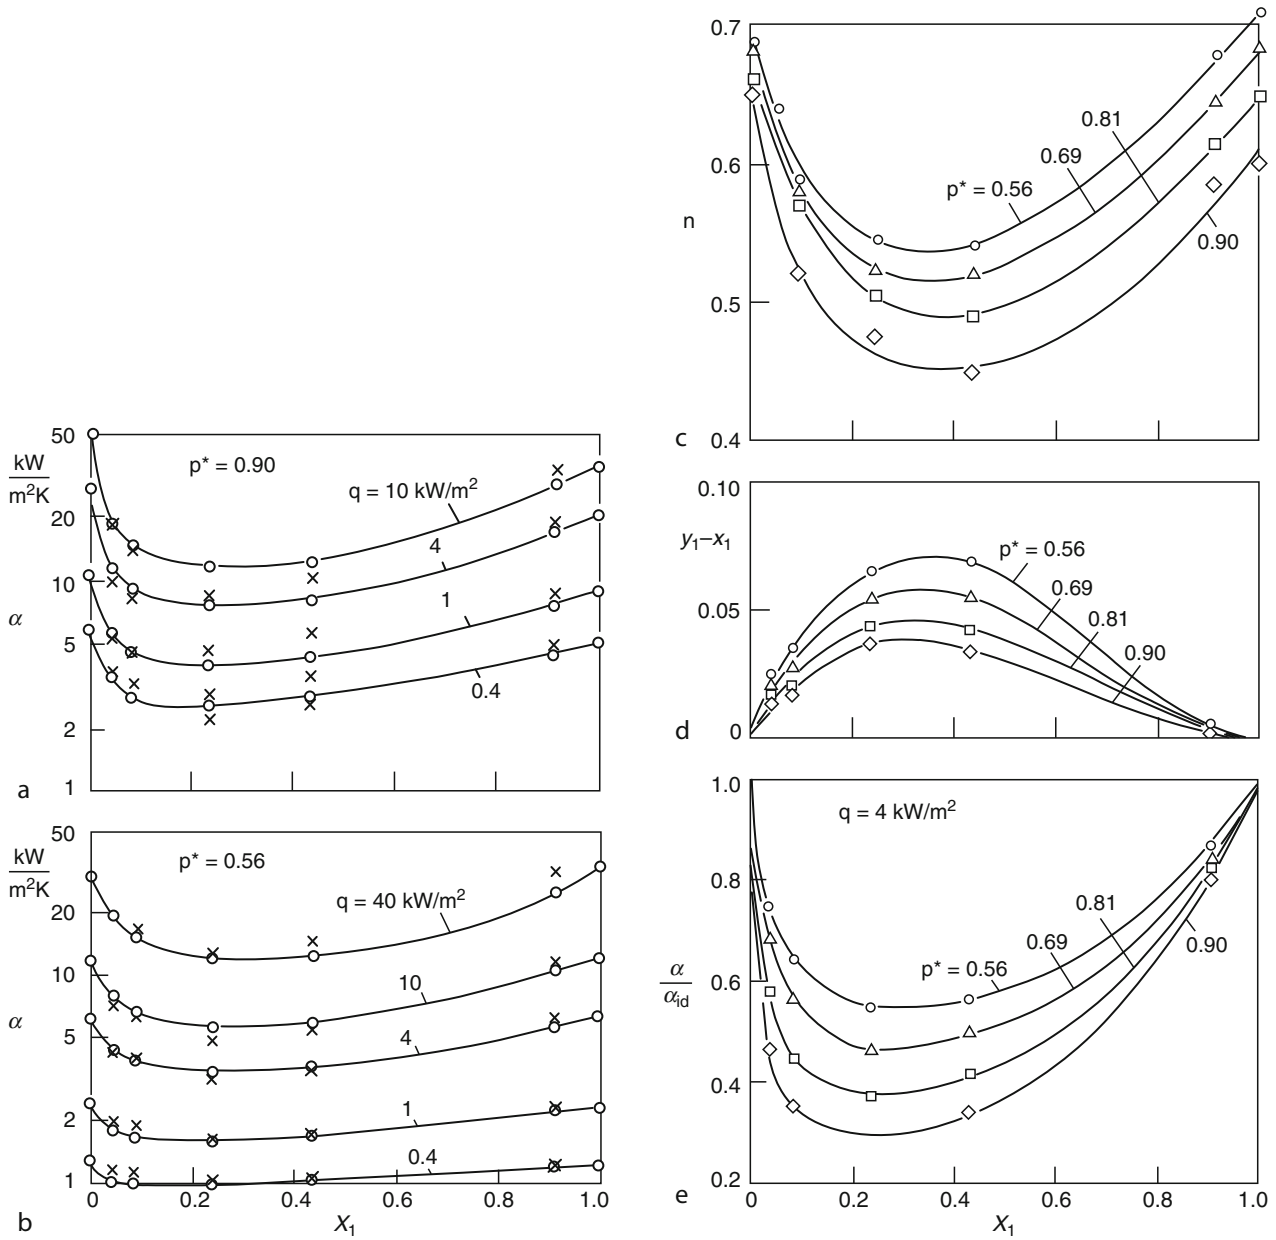


H2. Fig. 22. (**a**) Composition of the liquid and ΔT_{bp} for the ternary mixture R407C and the binary 407* with (almost) the same molar fraction of the higher boiling component R134a. (**b**) Pressure dependence of composition x and shift Δxy for the two mixtures. (**c**) Pressure dependence of α for the two mixtures, for two of the components, for the azeotropic mixture R507, and the ternary R404A (containing only a small fraction of the highest boiling R134a). (Modified from [41], see also [144]).

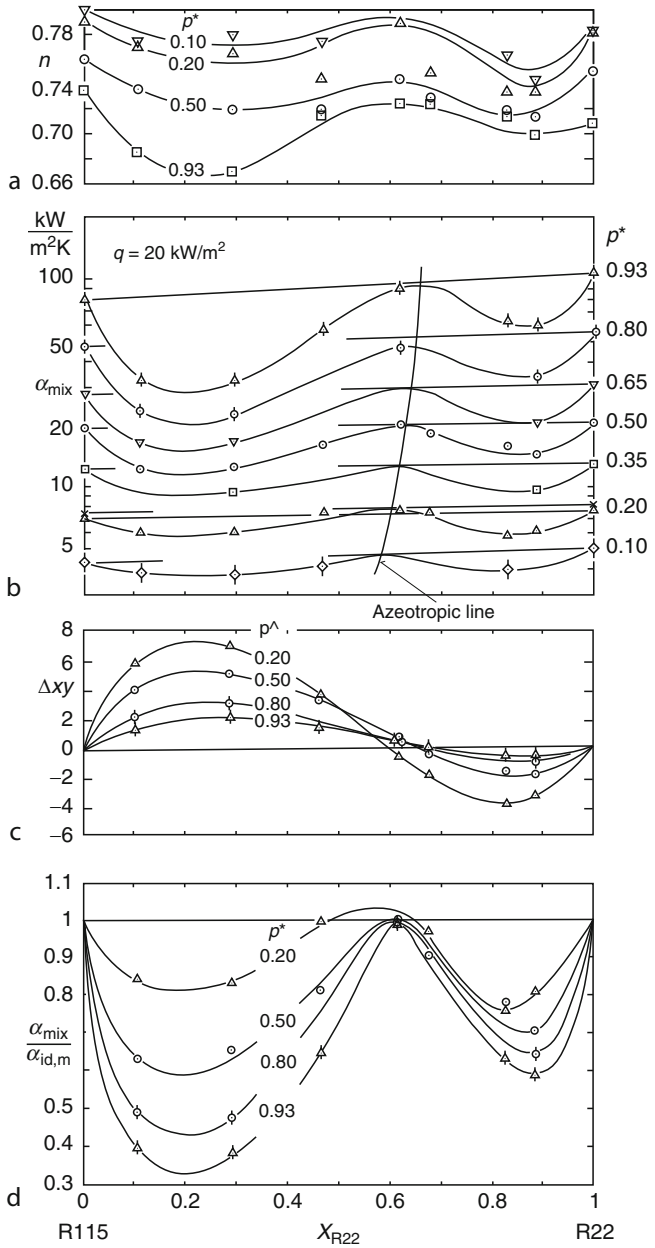
for the critical pressure p_c for each of the mixtures), and composition x of the liquid.

From the diagrams for n, it can be seen that the increase of α with q for zeotropic mixtures is always less than for the pure components; the effect is highest at intermediate compositions and increases with reduced pressure. For the mixtures with compositions along the azeotropic line in Fig. 24, however, n is the same as for the pure components (within experimental error, as also holds for the absolute values of α, diagram below), demonstrating that nucleate boiling heat transfer for azeotropes does not differ from that of the pure components. On the other hand, it also shows that a mixture with fixed composition behaves like an azeotrope only at a certain pressure, while there is zeotropic behavior with at least some difference in the compositions of the vapor and liquid phases at all other pressures.

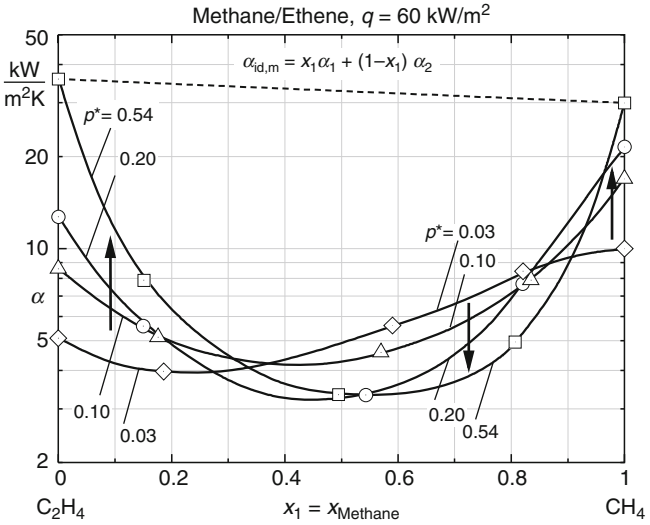
The diagrams in Figs. 21c, d; 23d, e and 24 b–d show that the enrichment $(y_1 - x_1) = (\Delta xy)_1$ of the lower boiling component in the vapor phase and the deterioration of heat transfer in mixture boiling, $\alpha_{id} - \alpha_{mix}$, are greatest for intermediate compositions of the mixtures. A more thorough examination reveals, however, that narrow limits exist for the analogy between the x-dependency of the ratio α_{mix}/α_{id} and those of the difference Δxy and of the "temperature glide" ΔT_{bp} between the dew point and bubble point temperatures at constant x. The two



H2. Fig. 23. Boiling of the binary system sulfur hexafluoride/R13B1 at elevated reduced pressures. Diagrams on the right: (**c**) Exponent n of the $\alpha(q)$-relationship, (**d**) shift Δxy of vapor/liquid compositions, and (**e**) ratio α_{mix}/α_{id} as functions of the molar fraction x_1 of the more volatile component SF_6 (parameter: p^*). According to [146, 147], but with slightly modified values of $n(p^*)$. Crosses (x) in the upper two diagrams: α_{calc} from Eq. (21a) with $B_0/\beta_l = 10^4$ s/m ($B_0 = 2$) for $p^* = \text{const}$.



H2. Fig. 24. *x*-dependence of α for the refrigerant system R22/R115 at seven reduced pressures (together with the *x*, *p**-dependence of the azeotropic compositions = "azeotropic line") and of the exponent *n*, shift Δ*xy*, and ratio α_{mix}/α_{id} at four selected *p**-values. From [148] (see also [149]).



H2. Fig. 25. Variation of α with composition x_1 and reduced pressure *p** for the system methane/ethene at constant, high heat flux (according to [30]).

characteristic phase equilibrium properties can be connected to a good approximation (Fig. 21b) by

$$\Delta T_{bp} = (dT/dx)_m \Delta xy \qquad (16)$$

The main differences in the *x*-dependencies of Δ*xy* and α_{mix}/α_{id} are

a. The minima of α_{mix}/α_{id} occur at significantly lower fractions x_1 than the maxima of Δ*xy* and
b. The impairment of heat transfer in mixture boiling becomes continuously more pronounced as the critical point is approached, whereas the difference in the molar fractions of vapor and liquid decreases (Figs. 22b, c; 23d, e and 24c, d).

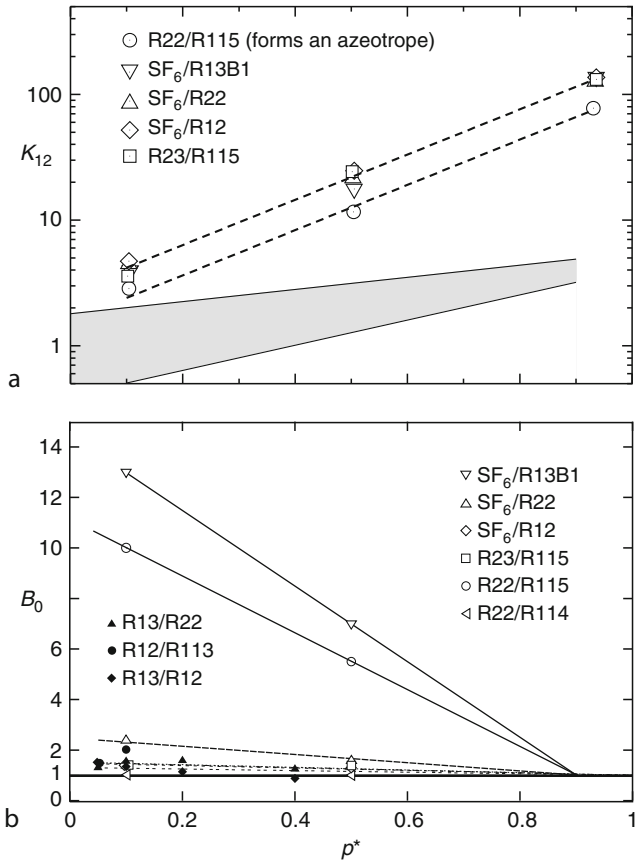
The fact that deterioration of heat transfer tends to vanish despite the increasing difference in the molar fractions toward very low reduced pressures, which is particularly obvious from Fig. 22b and c, is due to a vigorous remixing effect of the liquid in the superheated boundary layer near the heated wall, because (1) big, fast growing bubbles are formed and (2) the density difference between vapor and liquid is large. Both effects result in high acceleration of the vapor *and the liquid* in the immediate vicinity of the heated wall at the detachment of the bubbles and afterward, when they are sliding upward along the tube surface.

With increasing reduced pressure, however, bubble size and the vapor–liquid density difference diminish continuously. Therefore, the turbulent motion of the liquid near the heated wall steadily decreases and the enrichment of the higher boiling component in the liquid within the boundary layer cannot be compensated any longer, even though the difference Δxy decreases continuously, too.

For very wide boiling binaries, deterioration of heat transfer increases drastically with rising reduced pressure, thus compensating or even overcoming the strong increase of α with p^* according to Eq. (7) for the pure components. The latter can be seen in the example of Fig. 25 at intermediate to high fractions of the lower boiling component. This "negative" pressure dependence of α existing here – and for other wide boiling binaries reviewed in [30] – is not a peculiarity, but a continuous trend that may occur for this kind of binary and depends on heat flux and pressure.

4.2 Calculation Methods

Most of the correlations for nucleate boiling heat transfer to mixtures proposed in the past and collected in [41, 144] attempt



H2. Fig. 26. (**a**) Pressure dependence of the parameter K_{12} in Eqs. (18) and (19) as fitted in [151] (symbols) and as given originally (shaded area). (**b**) Pressure dependence of the parameter B_0 in Eqs. (21a) and (23) for various binary refrigerant systems according to [30].

to model the deterioration of heat transfer in terms of the ratio α_{mix}/α_{id} and relate it to the vapor/liquid phase equilibrium by one of its characteristic features Δxy or ΔT_{bp}, respectively.

In an early approach given by Stephan and Körner [150], the superheat ΔT_{mix} in Eq. (1a) is broken down into the ideal component ΔT_{id} and an excess component ΔT^E by analogy to the modeling of the "real" thermophysical properties of fluids, that is,

$$\Delta T_{mix} = \Delta T_{id} + \Delta T^E \text{ or } \Delta T_{mix}/\Delta T_{id} = 1 + \Delta T^E/\Delta T_{id} \quad (17)$$

and $\Delta T^E/\Delta T_{id}$ is linked to Δxy by

$$\Delta T^E/\Delta T_{id} = K_{12}\Delta xy. \quad (18)$$

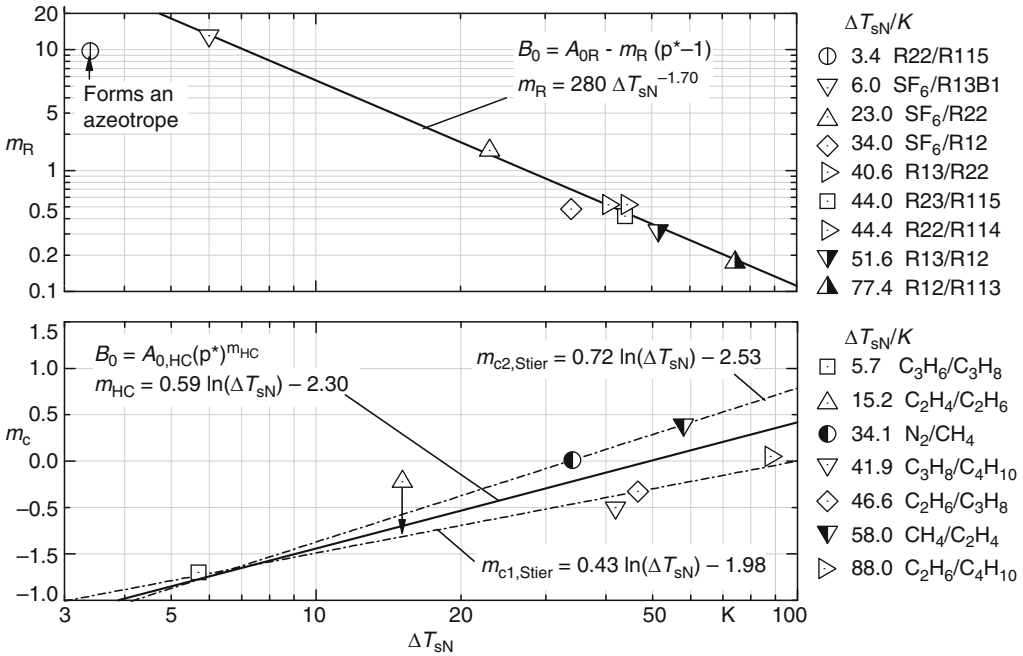
Combining Eqs. (17) and (18) with (15a) and (15b) yields

$$\alpha_{id,T}/\alpha_{mix} = 1 + K_{12}\Delta xy. \quad (19)$$

(The reciprocal relationship of the ratio α_{mix}/α_{id} mentioned above and shown in Figs. 23 and 24 is used in the following to simplify the form of the equations.)

The parameter K_{12} has been fitted at constant heat flux (q = 20 kW/m^2) to various binary systems of refrigerants in [151] – also comprising the two of Figs. 23 and 24 – resulting in a strong increase of K_{12} with reduced pressure (Fig. 26a), which is similar for the five binary systems investigated and reveals a trend of K_{12} increasing with the distance ΔT_{sN} of the normal boiling points of the components (cf. Fig. 27) that can be seen well at the intermediate value of p^* = 0.5 in Fig. 26a.

Using the modified K_{12}-values of Fig. 26a, the representation of experimental data is nearly as good as for recent more sophisticated approaches, particularly at high heat fluxes, as has been shown in [151]. (Originally, values for K_{12} at atmospheric pressure were given in [150, 152–154] together with a much weaker



H2. Fig. 27. Connection of the parameter B_0 with the distance ΔT_{sN} of the normal boiling points of the pure components for mixtures of halocarbon refrigerants (*top*) and hydrocarbons (*bottom*) according to [30].

pressure dependence, the shaded area in Fig. 26a, which restricted the method to near-atmospheric pressures, $p^* < 0.05$).

Employing the measurements on SF_6/R13B1 shown in Fig. 23 and on various other binary systems up to high reduced pressures [147], Schlünder developed a promising calculation method based on the mass transfer by diffusion that takes place in the liquid layer near the heated wall [155] (cf. [156, 157]). Introducing some simplifications that start with the assumption (Fig. 21b)

$$T_w - T_{ph} = \Delta T_{id}, \tag{20}$$

so that the effective temperature difference for heat transfer in the mixture is the same as in the pure components and there are no differences in the mechanisms for bubble formation and release between pure substances and mixtures, then

$$\Delta T_{mix}/\Delta T_{id} = \alpha_{id,T}/\alpha_{mix} = \left[\Delta T_{id} + \left(T_{ph} - T_s\right)\right]/\Delta T_{id} = 1 + \left(T_{ph} - T_s\right)/\Delta T_{id}. \tag{21}$$

Next, modeling $(T_{ph} - T_s)$ by diffusion leads to

$$\left(T_{ph} - T_s\right)] \approx (dT_{sat}/dx_1)(\Delta xy)_1[1 - \exp(-\Phi)] \tag{22}$$

so that Eq. (21) finally becomes

$$\alpha_{id,T}/\alpha_{mix} = 1 + [1 - \exp(-\Phi)](dT_{sat}/dx_1)(\Delta xy)_1/\Delta T_{id} \tag{21a}$$

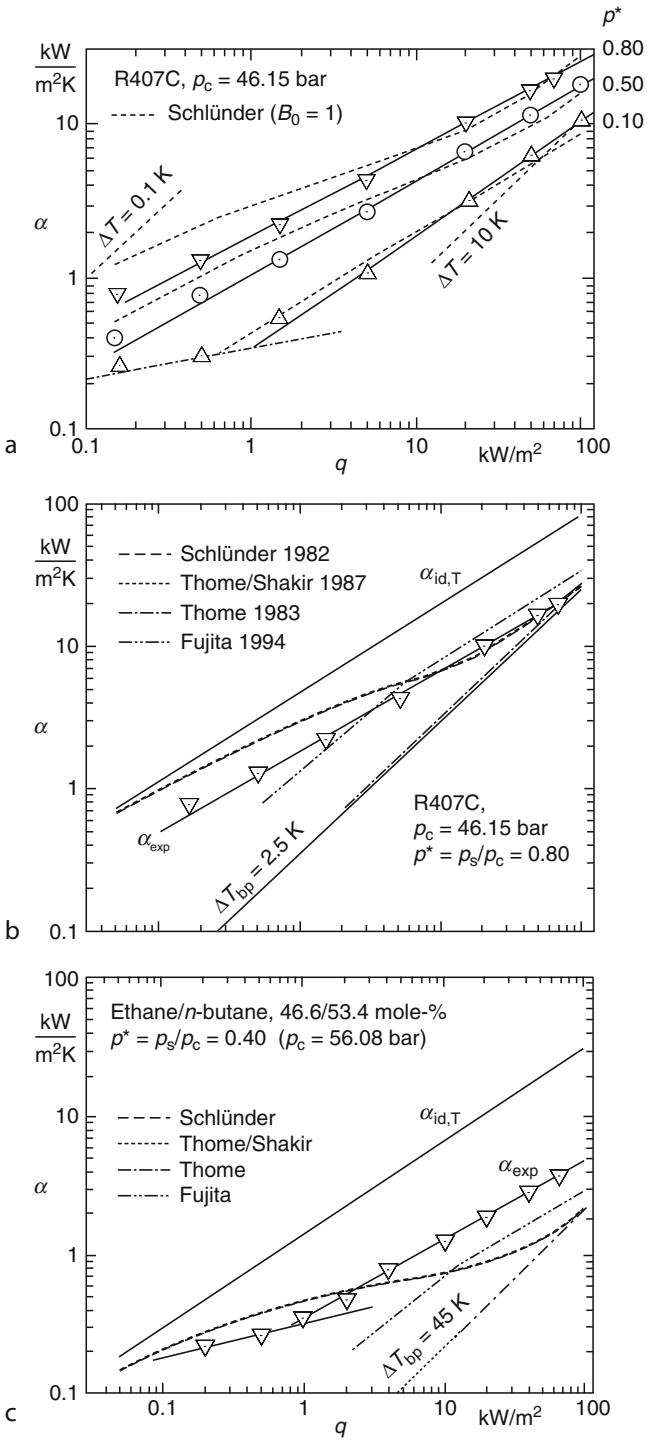
where

$$\Phi = B_0 q/\beta_l \rho_l \Delta h_v \tag{23}$$

β_l and ρ_l are the mass transfer coefficient and density in the liquid, Δh_v is the enthalpy of vaporization, and B_0 is a parameter that Schlünder approximated to unity but which can be used for fitting experimental results. When doing so at a constant intermediate heat flux (mostly $q = 20$ kW/m^2), B_0 is found to be a function of the reduced pressure p^*, particularly for narrow boiling binary systems ($\Delta T_{sN} < 10$ K) as can be seen for various binary refrigerant systems in Fig. 26b.

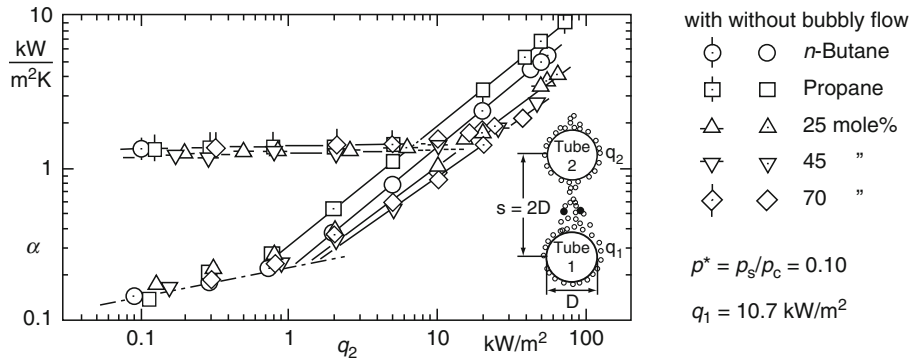
The result generally obtained at the highest pressure, that is, $B_0 = 1$, obviously confirms close to the critical point the assumption of diffusion controlled heat transfer that was made in deriving the model for Eqs. (21) and (21a) and also the numerical value that was inserted in Eq. (23): $\beta_l = 2 \cdot 10^{-4}$ m/s = 0.2 mm/s. Only the order of magnitude for β_l is known, viz. 0.1–0.5 mm/s, deduced from absorption measurements [156]. Hence, the quotient B_0/β_l can also be regarded as a fitting parameter, as had been done in the preceding editions of the *Heat Atlas*.

For wide boiling systems, that is, those for which the normal boiling points of the components are widely spaced ($\Delta T_{sN} >$ 30 K), the value of B_0/β_l remains approximately the same if fitted to moderate or high heat fluxes, even at low pressures (Fig. 26b). However, it increases if ΔT_{sN} is small as mentioned above, or if the heat flux is small [151, 158, 159]. In the latter case, a calculation method that was developed for pure substances [160–162] and applied to binary mixtures by Bier and Bayer [151] should be more appropriate because heat transfer by natural convection is included for those parts of the heated surface where no bubbles are produced [159].



H2. Fig. 28. α-values calculated with Eqs. (21a) and (24) and two more correlations [165, 166] in comparison with experimental data for the narrow boiling ternary R407C [41, 144] (*upper two diagrams*) and the very wide boiling C_2H_6/C_4H_{10} [26, 144] (*lowest diagram*).

Values calculated from Eq. (21a) have been plotted in the diagrams on the left of Fig. 23 (crosses). They reproduce fairly well the deterioration that was determined experimentally, despite the fact that only one numerical value of $B_0/\beta_l = 10^4$ s/m ($B_0 = 2$) was taken for all the heat fluxes and both pressures (corresponding approximately, however, to the average value



H2. Fig. 29. Simulation of convective improvement of α by bubbles streaming upward from lower tube banks in a bundle for propane/*n*-butane mixtures (from [168]).

following from Fig. 26b for this system and the comparatively high reduced pressures). If a function of q and p^* were to be substituted for B_0/β_l, the measured values would be better reproduced (see [146] for other systems), but the predictive capability would be lost.

Following earlier attempts [151, 159, 163], B_0 was modeled in [30] as a function of ΔT_{sN} (Fig. 27) for refrigerants and hydrocarbons in order to improve the predictive quality. It turns out that reproduction of experimental data is similar to using the interpolation lines in Fig. 26b [30]. In the case of the refrigerants, also the two systems with "negative" pressure dependence (half-closed symbols) are interpolated by the common line, while a different correlation was fitted in [30] to the two hydrocarbons with this behavior. It can be concluded, however, from the good representation of the experiments for C_2H_4/C_2H_6 by the lowest line instead of the triangle on its base in Fig. 27, that using the common full line for all the hydrocarbon systems shown will not increase the deviations of calculated and measured values significantly.

Introducing the temperature glide ΔT_{bp} at total vaporization into Eq. (22) by applying the approximate Eq. (16) results in

$$\left(T_{ph} - T_{sat}\right) = \Delta T_{bp}[1 - \exp(-\Phi)] \tag{22a}$$

and Eq. (21a) in the correlation of Thome and Shakir proposed some years later [164]

$$\alpha_{id,T}/\alpha_{mix} = 1 + [1 - \exp(-\Phi)]\Delta T_{bp}/\Delta T_{id}. \tag{24}$$

If the "mixture factor" K that has been defined (see Fig. 21b) by

$$\Delta T_{mix} = \Delta T_{id} + K\Delta T_{bp} \tag{25}$$

is used for expressing many of the correlations for mixture boiling in a uniform way [41, 144], Eq. (24) can be written as

$$\Delta T_{mix}/\Delta T_{id} = \alpha_{id,T}/\alpha_{mix} = 1 + K\Delta T_{bp}/\Delta T_{id} \text{ with}$$
$$K_{Thome/Shankir} = 1 - \exp(-\Phi). \tag{24a}$$

In Fig. 28, α-values calculated with Eqs. (21a) and (24) or (24a) and two more correlations [165, 166] are compared with experimental data for the narrow boiling ternary R407C [41, 144] and the very wide boiling C_2H_6/C_4H_{10} [26, 144]. As can be seen from Fig. 28a, deviations between the measurements and the values calculated by Eq. (21a) are small for the lowest pressure and all heat fluxes. This is mainly due to the fact that the "mixture effect" is small for this narrow boiling system at low reduced pressures, see Fig. 22c. The same will hold for all of the mixed refrigerants actually used in practice because they are similarly narrow boiling.

Representation of the experimental data is also very good for the two higher pressures at high heat fluxes, but the experiments are significantly overpredicted at the highest pressure and small heat fluxes. (In the calculation for the ternary system, Eq. (21a) has been used in the form extended to multicomponent mixtures as explained in [157], and the same procedure has been applied for the other correlations.)

Results would be the same for Eq. (24), as can be concluded from Fig. 28b. For the very wide boiling binary in Fig. 28c, however, the prediction of neither correlation is satisfactory. The best results are obtained by the correlation of Fujita and Tsutsui [166] for both systems at the intermediate to high reduced pressures shown. Recently, it has been recommended that Eqs. (21a) and (24) be combined to improve prediction for wide boiling binary systems with markedly asymmetric vapor/liquid equilibrium, for example, NH_3/H_2O [167].

Comments on calculation methods for mixture boiling:

a. On the whole, calculation methods for mixture boiling heat transfer are less satisfactory than those discussed in Sect. 3 for pure substances, except for narrow boiling systems at low reduced pressures when Δxy is small and the remixing effect of the bubbles within the boundary layer near the heated wall is high. In a tube bundle, the same effect will be produced by the bubbles rising from the lower banks of tubes, at least at low to intermediate heat fluxes, see Fig. 29 [168]. From the comparison with the pure components it is obvious that the reduction of heat transfer for the mixtures is entirely compensated within the domain where heat transfer is convection controlled, and it may even be improved both for mixtures and their components. The same holds for additional flow of liquid [169]. At higher fluxes, however, the additional convection has no visible influence.
b. The p, T, x phase diagram for systems with closely spaced normal boiling points ($\Delta T_{sN} < 10$ K), and particularly for those with azeotropes, is an important prerequisite for the calculation methods discussed above and must therefore be accurately known.

5 Critical Heat Flux and Film Boiling

5.1 Critical Heat Flux in Nucleate Boiling

According to Kutateladze [170] and Zuber et al. [171–173], the maximum heat flux q_{crit} in saturated pool nucleate boiling (point D in Fig. 2) on horizontal flat plates or plain tubes can be calculated from

$$q_{crit} = K_1 \Delta h_v \rho_v^{0.5} [\sigma(\rho_l - \rho_v)g]^{0.25} \quad (26)$$

where Δh_v is the enthalpy of vaporization, σ is the surface tension, and ρ_v and ρ_l are the densities of the vapor and the liquid respectively.

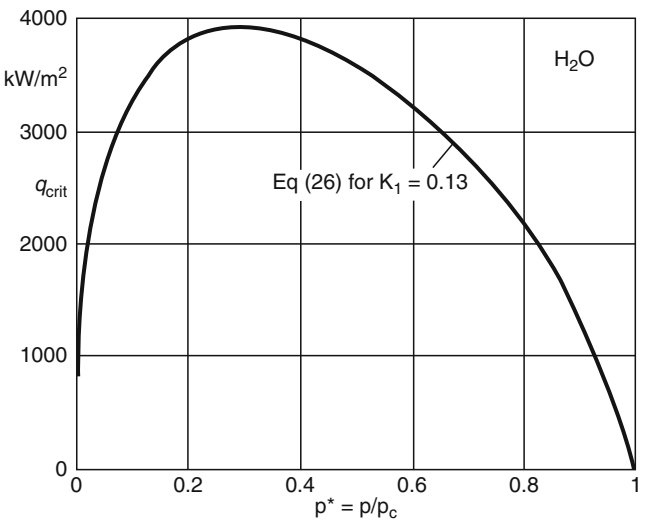
Zuber derived a numerical value of 0.13 for the factor K_1 from a simplified model for the development of instability in the counterflow of liquid and vapor normal to a horizontal plate. Kutateladze obtained $K_1 = 0.13$ to 0.16 by fitting to measured values.

The pressure dependence of q_{crit} for water according to Eq. (26) has been plotted in Fig. 30. It is similar for all fluids, with a maximum near $p^* = 0.3$. The absolute values, however, are lower by a factor of approximately 10 for organic liquids (as e.g., in Figs. 5 and 32).

As $\sigma \sim (\rho_l - \rho_v)^4$ to a good approximation, the liquid–vapor density difference is represented in Eq. (26) to the power of 1.25. The only other properties in the equation are the enthalpy of vaporization and the vapor density. Many other correlations exist in the literature for the calculation of q_{crit}; most of them contain the terms $\Delta h_v \rho_v^{0.5}$ and $(\rho_l - \rho_v)^m$ in which the exponent m is given by $1.25 < m < 1.5$ [170–177].

Of all the parameters important for q_{crit}, the effect of the pressure has been investigated most. From studies by Borishanskij [178] and Mostinskij [179] and the existing experimental data on q_{crit}, the following function can be interpolated for the relative pressure dependence of q_{crit}, which is analogous to Eq. (7) for the $\alpha(p^*)$-relationship

$$q_{crit}/q_{crit,0} = 2.8\, p^{*0.4}(1 - p^*) \quad (27)$$



H2. Fig. 30. Maximum heat flux q_{crit} in the nucleate boiling of water as determined from Eq. (26).

where $q_{crit,0}$ is the value for the maximum heat flux at the reference pressure $p_0^* = 0.1$.

In Fig. 31, the relative pressure dependence of q_{crit} according to Eq. (27) is compared with experimental data. It can be seen that the solid line for Eq. (27) lies between the center and the lower limit of the range of experimental scattering. The curve of q_{crit} for water, as determined from Eq. (26), has been included in the diagram in the form of a dashed line. For $0.001 < p^* < 0.6$, it deviates by less than 5% from the values determined from Eq. (27), but at higher p^*, q_{crit} determined from Eq. (26) is considerably higher than many of the experimental data at these pressures, particularly in the case of organic fluids [182, 183, 185–187] (and in [142], also for p^* near 0.1).

Therefore, it is it is recommended that q_{crit} be calculated from Eq. (27) and the reference value $q_{crit,0}$ be determined from experimental data for a particular system fluid – wall at any (reduced) pressure available and to fit the parameter A in

$$q_{crit}/q_{crit,0} = A\, p^{*0.4}(1 - p^*) \quad (27a)$$

to the measured value. If measurements do not exist, then $q_{crit,0}$ should be calculated from Eq. (26) for p_0^*.

Labuntsov [188] demonstrated that, at *very low* reduced pressures, the relative pressure dependence is noticeably less pronounced than following from Eqs. (26) and (27). According to the results of his measurements on water and ethanol at heated walls of various geometries and properties, the relationship is similar to that for liquid metals, which can be described by $q_{crit} \sim p^{*m}$ where $0.15 < m < 0.20$. Consequently, the exponent 0.4 in Eq. (27) is somewhat too high for very low reduced pressures as can also be concluded from the left edge of Fig. 31. (For this reason, it is recommended to divide the pressure range into two [189], e.g., $(q_{crit}/q_{crit,1}) = A_1\, p^{*0.4}(1 - p^*)$ for $p^* \geq 0.1$, and $(q_{crit}/q_{crit,2}) = A_2(p^{*0.2} + p^{*0.5})$ for $p^* \leq 0.1$.)

Equation (26) does not depend on the characteristic dimension L of the heated wall. If $L' = L/[\sigma/(\rho_l - \rho_v)g]^{0.5} < 2$, Lienhard and Dhir [177] proposed a correction

$$q_{crit,L} = K_2 q_{crit,26} \quad (28)$$

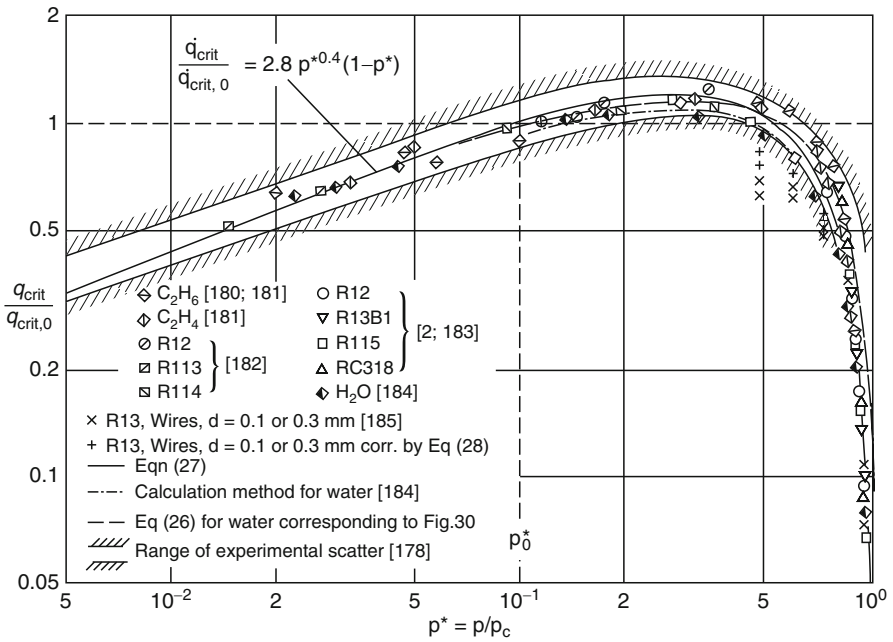
where

$$K_2 = 1.19(L')^{-0.25} \quad (29)$$

and $q_{crit,26}$ is the maximum heat flux as determined from Eq. (26). Equation (28) is valid for $0.1 \leq L' \leq 2$. Examples of the upper limits for the correction of Eq. (26) by Eqs. (28) and (29) are $L_{max} = 5$ mm for water at $p = 1$ bar ($p^* = 0.0045$) and $L_{max} = 1$ mm for R125 at $p = 19$ bar ($p^* = 0.53$).

For spheres and horizontal cylinders, the radius, and for fins, the height should be used as characteristic dimensions. The effect of the correction factor K_2 is indicated in Fig. 31 by the shift in the results of measurements on thin wires [185] at $p^* = \text{const.}$ (points marked by a cross are shifted to points marked by a plus sign). It can be seen that the correction reduces the systematic deviations in the results for thin wires.

Many other factors that affect the maximum heat flux in nucleate boiling are not embraced by Eqs. (26)–(29). Subcooling of the bulk liquid may produce a large increase in the

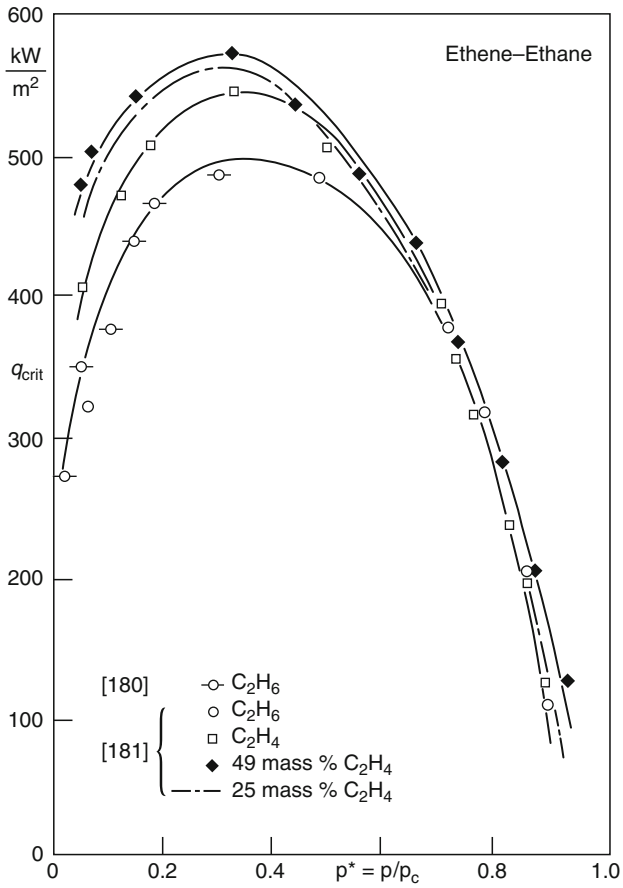


H2. Fig. 31. Relative pressure dependence of q_{crit} from Eqs. (26) and (27) compared with experimental data fitted to the values at $p^*_0 = 0.1$. If this pressure is not included in the range of measurements, the values have been fitted to the lowest experimental pressure [182] or to $p^* = 0.9$ [2, 185].

maximum heat flux, initially increasing linearly with subcooling, then approaching an asymptote. However, as noted in Sect. 1, subcooled conditions are difficult to sustain in pool boiling, unless there is a continuous flow of cold liquid into the vessel. Motion or agitation of the bubbly mixture that directs liquid toward the heated wall may also increase the maximum heat flux. Factors that modify the maximum heat flux in saturated pool boiling include the roughness of the heated surface [190], the type of heating [182], and impurities and the wetting of the heated surface [187]. The results of studies on these effects are inconsistent, so they cannot yet be included in correlations. Therefore, all that can be derived from Eqs. (26)–(29) is an approximate estimate for the maximum heat flux in saturated pool nucleate boiling.

Typical values measured for q_{crit} in nucleate boiling of *binary mixtures* have been plotted in Fig. 32. They lie between or above the corresponding values for the pure components to an extent that depends on the properties of the mixture and the pressure [181]. In analogy to the deterioration in heat transfer, the highest values of q_{crit} frequently occur at intermediate compositions, as can be seen from the curve for 49 mass% C_2H_4 in Fig. 32. The trend that the *relative* difference becomes particularly large at $p^* > 0.9$ (lowest closed rhomb in Fig. 32) is also found in experiments at even higher p^* with SF_6/R13B1 [191].

The same phenomena that are responsible for the impairment in heat transfer (i.e., the additional resistance to heat transport caused by diffusion and the lower numbers of bubbles) retard the coalescence of bubbles to form a film and thus provide a qualitative explanation. Bubble coalescence is further influenced by Marangoni flows driven by local variations in surface tension. Coalescence is opposed or promoted,



H2. Fig. 32. Maximum heat flux q_{crit} as a function of the reduced pressure for ethane, ethene, and two of their mixtures [181].

depending on whether surface tension increases (positive mixture) or decreases (negative mixture) with increasing fraction of the less volatile fluid [192].

Equation (26) can also be used to calculate q_{crit} for binary mixtures. The reservations are the same as those for the individual components, and the values to be inserted for the properties are those of the mixture. The same recommendation has been submitted by Stephan and Preusser [83], whose measured values for q_{crit} at near-atmospheric pressure always lie between those for the pure components. If the values for the mixture are higher, Eq. (26) yields a conservative estimate.

5.2 Film Boiling

In total film boiling there is no direct contact between the liquid phase and the heated surface so the surface and bulk properties of the heated wall are unimportant. On surfaces with a sloping component (inclined plates, cylinders, and spheres), the vapor in the film flows upward due to gravity and is eventually discharged to the pool. Heat transfer across the vapor film is influenced by the hydrodynamic conditions at the liquid–vapor boundary, including wave formation by Rayleigh–Taylor or Kelvin–Helmholtz instabilities. There is a weak dependence on the characteristic length of the system L. In large systems, the vapor flow may become turbulent. On horizontal surfaces with L larger than the wavelength for Rayleigh–Taylor instability, the vapor is discharged as large periodic bubbles at the wave nodes. (This is consistent with the condition $L/[\sigma/(\rho_l - \rho_v)\, g]^{0.5} > 2$ for the maximum heat flux in nucleate boiling q_{crit} given by Eq. (26) to be independent of L). Subcooling of the bulk liquid increases the heat transfer coefficient in film boiling and influences its stability.

Theoretical and experimental studies of film boiling for a wide range of conditions were reviewed in [197]. In applications aimed at achieving high heat transfer coefficients in boiling on tubes, designers try to avoid film boiling and the relatively simple methods described below may be used to estimate the low heat transfer coefficients for film boiling in saturated pool boiling.

Total film boiling including the effects of radiation was investigated by Bromley in theoretical studies backed up by experiments with carbon tubes (D = 5 to 12 mm) [193, 194] starting at comparatively large wall superheats. The result of his studies in pool boiling [193] is the following implicit relationship between the heat transfer coefficient α in film boiling, the coefficient α_{cond} for heat transport purely by conduction across a laminar film of vapor and the coefficient α_{rad} purely for radiation through the film of vapor:

$$\alpha = \alpha_{cond}(\alpha_{cond}/\alpha)^{1/3} + \alpha_{rad}. \tag{30}$$

His approximate explicit equation for the range which is of interest in engineering, $0 < \alpha_{rad} < 10\ \alpha_{cond}$, is

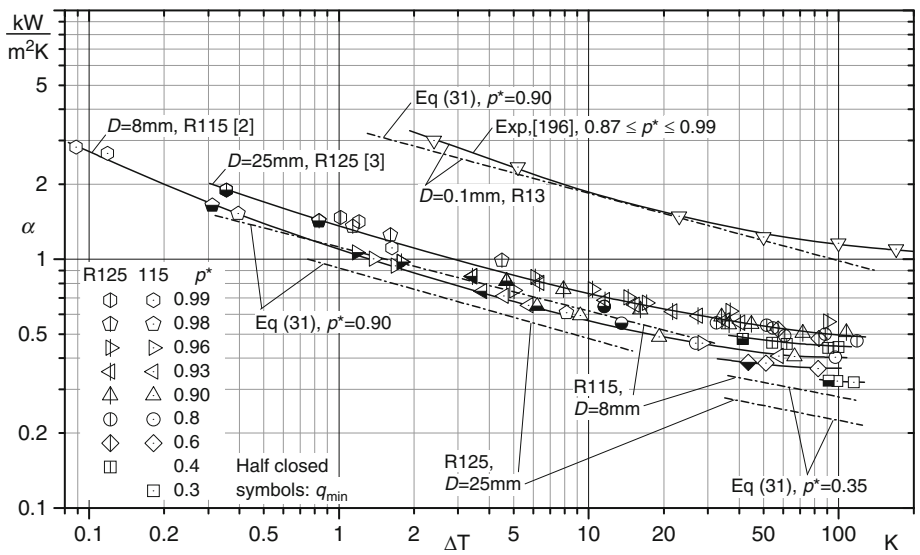
$$\alpha = \alpha_{cond} + \alpha_{rad}[(3/4) + (1/4)/(1 + 2.62\,\alpha_{cond}/\alpha_{rad})]. \tag{30a}$$

A more exact calculation by Roetzel [195] led to an equation that yields values for α a few percent higher than those obtained from Eq.(30a).

The heat transfer coefficient α_{rad} for the radiation component is obtained from Eq.(1) by substituting q_{rad} for q, where $q_{rad} = C_{12}\,(T_w^{\,4} - T_l^4)$, given in Chap. K1. The transport of heat by conduction through the laminar vapor film is given by

$$\alpha_{cond} = K_f (L\Delta T)^{-1/4} \left(\lambda_v^3 \rho_v\, \Delta h\, \Delta\rho\, g/\eta_v\right)^{1/4} \tag{31}$$

where λ_v, ρ_v, η_v are the thermal conductivity, density, and dynamic viscosity of the vapor, evaluated at $T_m = 0.5\,(T_w + T_l)$, and $\Delta\rho = \rho_l\,(T_{sat}) - \rho_v\,(T_m)$, $\Delta h = h_l\,(T_{sat}) - h_v(T_m)$ are the differences in density and specific enthalpy between the vapor and the liquid. $\Delta T = T_w - T_l$ (with $T_l = T_{sat}$) is the superheat of the wall, L is the characteristic dimension of the heater ($L = D$



H2. Fig. 33. Comparison of heat transfer coefficients calculated from Eq.(31) with experimental data for film boiling of refrigerants on a thin Pt-wire or copper tubes with different diameters at small superheats ΔT.

for horizontal tubes; $L = H$ for vertical walls). The empirical parameter for horizontal heaters is $K_f = 0.62 \pm 0.04$ [193]; and for vertical walls, 0.8 [195].

Most of the experimental data on which these equations are based have been obtained in experiments at low reduced pressures. Examples of measurements for p^* up to 0.99 are shown in Fig. 33 for refrigerants R115 and R125 on 8 and 25 mm diameter horizontal tubes and R13 on a 0.1 mm wire. Unfilled symbols correspond to total film boiling; half-filled symbols indicate the lower limit q_{min}. For these conditions, the superheats ΔT and the absolute temperatures of the interfaces for film boiling are comparatively small, so α_{rad} is only a few % of α_{cond}.

In this logarithmic plot of α vs. ΔT, the heat transfer coefficients calculated from Eq.(31), approximately straight dot-dashed lines, are compared with the experimental data (slightly curved solid interpolation lines) in the range $0.3 < p^* < 0.99$. For the 0.1 mm wire and the 8 mm tube at intermediate values of ΔT, Eq.(31) is in close agreement with the experimental data, indicating that it continues to represent well the influences of ΔT, D, and fluid properties at large values of p^*. For a given fluid, the change in the combination of properties in Eq.(31) with pressure is small and the experimental data for R115 and R125 in the range $0.8 < p^* < 0.99$ lie on the same line within experimental uncertainty, with only a comparatively small decrease at $p^* < 0.6$.

At small and large values of ΔT, the experimental values of α become larger than the predictions of Eq.(31). For the 25 mm tube, the predictions are exceeded by approximately 50%, even at intermediate superheats.

Photographs and high-speed videos of the large tube reveal waves on the liquid – vapor interface. Waves are also visible for smaller tubes and ΔT's at very high p^*. Enhancement of the conduction assumed in Eq.(31) by convection and/or turbulence is then to be expected, as reviewed in [197].

A somewhat more pronounced influence of pressure than that predicted by Eq.(31) has been found in [198] for the entire range of existence of the liquid phase between triple point and critical point for CO_2 boiling on thin wires of $D = 0.05$, 0.1, and 0.4 mm diameter. Pitschmann and Grigull [199] extended Bromley's theory particularly to thin wires and developed a correlation that has been well confirmed by experiment [185, 187, 198].

A calculation method that has been proposed for film boiling of *binary mixtures* on vertical heater surfaces [200] includes the effect of diffusion on the temperature at the surface of the film and on the heat transfer coefficient (see also [201]).

The surface condition and bulk properties of the wall conditions have a strong effect on the reversion of film boiling to transition boiling and then nucleate boiling at a minimum heat flux q_{min} during transient cooling and this leads to variations between the results of different studies that are important in processes that involve quenching, such as heat treatment, cooldown of cryogenic systems, and firefighting. When the superheated surface is liquid and the evaporating liquid is subcooled, hydrodynamic instabilities of both interfaces at q_{min} may lead to an explosive increase in the generation of vapor, with potentially disastrous consequences in severe nuclear accidents, continuous casting, and spills of cryogenic fluids on water.

Theoretical predictions of this lower limit (point F in Fig. 2 and half-closed symbols in Fig. 33), reviewed in [185, 187], differ widely from one another and from measured values [183, 187]. It can be shown from measurements at reduced pressures $p^* \geq 0.6$ that the ratio of the maximum heat flux q_{crit} in nucleate boiling and the minimum heat flux q_{min} in film boiling is roughly independent of pressure and the properties of the fluid [2, 3, 182, 183, 202]. Thus

$$q_{crit}/q_{min} = 8 \pm 2. \tag{32}$$

Together with Eqs. (26) and (27), this relationship provides a first approximation for q_{min} at $p^* > 0.6$ in saturated pool boiling.

H3 Flow Boiling – An Introduction

Matthias Kind
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

This and the following subchapters are about heat transfer from a wall of an evaporator to a flowing and boiling subcooled, saturated or superheated liquid–vapor system. Flow boiling is an effective means to achieve high heat transfer rates at moderate temperature differences and is used in a multitude of technical applications like power plants, refrigerators, chemical and nuclear reactors, and evaporators in process industry.

A liquid (pure substance or mixture) is subcooled at point z in the direction of flow, if its average temperature is below the equilibrium temperature T_{sat} corresponding to the local pressure p. Saturation of a two-phase flow is reached when its average temperature is equal to the equilibrium temperature T_{sat}. The mixture may be superheated in the case that droplets evaporate into superheated steam as is the case at the end of an evaporation process.

The quality of two-phase flow at point z in the direction of flow is described by the local value of the vapor mass fraction $\dot{x}$, which is defined as the ratio of the local area specific mass flow rate of vapor $\dot{m}_V$ to the total area specific mass flow rate $\dot{m}$. (For special symbols used in flow boiling, see Subchap. H3.8.)

$$\dot{x} \equiv \frac{\dot{m}_V}{\dot{m}}. \tag{1}$$

At thermodynamic equilibrium the vapor mass fraction $\dot{x}$ at point z in the direction of flow can be obtained from the local specific enthalpies of the saturated liquid h' and of the two-phase fluid h using the enthalpy of evaporation Δh_{LV},

$$\dot{x} = \dot{x}_{eq} \equiv \frac{h - h'(p)}{\Delta h_{LV}(p.)} \tag{2}$$

$\dot{x}_{eq}$ is the only value that can be predicted by an energy balance and thus can be used for evaporator design. A schematic comparison between this value and the actual vapor mass fraction $\dot{x}$ is shown in Fig. 1. The greatest differences between these values occur at low and high values of $\dot{x}$ depending on various parameters. Generally, in the medium range of $\dot{x}_{eq}$, the difference is negligible, and is thus been completely ignored in the following sections, i.e., no distinction is made between $\dot{x}$ and $\dot{x}_{eq}$.

Below the critical heat flux, the following two boiling mechanisms can be observed: the so-called convective flow boiling mechanism and the nucleate flow boiling mechanism. The mechanism of convective flow boiling is characterized by the phenomenon that no vapor bubbles emerge at the wall. Rather, the vapor is generated close to or at the existing liquid–vapor interface. The mechanism of nucleate flow boiling is characterized by the phenomenon that steadily new vapor bubbles are nucleated at the wall due to sufficiently high superheating at the wall.

The parameters that decide which of the two mechanisms will predominate are the heat flux $\dot{q}$, the pressure p, the mass velocity $\dot{m}$, the vapor mass fraction $\dot{x}$, and the inner diameter d and the angle of inclination of the tube. A clear distinction between the two regimes can be drawn from Fig. 2. Thus in convective flow boiling, the heat transfer coefficient α does not depend on the heat flux $\dot{q}$ or the temperature difference $\Delta T = T_w - T_{eq}$ between the wall and the thermodynamically equilibrated two-phase fluid. If, however, α depends significantly on the heat flux, the nucleate boiling mechanism predominates.

A schematic diagram of the phenomena that occur within a horizontal evaporator tube at a moderate mass velocity is presented in Fig. 3. The flow patterns are sketched for low heat flux between $\dot{x}_{eq} = 0$ and $\dot{x}_{eq} = 1$. Under these circumstances the flow patterns are practically identical to those in an unheated tube.

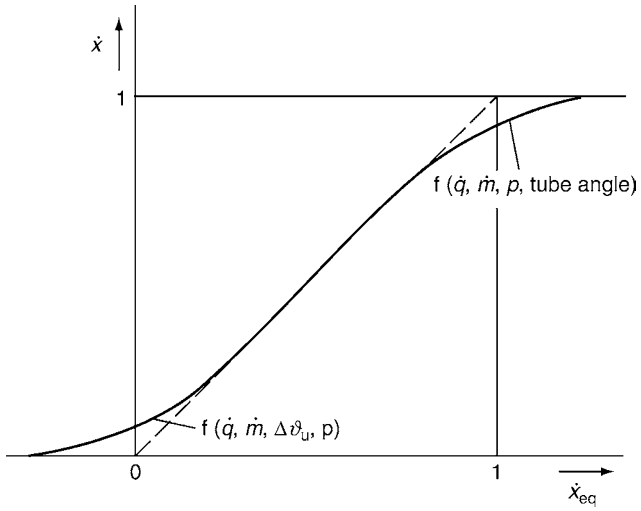
For subcooled liquids up to $\dot{x}_{eq} = 0$ and at low heat fluxes (no nucleate boiling), heat transfer is convective and the value of the heat transfer coefficient is $\alpha(z)_{conv} = \alpha_{L0}$. Beyond $\dot{x}_{eq} = 0$ the heat transfer coefficient $\alpha(z)_{conv}$ commences to increases rapidly, because the convective flow boiling mechanism becomes active. However, a considerable impairment of $\alpha(z)_{conv}$ takes place in the stratified-wavy flow regime owing to incomplete wetting. In the flow regimes of slug and annular flow, wetting is so effective that the heat transfer coefficient $\alpha(z)_{conv}$ again increases with $\dot{x}$ until the onset of partial dry out, after which $\alpha(z)_{conv}$ drops rapidly to the value α_{G0} for pure vapor flow.

Figure 3 also includes a curve for the heat transfer coefficient in nucleate boiling $\alpha(z)_{nb}$, which occurs if the heat flux is correspondingly high. This curve also embraces the subcooled boiling regime, i.e., vapor generation before the point $\dot{x}_{eq} = 0$ is attained. Before the end of the tube is reached, the vapor mass fraction becomes so large that the critical boiling regime (point A) is attained.

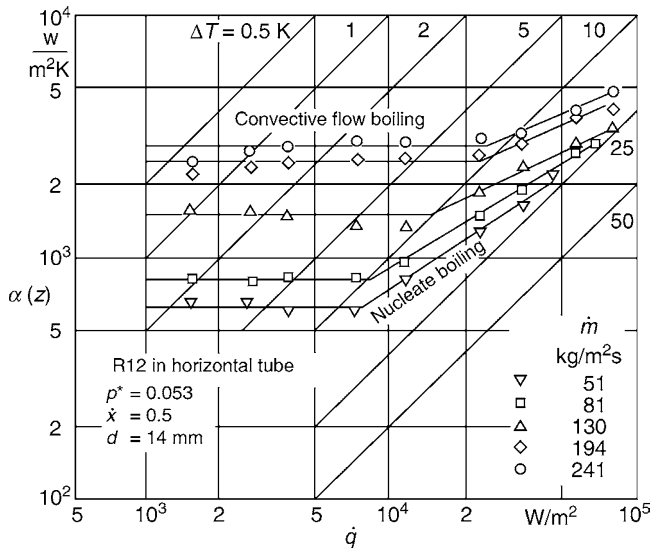
Also in Fig. 3 the temperature profile versus the length of the tube $T(z)$ is shown. Below $\dot{x}_{eq} = 0$ the temperature rises until $T_{eq}\ (p)$ is reached at $\dot{x}_{eq} = 0$. If due allowance is made for the pressure drop, $T_{eq}(p)$ can be obtained for $\dot{x}_{eq} > 0$ with the aid of the vapor pressure curve. For $\dot{x}_{eq} > 1$ no more liquid is present and the temperature of the fluid (pure vapor) rises steadily. In the case of exceeding the critical boiling point (point A), the temperature deviates from $T_{eq}\ (p)$ as is shown by the dashed line. Owing to entrained liquid droplets, in this case the actual vapor mass fraction $\dot{x}$ deviates from the theoretical value $\dot{x}_{eq}$.

Since in the nucleate boiling regime $\alpha(z)_B = f(\dot{q})$, and since $\alpha(z)_{conv}$, $\alpha(z)_B$, and T_{eq} are functions of the tube length z, it is justified to restrict the prediction of the corresponding heat transfer coefficients to local values in the direction of flow z. By definition, $\alpha(z)$ is given by

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_35,



H3. Fig. 1. Relationship between actual and thermodynamic vapor fraction.



H3. Fig. 2. Parameter-averaged heat transfer coefficient as a function of heat flux (measurements on R 12 in horizontal tubes [R18]).

$$\alpha(z) = \frac{\dot{q}(z)}{T_w(z) - T_{sat}(p(z.))} \qquad (3)$$

The temperature of the inner wall and the heat flux are averaged over the circumference of the tube. In other words, the heat transfer coefficient $\alpha(z)$ is a perimeter-averaged value. This fact must be particularly borne in mind in predictions for nonvertical tubes, the circumferences of which are generally incompletely wetted. If the tubes are vertical, $\alpha(z)$ is uniform over the entire circumference.

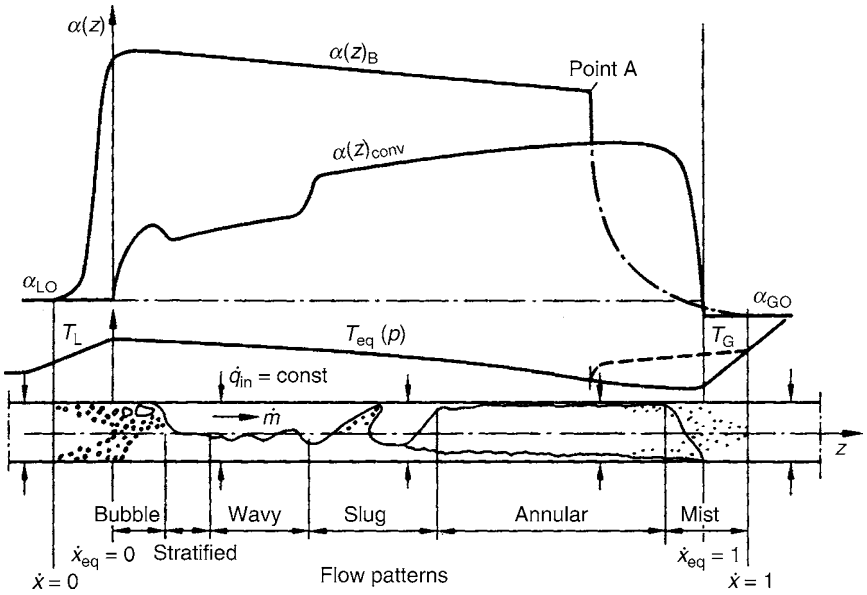
The numerical value for the perimeter-averaged heat transfer coefficient depends on the extent to which the tube is wetted. Hence, the flow pattern, i.e., the description of the phase distribution, must also be taken into account in the determination of heat transfer. In Subchap. H3.1, a method to predict the flow patterns in an evaporator tube is given.

Another prerequisite is the knowledge about the local pressure p in the evaporator tube which can be evaluated from the pressure drop in the evaporator tube (Subchap. H3.2).

Subcooled nucleate flow boiling (Subchap. H3.3) occurs, if a liquid, which in average is subcooled, flows in an evaporator tube under high heat flow conditions and vapor bubbles occur at the wall.

Saturated nucleate flow boiling (Subchap. H3.4) takes place, if a saturated liquid–vapor mixture flows in an evaporator tube at moderate heat fluxes below the critical heat flux, and either convective or nucleate boiling occur.

Above the critical heat flux critical boiling states occur (Subchap. H3.5). Here either a vapor film interrupts the direct



H3. Fig. 3. Schematic diagram illustrating flow patterns and the profiles for the fluid temperature and the perimeter-averaged heat transfer coefficient in a horizontal tube.

thermal contact of the liquid with the wall (film boiling, departure from nucleate boiling), or film dryout takes place.

Heat transfer beyond the critical heat flux (Subchap. H3.6) depends on the occurrence of either of these two phenomena.

In Subchap. H3.7, the treatment of heat transfer during flow boiling is extended to multicomponent systems.

H3.1 Flow Patterns in Evaporator Tubes

Dieter Steiner† · *Matthias Kind*
Karlsruhe, Germany

Phase distribution can be described by the observation of flow patterns in unheated sight glasses, and the patterns can be predicted by flow regime maps. The regimes formed by the dividing lines in the maps represent idealized states because, in reality, continuous transitions occur between the individual flow patterns.

1 Flow Patterns in Vertical Tubes

Upward flow patterns that have been observed are sketched in Fig. 1. Up to now, measurements of upward and downward flows in vertical tubes have failed to reveal any effect of the flow patterns on heat transfer. Since the heated wall is always, except in mist flow, completely wetted, there is no point in reproducing flow pattern maps here. Maps for upward and downward flows can be found in the literature [1–4]. (For literature and special symbols, see Subchap. H3.8.)

2 Flow Patterns in Horizontal and Slightly Inclined Tubes

In horizontal and slightly inclined tubes and under certain flow conditions, stratification of two phases occurs due to gravity.

Flow patterns for horizontal and slightly inclined tubes (angle of inclination to the horizontal $\Theta = \pm 10°$ at the most) are sketched in Fig. 2. For hydraulic reasons, only part of the heated wall is wetted in stratified, wavy, and slug flows. Since incomplete wetting exerts an effect on the heat transfer coefficient, a knowledge of the flow pattern is essential. Steiner [5] adapted a publication by Taitel and Dukler [6] as a basis for revising the regime transitions for wavy flow into slug, plug, and annular flow regimes and in checking them against measured data. Accordingly, the flow pattern map reproduced in Fig. 3 applies for liquids with low and medium boiling points.

2.1 Application of the Flow Pattern Map

The following scheme is advised for application of the map.

(a) Determination of the *Martinelli* parameter X

$$X = \frac{\left|(\mathrm{d}p/\mathrm{d}z)_\mathrm{L}\right|}{\left|(\mathrm{d}p/\mathrm{d}z)_\mathrm{G}\right|} = \left(\frac{1-\dot{x}}{\dot{x}}\right)^{0.875}\left(\frac{\rho_\mathrm{G}}{\rho_\mathrm{L}}\right)^{0.5}\left(\frac{\eta_\mathrm{L}}{\eta_\mathrm{G}}\right)^{0.125} \quad (1)$$

with index "G" for vapor and "L" for liquid.

(b) If Θ is the angle of inclination to the horizontal, the four dimensionless numbers are given by

$$\left(\mathrm{Re_L Fr'_G}\right)^{0.5} = \left(\frac{\dot{m}^3\dot{x}^2(1-\dot{x})}{\rho_\mathrm{G}(\rho_\mathrm{L}-\rho_\mathrm{G})\eta_\mathrm{L} g\cos\Theta}\right)^{0.5}, \quad (2)$$

$$\mathrm{Fr}^{0.5}_{\mathrm{G}m} = \left(\frac{\dot{m}^2\dot{x}^2}{gd\rho_\mathrm{L}\rho_\mathrm{G}}\right)^{0.5}, \quad (3)$$

$$\left(\mathrm{Fr\,Eu}\right)^{0.5}_\mathrm{L} = \left(\frac{\xi_\mathrm{L}\dot{m}^2(1-\dot{x})^2}{2d\rho_\mathrm{L}(\rho_\mathrm{L}-\rho_\mathrm{G})g\cos\Theta}\right)^{0.5}, \quad (4)$$

$$\left(\frac{\mathrm{We}}{\mathrm{Fr}}\right)_L = \frac{gd^2\rho_\mathrm{L}}{\sigma}. \quad (5)$$

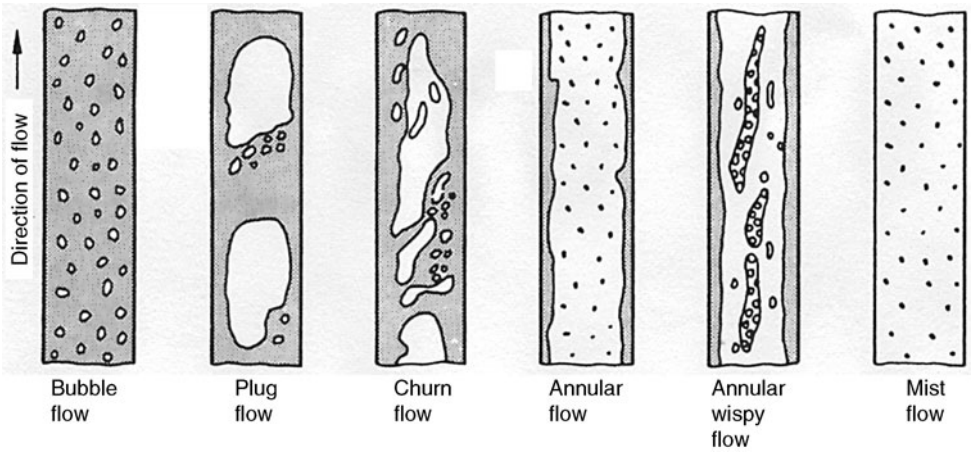
The *Reynolds* number and the friction factor are obtained from the following equations:

$$\mathrm{Re_L} = \frac{\dot{m}(1-\dot{x})d}{\eta_\mathrm{L}}, \quad (6)$$

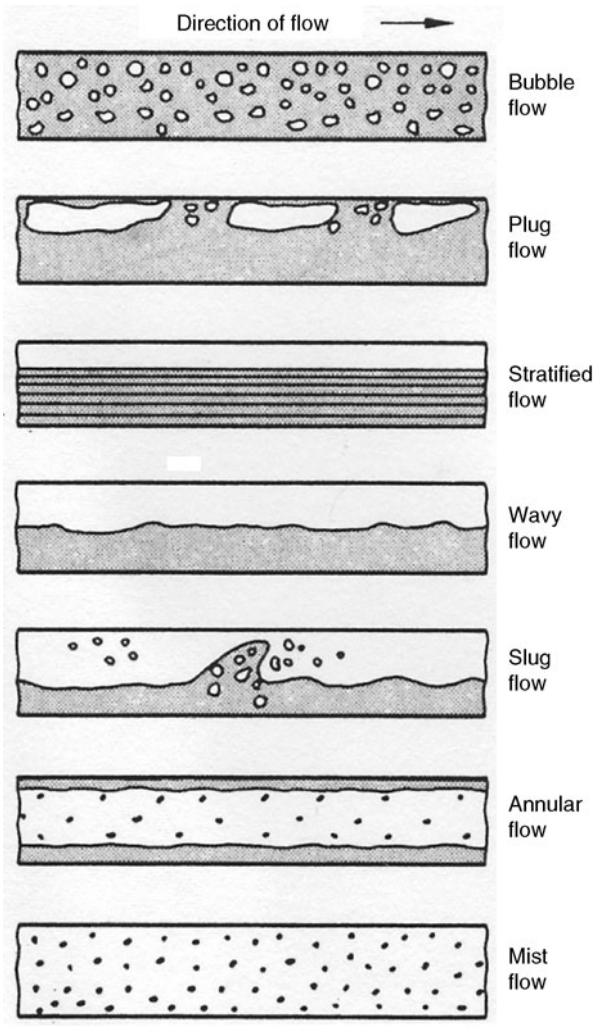
$$\xi_\mathrm{L} = \frac{0.3164}{\mathrm{Re}^{0.25}_\mathrm{L}}. \quad (7)$$

(c) The next step is to sound out the limiting conditions in the light of the actual value of the *Martinelli* parameter X. The following magnitudes with the subscript "lim" correspond to the limiting curves in Fig. 3. In order to obtain a definite result it is essential that the limiting conditions are sounded out in the following sequence.

†Deceased



H3.1. Fig. 1. Flow patterns for upward flow in vertical tubes.



H3.1. Fig. 2. Flow patterns in horizontal tubes.

Flow is stratified if

$$\left(\mathrm{Re_L Fr'_G}\right)^{0.5} \leq \left(\mathrm{Re_L Fr'_G}\right)^{0.5}_{\mathrm{tt,lim}}.$$

If $(\mathrm{We/Fr})_\mathrm{L}$ is taken into consideration, the condition for wavy flow is

$$\mathrm{Fr}_\mathrm{G}^{0.5} \leq (\mathrm{Fr}_{\mathrm{G}m})^{0.5}_{\mathrm{tt,\,lim\ 1}}.$$

Bubble flow exists if

$$(\mathrm{Fr\,Eu})_\mathrm{L}^{0.5} \geq (\mathrm{Fr\,Eu})^{0.5}_{\mathrm{L,lim}}.$$

Under the following conditions, plug or slug flow exists:

$$X \geq 0.34 \quad \text{and} \quad \mathrm{Fr}_{\mathrm{G}m}^{0.5} > (\mathrm{Fr}_{\mathrm{G}m})^{0.5}_{\mathrm{tt,\,lim\ 1}}.$$

Dependent on $(\mathrm{We/Fr})_\mathrm{L}$, the condition for mist flow is

$$X < 0.51 \quad \text{and} \quad \mathrm{Fr}_{\mathrm{G}m}^{0.5} \geq (\mathrm{Fr}_{\mathrm{G}m})^{0.5}_{\mathrm{lim\ 2}}.$$

The final alternative is annular flow, and it is defined by more than one boundary curves.

The limits for turbulent flow of both the gas and the liquid (subscript "t,t") and also for laminar liquid and turbulent gas flow (subscript "l,t") are indicated in Fig. 3. Since the differences are of no significance in practice, the only equations that have been given are those that apply to the turbulent case. Exemptions are cited in the literature [5].

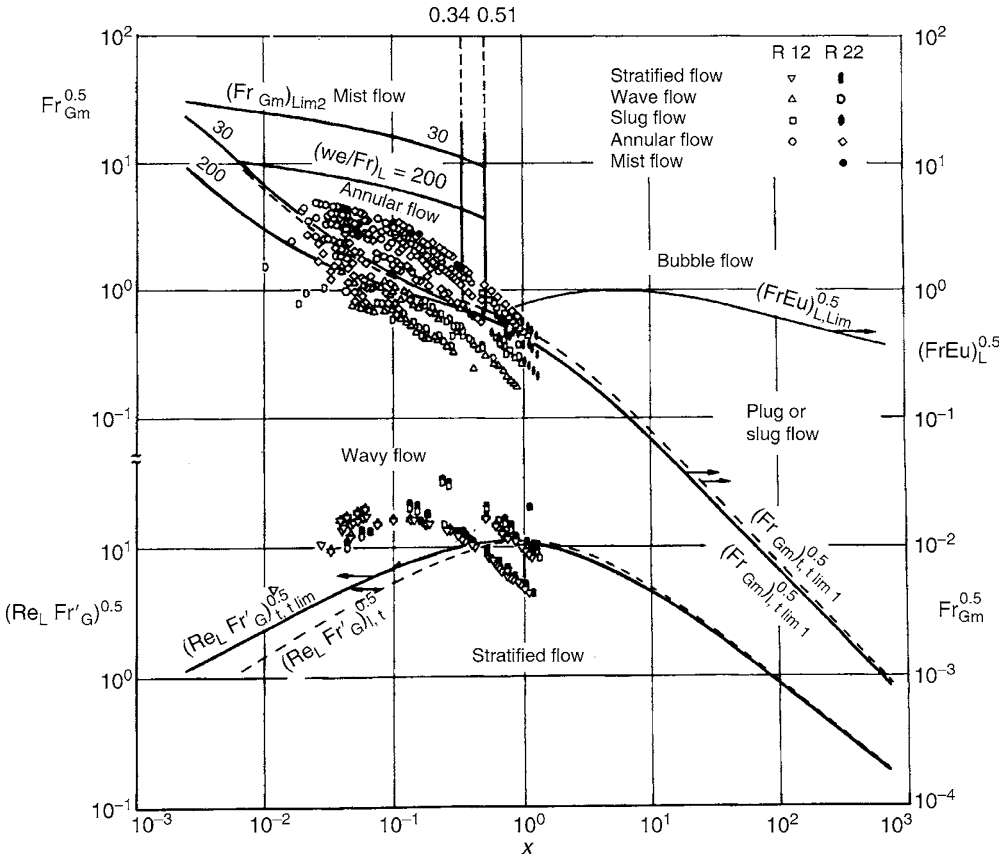
Example 1

Refrigerant R 12 flows in a horizontal evaporator tube of $d = 14$ mm at a pressure of $p = 1.51$ bar at its boiling point ($T_\mathrm{eq} = -20°\mathrm{C}$). The area-specific mass flow rate is $\dot{m} = 80\ \mathrm{kg/(m^2\ s)}$. Determine the flow patterns that are formed at the following values of $\dot{x}$: 0.01; 0.02; 0.1; 0.2; 0.3; 0.5; 0.7; 0.8; and 0.9.

It is assumed that the heat flux is moderate, i.e., $\dot{q} \leq 5\ \mathrm{kW/m^2}$, so that the flow patterns formed can be roughly determined from Fig. 3 for unheated tubes. The required properties of R12 are

$$\rho_\mathrm{L} = 1459.9\,\mathrm{kg/m^3}, \quad \eta_\mathrm{L} = 3.25 \cdot 10^{-4}\,\mathrm{kg/(m\,s)},$$
$$\rho_\mathrm{G} = 9.15\,\mathrm{kg/m^3}, \quad \eta_\mathrm{G} = 1.08 \cdot 10^{-5}\,\mathrm{kg/(m\,s)},$$
$$\sigma = 1.43 \cdot 10^{-2}\,\mathrm{kg/s^2}, \quad \Theta = 0°.$$

The solution is obtained from Eqs. (1–7) and the flow pattern map (Fig. 3). The sequence stipulated above must be adhered to in sounding out the likely flow patterns. The results are listed in Table 1.



H3.1. Fig. 3. Flow pattern map for horizontal pipe flow ($\Theta = 0°$).

H3.1. Table 1. Results obtained in specimen calculation (Example 1)

$\dot{x}$	0.01	0.02	0.1	0.2	0.3	0.5	0.7	0.8	0.9
X	6.75	3.65	0.83	0.41	0.25	0.12	0.058	0.036	0.018
$(\mathrm{Re_L Fr'_G})^{0.5}$	1.09	2.18	10.44	19.69	27.62	–	–	–	–
$\mathrm{Fr}^{0.5}_{Gm}$	0.019	0.037	0.187	0.374	0.561	0.934	1.31	1.5	1.68
$(\mathrm{FrEu_L})^{0.5}$	0.021	0.021	0.019	–	–	–	–	–	–
$(\mathrm{We/Fr})_L$	–	–	–	–	–	–	196	196	196
$\mathrm{Re_L}$	3412.7	3378.3	3102.5	–	–	–	–	–	–
ξ_L	0.0414	0.0415	0.0424	–	–	–	–	–	–
Result (cf. Fig. 3)	Stratified flow	Stratified flow	Stratified flow	Wavy flow[a]	Wavy flow	Wavy flow	Annular flow	Wavy flow	Wavy flow

[a]According to Subchap. H3.4 the stratified–wavy flow range occurs at $\dot{x} = 0.2$, because $(\mathrm{Re_L Fr'_G})^{0.5} \leq 2(\mathrm{Re_L Fr'_G})^{0.5}_{\mathrm{lt,lim}}$. If, in accordance with the criteria for sounding out the boundaries, the other dimensionless numbers are not required, the numerical values are not listed in the table.

2.2 Determination of the Boundary Curves in the Flow Pattern Map

The requisite correlations with X must be known for the computer plotting of the boundary curves and for sounding out the anticipated flow pattern. The relationships between the given parameters and the equations for the dimensionless numbers have already been formulated [Eq. (1) and Eqs. (2–7), respectively]. Another relationship that applies is

$$X^2 = \left[\left(\frac{\tilde{U}_G + \tilde{U}_i}{\pi}\right)^{0.25}\left(\frac{\pi^2}{64\,\tilde{A}_G^2}\right)\left(\frac{\tilde{U}_G + \tilde{U}_i}{\tilde{A}_G} + \frac{\tilde{U}_i}{\tilde{A}_L}\right) - \frac{1}{(\mathrm{Fr\,Eu})_G}\right] \cdot \left(\frac{\pi}{\tilde{U}_L}\right)^{0.25}\left(\frac{64\,\tilde{A}_L^3}{\pi^2\,\tilde{U}_L}\right), \quad (8)$$

where

$$(\mathrm{Fr\,Eu})_G = \frac{\xi_G(\dot{m}\dot{x})^2}{2dg\rho_G(\rho_L - \rho_G)\sin\Theta}, \quad (9)$$

$$\xi_G = \frac{0.3164}{Re_G^{0.25}}, \tag{10}$$

$$Re_G = \frac{\dot{m}\dot{x}\, d}{\eta_G}. \tag{11}$$

The other dimensionless variables that are required for an analysis can be derived from the geometry (see Fig. 4) for a given height h of liquid or for a given relative liquid level $\tilde{h}_L$, which is given by

$$\tilde{h}_L = \frac{h}{d}. \tag{12}$$

The subscripts "L," "G," and "i" in the following equations indicate the liquid and gas (vapor) phases and the phase interface. The one that is appropriate for the case in question should be inserted in the equation concerned.

$$\tilde{U}_{L,G,i} = \frac{U_{L,G,i}}{d}, \tag{13}$$

$$\tilde{A}_{L,G} = \frac{A_{L,G}}{d^2}. \tag{14}$$

For $0 \le \tilde{h}_L \le 1$ is

$$\tilde{U}_i = 2\sqrt{\tilde{h}_L\left(1 - \tilde{h}_L\right)}. \tag{15}$$

Case $\tilde{h}_L \le 0.5$, with $\psi = 360° - \varphi$ (φ see Fig. 4):

$$\psi = 2\,\mathrm{Arcsin}\,\tilde{U}_i, \tag{16}$$

$$\tilde{U}_L = \frac{\psi}{2}, \tag{17}$$

$$\tilde{U}_G = \pi - \tilde{U}_L, \tag{18}$$

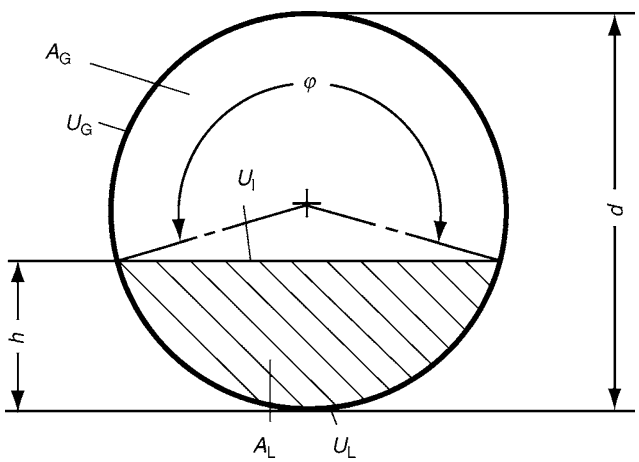
$$\tilde{A}_L = \frac{\psi - \sin(\psi 180/\pi)}{8}, \tag{19}$$

$$\tilde{A}_G = \frac{\pi}{4} - \tilde{A}_L. \tag{20}$$

Case $\tilde{h}_L > 0.5$:

$$\varphi = 2\,\mathrm{Arcsin}\,\tilde{U}_i, \tag{21}$$

$$\tilde{U}_G = \frac{\varphi}{2}, \tag{22}$$



H3.1. Fig. 4. Cross-sectional and peripheral fractions in a circular tube.

$$\tilde{U}_L = \pi - \tilde{U}_G, \tag{23}$$

$$\tilde{A}_L = \frac{\varphi - \sin(\varphi 180/\pi)}{8}, \tag{24}$$

$$\tilde{A}_L = \frac{\pi}{4} - \tilde{A}_G. \tag{25}$$

Since $\tilde{U}_{L,G,i} = f(\tilde{h}_L)$ and $\tilde{A}_{L,G} = f(\tilde{h}_L)$, the average reference liquid height $\tilde{h}_L(X)$ can be obtained from Eq. (8) by iteration. For this purpose, a suitable approximate solution should generally be known. Apart from the case of $\tilde{h}_L \approx 0.5$, a reliable approximate value also permits a decision to be taken on whether $\tilde{h}_L \le 0.5$ or $\tilde{h}_L \ge 0.5$ and thus on which equations are valid.

The mean liquid height in stratified flow patterns can be obtained from the void fraction ε as defined in Chap. H3. The following correlation proposed by Rouhani [7] agrees well with the measured values [8]:

$$\varepsilon = \frac{\dot{x}}{\rho_G}\left[(1 + 0.12(1-\dot{x}))\left(\frac{\dot{x}}{\rho_G} + \frac{1-\dot{x}}{\rho_L}\right) + \frac{1.18(1-\dot{x})(g\sigma(\rho_L - \rho_G))^{0.25}}{\dot{m}\rho_L^{0.25}}\right]^{-1}. \tag{26}$$

The angle φ in radians subtended by the unwetted surface is obtained by iteration from ε, i.e.,

$$\varphi = 2\pi\varepsilon + \sin\left(\varphi\frac{180}{\pi}\right). \tag{27}$$

Then with this value of ε, the appropriate value for $\tilde{h}_{L,o}$ can be determined

$$\tilde{h}_{L,o} = \frac{15\,\pi\,(1-\varepsilon)}{8(3\ \sin\ \varphi/2\ +\ 4\ \sin\ \varphi/4)} \tag{28}$$

The limiting curves can now be delineated by inserting the known values for the relative liquid height $\tilde{h}_L(X)$ in the required functions $\tilde{A}_L$, $\tilde{A}_G$, and $\tilde{U}_i$. In doing so, it is essential to adhere to the following sequence in sounding out the boundary conditions in order to obtain a unique result.

Stratified flow:

$$Re_L Fr'_G \le \left(Re_L Fr'_G\right)_{tt,lim} = \frac{(226.3)^2}{\pi^3}\tilde{A}_L\tilde{A}_G^2. \tag{29}$$

Wavy flow:

$$Fr_{Gm} \le (Fr_{Gm})_{tt,lim\ 1} = \frac{16\tilde{A}_G^3}{\pi^2\sqrt{1 - \left(2\tilde{h}_L - 1\right)^2}}\left[\frac{\pi^2}{25\tilde{h}_L^2}\left(\frac{Fr}{We}\right)_L + \frac{1}{\cos\Theta}\right]. \tag{30}$$

Bubble flow:

$$(Fr\,Eu)_L \ge \left[(Fr\,Eu)_L\right]_{lim} = \frac{128\tilde{A}_G\tilde{A}_L^2}{\pi^2\tilde{U}_i}. \tag{31}$$

Plug or slug flow:

If $X \ge 0.34$, $Re_L \ge 1{,}187$, and $Re_G \ge 1{,}187$, the following must apply:

$$Fr_{Gm} > (Fr_{Gm})_{tt,lim\ 1}. \tag{32}$$

The following conditions must be satisfied for turbulent gas and laminar liquid flow, i.e., $Re_G \geq 1{,}187$ and $Re_L < 1{,}187$:

$$X \geq 0.51 \quad \text{and} \quad Fr_{Gm} \geq (Fr_{Gm})_{tt,lim\ 1}. \tag{33}$$

Mist flow:

$$X < 0.51$$

and

$$Fr_{Gm} \geq (Fr_{Gm})_{lim\ 2} = \frac{7680\,\tilde{A}_G^2}{\pi^2 \xi_{Ph}} \left(\frac{Fr}{We}\right)_L, \tag{34}$$

where

$$\xi_{Ph} = \left[1.138 + 2\,\log\left(\frac{\pi}{1.5\,\tilde{A}_L}\right)\right]^{-2}. \tag{35}$$

Annular flow:

The conditions that must be satisfied in this case are

$$X < 0.51$$

and

$$(Fr_{Gm})_{tt,lim\ 1} < Fr_{Gm} < (Fr_{Gm})_{lim\ 2}. \tag{36}$$

All the properties denoted by the subscript "L" for boiling liquid/vapor mixtures without inert components are identical to the corresponding properties of the saturated liquid. All values denoted by the subscript "G" apply to the saturated vapor.

Slight angles of inclination, i.e., $\Theta \geq 0.5°$, suffice for a significant shift in the limits. This applies to the boundary between stratified and wavy flow and from wavy to plug or slug and annular flow. The mathematically predicted transitions agree quite well with the observations by Bornea et al. [9].

If the tubes are not circular, acceptable approximations for determining the flow pattern can be obtained by substituting the hydraulic diameter d_h for the diameter d in all the above dimensionless numbers. Thus,

$$d_h = \frac{4\,A}{U}, \tag{37}$$

where U is the wettable periphery in the assumed case that the entire cross-sectional area A is filled by the liquid.

Recently, Katan et al. [10] and Thome and El Hajal [11] have reconsidered the above procedure and transformed the above dimensionless representation of the limiting curves into non-dimensionless representations of mass flow density $\dot{m}$ versus quality $\dot{x}$. Charts produced in this manner are more easy to read than Fig. 3, nevertheless, they are only valid for a single system at a given pressure.

H3.2 Pressure Drop in Evaporator Tubes

Jogindar Mohan Chawla[1,†] · *Matthias Kind*[2]
[1]Ettlingen, Germany
[2]Karlsruhe, Germany

The pressure drop of flows through evaporator tubes is composed of three components: the frictional and the static pressure drops, and the pressure drop due to acceleration.

$$\Delta p = (\Delta p)_{\text{friction}} + (\Delta p)_{\text{static}} + (\Delta p)_{\text{acceleration}} \tag{1}$$

1 Frictional Pressure Drop

The total pressure drop due to friction can be found by integrating over the whole pipe length $l = l_2 - l_1$:

$$(\Delta p)_{\text{friction}} = \int_{l_1}^{l_2} \left(\frac{\mathrm{d}p}{\mathrm{d}l}\right)_{\text{friction}} \mathrm{d}l, \tag{2}$$

where $(\mathrm{d}p/\mathrm{d}l)_{\text{friction}}$ is the local gradient of the pressure drop due to friction.

This results from the momentum transfer among the liquid and vapor phases themselves and between them and the pipe wall. The equations for the determination of the local frictional pressure drop gradients are given in Table 1. It must be distinguished between the cases where the vapor phase is continuous or dispersed [1]. (For literature and special symbols, see Subchap. H3.8.)

2 Static Pressure Drop

The total static pressure drop can be calculated similar to the frictional pressure drop by integration of the local pressure drop gradient over the whole pipe length l:

$$\left(\frac{\mathrm{d}p}{\mathrm{d}l}\right)_{\text{static}} = \left[\rho_{\text{l}}(1-\varepsilon) + \rho_{\text{g}}\varepsilon\right] g \sin\theta, \tag{3}$$

where θ denotes the angle of inclination of the tube. The local gradient of the static pressure drop is calculated by superposition of the contribution of the liquid and vapor phases. The equations for the determination of the vapor volume fraction ε in the above equation are given in Table 2. Like in the previous case of local frictional pressure drop gradient it must be distinguished whether the vapor phase is dispersed or not [1].

3 Pressure Drop due to Acceleration

The component of the pressure drop which is due to acceleration arises from momentum change of both of the flowing phases after heat supply. With the knowledge of the mean flow velocities of both phases this can be calculated rather accurately. The local pressure drop due to acceleration is given by the following equation that takes the change $\mathrm{d}\dot{x}$ of vapor content with the change of momentum flow $\mathrm{d}(I)/\mathrm{d}(t)$ into consideration:

$$(\mathrm{d}p)_{\text{acceleration}} = \frac{\mathrm{d}(I)/\mathrm{d}(t)}{\pi d^2/4} = \frac{\mathrm{d}(\dot{I})}{\pi d^2/4}. \tag{4}$$

The flow of momentum is

$$\dot{I} = \frac{\pi d^2}{4}\dot{m}^2\left[\frac{\dot{x}^2}{\varepsilon\rho_{\text{g}}} + \frac{(1-\dot{x})^2}{(1-\alpha)\varepsilon\rho_{\text{l}}}\right]. \tag{5}$$

Then, the total pressure drop caused by acceleration becomes

$$(\Delta p)_{\text{acceleration}} = \dot{m}^2 \int_{\dot{I}_1}^{\dot{I}_2} d\left[\frac{\dot{x}^2}{\varepsilon\rho_{\text{g}}} + \frac{(1-\dot{x})^2}{(1-\varepsilon)\rho_{\text{l}}}\right] \tag{6}$$

$$(\Delta p)_{\text{acceleration}} = \dot{m}^2 \left|\frac{\dot{x}^2}{\varepsilon\rho_{\text{g}}} + \frac{(1-\dot{x})^2}{(1-\varepsilon)\rho_{\text{l}}}\right|_{x_1}^{x_2}. \tag{7}$$

For a complete evaporation, the vapor content changes from 0 to 1 and the pressure drop is

$$(\Delta p)_{\text{acceleration}} = \dot{m}^2\left(\frac{1}{\rho_{\text{g}}} - \frac{1}{\rho_{\text{l}}}\right). \tag{8}$$

H3.3 Subcooled Boiling

Matthias Kind[1] · *Jens-Jürgen Schröder*[2,†]
[1]Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany
[2]Hannover, Germany

This chapter considers boiling during the transfer of high heat fluxes to a subcooled flowing liquid. It demonstrates how the associated changes in wall temperature, density, and pressure can be quantitatively predicted. An important application is in reactor technology, when information has to be acquired on the average vapor flow rate per unit of cross-sectional area that can be obtained from a given heat flux.

As a general rule, subcooled boiling frequently gives rise to two-phase instability and fluctuations in mass flow rate in process circuits.

1 Description of the Phenomena

When a liquid, which is undercooled with respect to its boiling point, flows through a heated channel, as illustrated in Fig. 1, subcooled boiling commences at the point where the first bubbles are formed on the wall. This point is referred to as the initial point (subscript *i*). In most of the cases that have been investigated up to now, the initial point is not followed immediately by a significant increase in the vapor volumetric fraction per unit area of cross-section, referred to as the void fraction ε (Fig. 1, Part C), where (for literature and special symbols, see Subchap. H3.8)

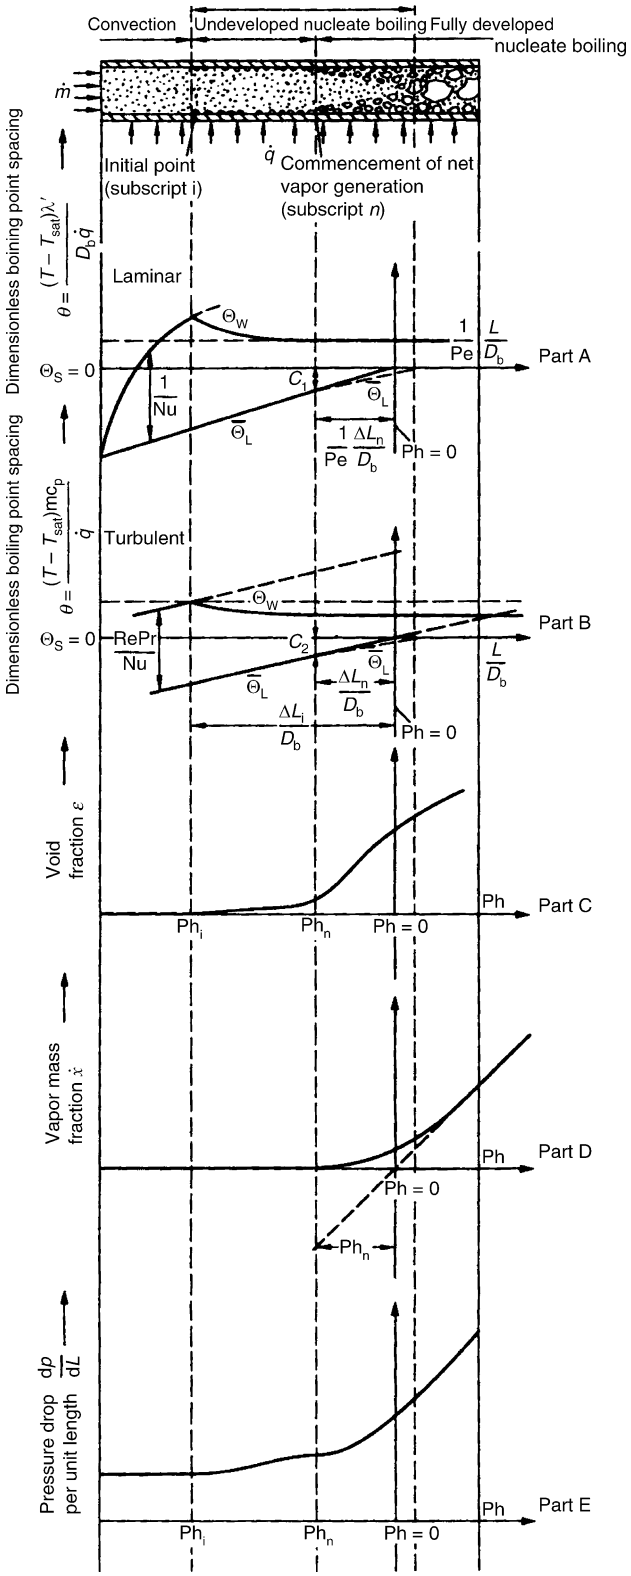
$$\varepsilon = A_G/A. \tag{1}$$

The reason for this is that the bubbles collapse either at the wall itself or in its near vicinity immediately after they have been formed. Thus, heat transfer is improved. The rise in wall temperature, thus, decreases and may even become negative (Fig. 1, Parts A and B). (The purpose of presenting two separate dimensionless temperature profiles – the one for purely laminar flow (Part A) and the other for completely developed turbulent flow (Part B) – will be evident in many of the passages that follow.) The decrease is caused by simultaneous evaporation and condensation: the bubbles act as a heat pipe in the boundary layer. Another reason is the increased turbulence in the layer of liquid close to the wall and downstream from the initial point. The superheating of the wall prior to the initial point may be an undesirable phenomenon, for instance, during evaporative cooling of electronic parts by wetting liquids [1–4].

Afterwards, the bubbles slide along the wall [5] and do not enter the bulk of the liquid until a point further downstream is reached at which the temperature of the bulk has also risen to the vicinity of the boiling point. Penetration of the bubbles into the bulk is accompanied simultaneously by a decided increase in the void fraction and the commencement of net vapor generation (subscript *n*). At this point, the vapor mass fraction $\dot{x}$ commences to rise (Fig. 1, Part D), where

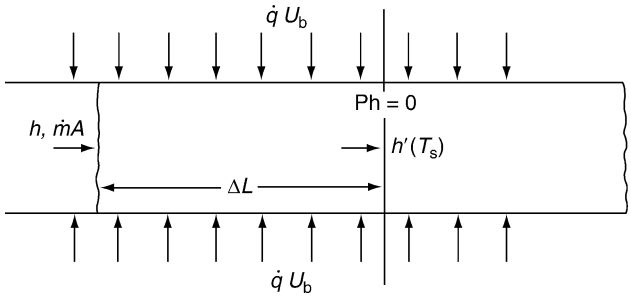
$$\dot{x} = \dot{m}_G/\dot{m}. \tag{2}$$

†Deceased



H3.3. Fig. 1. Phenomena occurring during heat transfer in a heated channel.

Still further downstream, recondensation is no longer a significant factor, and the heat transfer mechanism commences to develop in the same way as forced-convection saturation boiling (see Subchap. H3.4).



H3.3. Fig. 2. Energy balance for subcooled flow through a channel.

1.1 Location of Points in the Heated Channel

If the mean heat flux in the direction of flow is $\dot{q}_m$ and the mass velocity in the cross-sectional area A is $\dot{m}$, the following relationship can be obtained from an energy balance between any one point in the channel through which the subcooled liquid flows (Fig. 2) and the point at which the saturation enthalpy h' is attained:

$$\frac{\dot{m}(h' - h)}{4\dot{q}_m} = \frac{\Delta L}{D_b}, \tag{3}$$

where D_b is a characteristic length derived from the cross-sectional area A and the heated periphery U_b, that is,

$$D_b = \frac{4A}{U_b}. \tag{4}$$

If the channel is a tube that is heated uniformly over its entire circumference, D_b is its diameter.

Hence, $\Delta L/D_b$ is the dimensionless distance between the cross-section at any given point and the cross-section with the caloric mean saturation temperature. The enthalpy h is also taken to be the caloric mean value at the cross-section in question.

In the following analysis, the point at which the enthalpy h is attained, is identified by the phase number Ph, which is a dimensionless boiling point spacing, that is,

$$\mathrm{Ph} \equiv \frac{h - h'}{\Delta h_v}. \tag{5}$$

If $h' \le h \le h''$, which is a case that is not considered here, Ph is identical to the vapor mass fraction at thermodynamic equilibrium, that is, the vapor quality. It is a caloric dimension that is not necessarily proportional to $\Delta L/D_b$. This can be demonstrated by substituting $\mathrm{Ph}\Delta h_v$ for $(h - h')$ on the left of Eq. (3) and multiplying by the term N_{bm} which is given by

$$N_{bm} \equiv \frac{\dot{q}_m}{\dot{m}\,\Delta h_v}. \tag{6}$$

The relationship, thus, obtained is

$$-\frac{\mathrm{Ph}}{4\,\Delta h_v} = \frac{\Delta L}{D_b}. \tag{7}$$

N_{bm} is the boiling number, that is, a dimensionless expression for the mean heat load in a given stretch of boiling liquid. As a rule, it is not a constant.

Equation (7) can be applied to the balance between any two points in the channel, in which it becomes

$$-\frac{(\mathrm{Ph}_1 - \mathrm{Ph}_2)}{4\,N_{bm\,1,2}} = \frac{\Delta L_{1,2}}{D_b}. \tag{7a}$$

If the two points are the channel inlet and $\mathrm{Ph} = 0$, Eq. (7) becomes

$$-\frac{\mathrm{Ph}_0}{4\,N_{bm\,0}} = \frac{\Delta L_0}{D_b}. \tag{7b}$$

1.2 Initial Conditions

The generation of vapor bubbles in subcooled liquids on a heated wall is closely connected to the temperature profile. Thus, if single-phase heat transfer is assumed, the first step in a calculation is to determine the temperature profile in the wall T_W (if it is not already given) and that in the inflowing liquid.

In practice, the conditions will lie between two limiting cases: purely laminar flow of the heated liquid ($\mathrm{Re} < 2 \times 10^3$) and completely turbulent flow ($\mathrm{Re} > 10^5$). If the hydrodynamic profile is fully developed, both cases are quite easy to calculate. Parts A and B in Fig. 1 illustrate qualitatively the characteristic wall temperature and the mean liquid temperature profiles in a generalized dimensionless form for a constant heat flux $\dot{q}$. They extend to the initial point i, which can be determined as described in Chap. G1.

A distinction has been drawn between the definition for the dimensionless boiling point spacing in purely laminar flow (Part A) and that in fully turbulent flow (Part B). It allows for the fact that, in the first case, it is the molecular term λ' that is responsible for heat transport that is not brought about by vapor bubbles; and, in the second case, it is the turbulent term $\lambda' \mathrm{Pe}$.
Clausse and Lahey [6] have demonstrated that the occurrence of subcooled boiling also depends on whether the thermal conditions allow hydrodynamic flow to develop at as early a stage as possible.

1.3 Laminar Flow ($\mathrm{Re} < 2 \times 10^3$)

(Fully developed hydrodynamic profile; the section for thermal development is generally very long.)

The following applies for tubular cross-sections in which $d = D_b = D_h$ (hydraulic diameter);
For $\dot{q}$ = constant,

$$\mathrm{Nu}(l) = \frac{\alpha(l)\,d}{\lambda} = 4.36\left[1 + \left(0.0292\mathrm{Pe}\,\frac{d}{l}\right)^2\right]^{0.15}\left(\frac{\mathrm{Pr}}{\mathrm{Pr}_w}\right)^{0.14}. \tag{8a}$$

For T_W = constant, the local coefficient $\alpha(l)$ is

$$\mathrm{Nu}(l) = \frac{\alpha(l)\,d}{\lambda} = \frac{3.66^3 + 2/3(1.61^3\mathrm{Pe}\cdot d/l)}{(3.66^3 + 1.61^3\mathrm{Pe}\cdot d/l)^{2/3}}\left(\frac{\mathrm{Pr}}{\mathrm{Pr}_w}\right)^{0.14} \tag{8b}$$

and the average coefficient is

$$\mathrm{Nu}(l) = \frac{\alpha(l)\,d}{\lambda} = \left(3.66^3 + 1.61^3\mathrm{Pe}\cdot d/l\right)^{1/3}\left(\frac{\mathrm{Pr}}{\mathrm{Pr}_w}\right)^{0.14}. \tag{8c}$$

Mathematical methods for other cross-sections have been proposed by Kay [7].

1.4 Turbulent flow ($\mathrm{Re} < 10^5$)

For $\dot{q}$ = constant,

$$\frac{\mathrm{Nu}(l)}{\mathrm{Pe}} = \frac{\alpha(l)}{\dot{m}\cdot c_p} = \frac{\xi/8}{1 + 12.7\sqrt{\xi/8}\,(\mathrm{Pr}^{2/3} - 1)}\left[1 + \left(\frac{d}{l}\right)^{2/3}\right]\left(\frac{\mathrm{Pr}}{\mathrm{Pr}_w}\right)^{0.14}. \tag{9a}$$

For T_W = constant, the local coefficient $\alpha(l)$ is

$$\frac{\mathrm{Nu}(l)}{\mathrm{Pe}} = \frac{\alpha(l)}{\dot{m}\cdot c_p} = \frac{\xi/8}{1 + 12.7\sqrt{\xi/8}\,(\mathrm{Pr}^{2/3} - 1)}\left[1 + \frac{1}{3}\left(\frac{d}{l}\right)^{2/3}\right]\left(\frac{\mathrm{Pr}}{\mathrm{Pr}_w}\right)^{0.14}. \tag{9b}$$

For the average coefficient $\alpha(l)$, see Eq. (9a) where

$$\xi = (0.790\ln\mathrm{Re} - 1.64)^{-2}. \tag{10}$$

The length of the section l is measured from the point at which heating commences. All the properties must be referred to the average liquid temperature, which is obtained from the wall temperature, for which an estimate must be made first. However, Pr_w must be referred to the wall temperature. The full Gnielinski [8] equation (Eq. (24) in Chap. G1) must be resorted to for the transition between purely laminar and fully developed turbulent flow. Thus,

$$T_W - T_L = \frac{\dot{q}}{\alpha}. \tag{11}$$

2 Nucleate Boiling Incipience

The length l_i that is traversed by the liquid before nucleate boiling commences, is obtained from

$$\frac{l_i}{D_b} = \frac{\Delta L_0}{D_b} - \frac{\Delta L_i}{D_b},$$

where ΔL_0 is the length of the channel between the inlet and the point at which saturation enthalpy is attained, $\Delta L_0/D_b$ is obtained from Eq. (3) by substituting the enthalpy at the inlet cross-section for h, and $\Delta L_i/D_b$ follows from Eq. (7) if $\mathrm{Ph}_i = (h_i - h)/\Delta h_v$ is known.

There are special cases in which Ph_i can be determined directly from empirical equations [9]. The following procedure must be adopted in other cases.

If $T_L(l_i)$ is the average temperature of the liquid at the initial point, the corresponding enthalpy h_i is obtained from

$$h' - h_i = c_p[T_{sat} - T_L(l_i)]. \tag{12}$$

Since $\dot{q} = \alpha(l_i)\,[T_W - T_L\,(l_i)]$, Eq. (12) can be transformed into

$$\begin{aligned} h' - h_i &= c_p\,[(T_W - T_L(l_i)) - (T_W - T_{sat})_i], \\ h' - h_i &= c_p\left[\frac{\dot{q}}{\alpha(l_i)} - (T_W - T_{sat})_i\right]. \end{aligned} \tag{12a}$$

Inserting Ph_i from Eq. (5) gives

$$\mathrm{Ph}_i = \frac{h_i - h'}{\Delta h_v} = -\frac{c_p}{\Delta h_v}\left[\frac{\dot{q}}{\alpha(l_i)} - (T_W - T_{sat})_i\right]. \tag{12b}$$

The terms $\alpha(l_i)$ and $(T_W - T_{sat})_i$ must be known in order to determine the length l_i up to the initial point. $\alpha(l_i)$ is derived from Eqs. (8a), (8b), (9a), or (9b); the choice depends on how the heat is transferred. The wall superheat $(T_W - T_{sat})_i$ can then be calculated either from empirical equations [10] or from theoretical models [11].

2.1 Determination of the Initial Point from Residual Subcooling of Water in Turbulent Flow and Elevated Pressures in Vertical Tubes

The term $\overline{T}_L$ in the expression $(T_L - T_{sat})_i$ for residual subcooling is the caloric mean liquid temperature corresponding to h. Even if the wall temperature profile is unknown, the initial point for a given heat flux can be determined from a relationship suggested by Hodgson [9] for $(7 \le p \le 138$ bar), that is,

$$141\left(N_{b,i}\right)^{0.7} = (-\mathrm{Ph}_i)^{0.55} H_b^{0.08}. \tag{13}$$

The term H_b allows for the effect of pressure:

$$H_b = -\frac{\Delta h_v}{c'_p} \frac{d\left(\frac{\rho'}{\rho''}\right)\Big/ \mathrm{d}p}{\mathrm{d}T_b/\mathrm{d}p} \approx \frac{\Delta h_v^2}{c'_p T\, v'\, p}. \tag{14}$$

The following relationship applies for water:

$$H_b^{0.08} \approx 1.25\left(\frac{p}{p_c}\right)^{-0.1}, \tag{14a}$$

where p_c is the critical pressure.

The location of the point associated with Ph_i is determined from Eq. (7) or (7a). Equation (13) was derived by extrapolating the ratio of heat transfer coefficients α/α_1 obtained from measurements toward a limit of unity, that is, $\alpha/\alpha_1 \to 1$. It has been checked by Guglielmini et al. [12] in the light of measurements, inc1uding those by other authors, and has also been confirmed by data extracted from more recent literature (cf. Fig. 3).

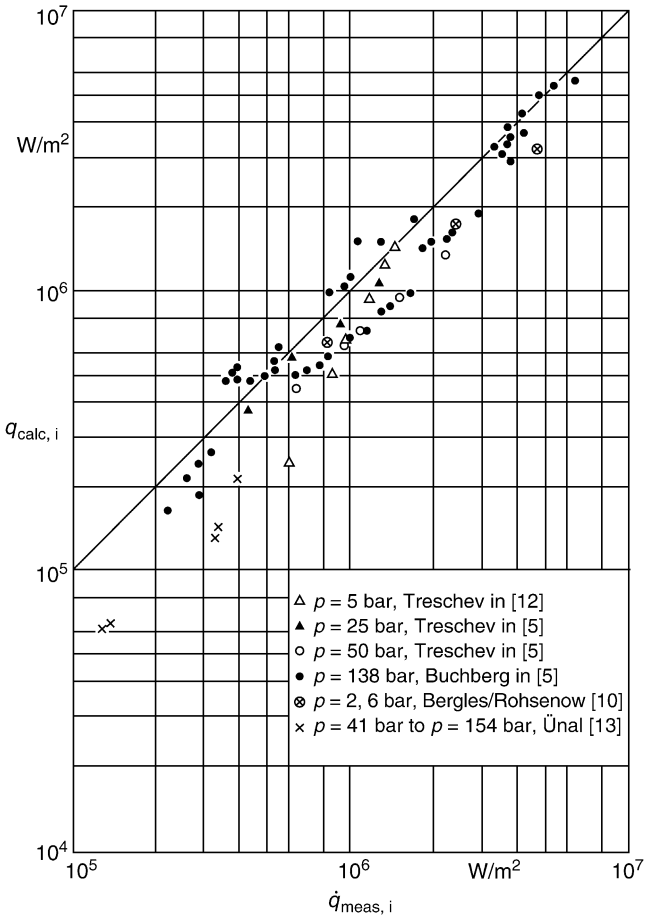
Almost the same exponential relationship, namely, $N_{bi} \sim \mathrm{Ph}_i^{0.773}$, as opposed to $N_{bi} \sim \mathrm{Ph}_i^{0.786}$, was determined by Bräuer and Mayinger [14] in their experiments on R 12 in an annulus. The results also revealed that the constant of proportionality depends slightly on the Reynolds number.

Bucher [15], Müller-Steinhagen et al. [16], You et al. [4], and other authors studied the effect of dissolved inert gases on the initial point.

2.2 Determination of the Initial Point from the Wall Superheat in Boiling Water at Elevated Pressures in Vertical Tubes

As long as free convection can be neglected, an effect of vertical flow cannot be determined [17, 18].

Good results for water have been obtained with an empirical equation developed by Bergles and Rosenow [10]. At pressures



H3.3. Fig. 3. Comparison of values of heat flux calculated from Eq. (13) with measured values.

of 1–140 bar, the wall superheat for $\dot{q}$ = constant at the initial point is given by

$$(T_W - T_{sat})_i = \frac{5}{9}\left[\left(\frac{\dot{q}}{1120}\right)^{0.463} p^{-0.535}\right]^{p^{0.0234}}, \tag{15}$$

where $(T_W - T_{sat})_i$ is in K, $\dot{q}$ in W/m^2, and p in bar. This relationship for water has proved to be independent of the properties of the heated surface.

2.3 Initial Point in Boiling Water at Elevated Pressures in Horizontal and Inclined Tubes

In these cases, boiling may commence earlier if free convection within the liquid is a significant factor. The subject has been dealt with by Hein et al. [19].

2.4 Wall Superheat in Boiling Water ($p \sim 1$ bar), Organic Liquids, Refrigerants, and Liquefied Gas

Refer to Subchap. H2.2 "Physical conditions for the initiation of the bubble formation" and the respective equation, given there.

Example 1

Determine $(T_W - T_{sat})_i$ for water under the following conditions: $T_{sat} = (273 + 200)\ K = 473\ K$; $p = 15.55$ bar; $\dot{q} = 2\ MW/m^2$.

Inserting the corresponding values for the properties, which can be obtained in Subchap. H2.2, Eq. (17) gives $(T_W - T_{sat})_i \approx 5.3$ K. This agrees well with the figure obtained from Eq. (15), namely, $(T_W - T_{sat})_i \approx 4.8$ K. Inserting the values for the properties in Eq. (16) gives $r_{crit,i} = 1\ \mu m$. Since water is generally a very poor wetting agent, there is no doubt that a nucleation site of this order will be present on a technically rough heated surface. Hence, the first bubbles are very likely to appear at a wall superheat of approximately 5 K.

3 Onset of Net Vapor Generation

A quantitative description can be obtained with the aid of a simple model developed by Saha and Zuber [20]. According to this, net vapor generation commences when, owing to slight subcooling $(T - T_{sat})$, recondensation of the vapor bubbles close to the wall no longer suffices to remove the applied heat. Since the latent heat of condensation is removed by conductivity in purely laminar flow, the following equation holds:

$$\frac{1}{C_1}\left(T_{sat} - \overline{T}_L\right)_n \frac{\lambda'}{D_b} = \dot{q}. \tag{16}$$

Alternatively, if $\dot{q}$ = constant, Eq. (7) can be applied to give

$$\frac{\left(T_{sat} - \overline{T}_L\right)_n \lambda'}{\dot{q} D_b} = -\frac{1}{Pe}\frac{Ph_0}{N_b} = 4\frac{N_{bm}}{N_b}\frac{1}{Pe}\frac{\Delta L_n}{D_b} = C_1.$$

Heat transfer is much more intensive in completely developed turbulent flow. As a first approximation, the ratio of the turbulent to the molecular component is proportional to the Péclet number, that is,

$$\frac{1}{C_2}\left(T_{sat} - \overline{T}_L\right)_n \frac{\lambda'}{D_b} Pe = \dot{q}. \tag{17}$$

Alternatively, if $\dot{q}$ = constant, Eq. (7) can be applied to give

$$\frac{\left(T_{sat} - \overline{T}_L\right)_n \dot{m} c_p}{\dot{q}} = -\frac{Ph_n}{N_b} = 4\frac{N_{bm}}{N_b}\frac{\Delta L_n}{D_b} = C_2.$$

Since the nucleation sites have already been completely activated, it can be expected that the proportionality constants C_1 and C_2 hardly depend any longer on the specific properties of the heated surfaces and thus, remain the same in all cases that are otherwise physically similar.

Hence C_1 and C_2 characterize specifically similar caloric states and can be uniquely described only if Ph_n and the type of flow (laminar or turbulent) are given. There is no similarity to the $\Delta L_n/D_b$ model unless $\dot{q}$ = constant or $N_{bm} = N_b$.

In the light of the experimental results at their disposal, Saha and Zuber [20] arrived at the following figures:

$1/C_1 = 455$ for $Pe \le 70,000$ and $1/C_2 = 0.0065$ for $Pe \ge 70,000$.

The evaluation of other experimental data indicates the following relationship for the transition zone between purely laminar and completely developed turbulent flow:

$$\frac{1}{C_2} = \left[\left(\frac{455}{Pe}\right)^2 + 0.0065^2\right]^{1/2}. \tag{18}$$

In Fig. 4, values calculated from this equation are compared with experimental results.

In the turbulent region ($Pe > 70,000$), experimental data for refrigerant R 113 lie below the constant $C_2 = 1/0.0065$ given by Saha and Zuber [20]. In this case, they are approximated better by $C_2 = 1/0.0033$.

Bartolomei et al. [34] derived a purely empirical equation for the phase number Ph_n. It permits the conclusion that C_2 possibly still depends on pressure and, to a slight extent, on the heat and mass fluxes.

In the experiments on annular channels in the *Slowpoke* project, Rogers et al. [32] discovered that subcooling at the point n increased with the velocity, although the Péclet number was $Pe < 70,000$. As can be seen from Fig. 5, this does not affect the Saha and Zuber relationship in the first instance.

4 Improvement in Heat Transfer and the Wall Temperature Profile

4.1 Constant Heat Flux

A measure for any improvement is the following ratio:

$$\frac{T_W - \overline{T}_L}{\left(T_W - \overline{T}_L\right)_i} = \frac{\alpha_i}{\alpha}.$$

4.1.1 Determination on the Basis of Experimental Data: Water at Elevated Pressure ($7 \le p \le 138$ bar)

The Hodgson [9] empirical equation is valid in this range, that is,

$$\frac{\alpha_i}{\alpha} = 0.0152\left(\frac{\Delta L}{D_b}\right)^{0.55} N_b^{-0.15} H_b^{0.03}, \tag{19}$$

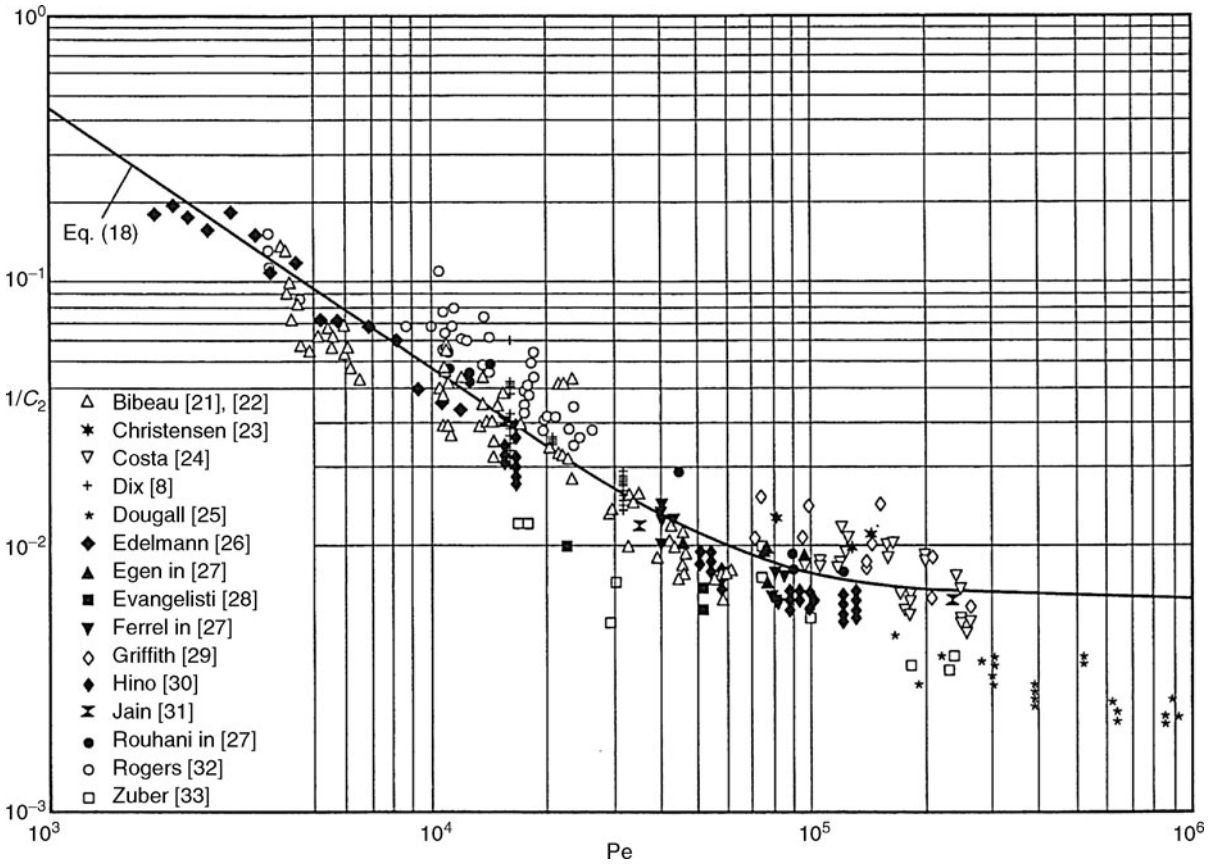
where α_i is as determined from Eq. (9) and

$$\frac{\Delta L_n}{D_b} < \frac{\Delta L}{D_b} \le \frac{\Delta L_i}{D_b}.$$

Since Eq. (19), which is analogous to Eq. (13), was derived from measurements on very short tubes, α_i/α can be regarded as a local ratio. Figures calculated from the equation correspond to within ±20% to values measured by Hodgson [9] and other authors. It does not allow for the hysteresis that is observed between rising and falling values of heat flux.

In this range of pressures, $H_b^{0.08}$ is given by

$$H_b^{0.08} \approx 1.25\left(\frac{p}{p_c}\right)^{-0.10}. \tag{20}$$



H3.3. Fig. 4. Comparison of measured values with figures calculated from Eq. (21). (Many of the data plotted in this diagram are dealt with in greater detail by Saha and Zuber [20].)

4.1.2 Determination on the Basis of Experimental Data: Other Liquids and Water at $p \cong 1$ bar

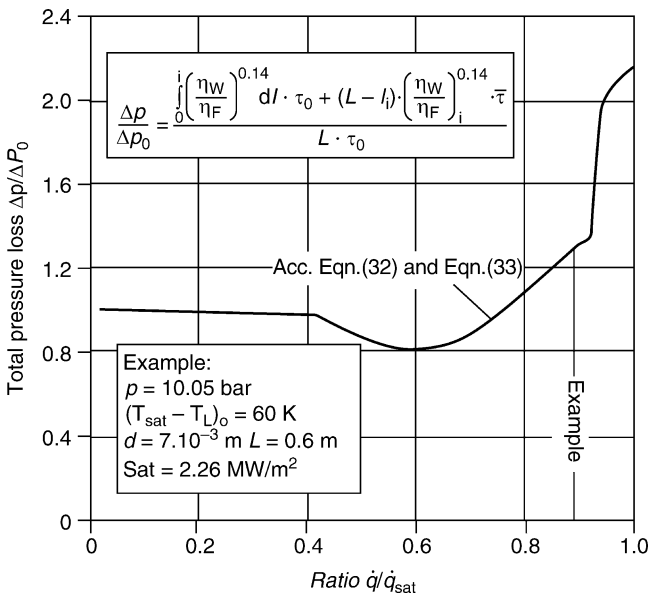
Equation (21) has been suggested by Moles and Shaw [35] for water and other liquids. It was derived from numerous measurements on short tubes:

$$\frac{\alpha_i}{\alpha} = 0.0254 \left(\frac{\Delta L}{D_b}\right)^{0.50} N_b^{-0.17} \mathrm{Pr}^{0.46} \left(\frac{\rho'}{\rho''}\right)^{0.03}, \qquad (21)$$

where

$$\frac{\Delta L_n}{D_b} < \frac{\Delta L}{D_b} \leq \frac{\Delta L_i}{D_b}.$$

This equation yields figures that conform to within ± 40% with 90% of all values measured on water, ethanol [36], 1-butanol [19], ammonia [19], and hydrazine [37]. It also gives good results for R 12 [36].



H3.3. Fig. 5. Example 2f: total pressure loss.

4.1.3 Determination on the Basis of Experimental Saturation Boiling Data: All Substances

Justification of the mathematical method presented here exists in the fact that its results agree well with those obtained for water from Eq. (19). In fact, in a check against values determined for R 12 [38], it proved to be superior to other mathematical methods given in the literature. In any case, it continuously phases into the method described in Subchap. H3.4 for the determination of heat transfer during the boiling of saturated liquids.

The entire heat flux is split up into a hydrodynamic component and a component that is described by a boiling point curve that is independent of the mass flux and its vapor fraction. The local heat flux is given by

$$\dot{q}(l) = \dot{q}_{\mathrm{conv}}(l) + \dot{q}_B(l), \tag{22}$$

where $\dot{q}_{\mathrm{conv}} = \alpha_i(l)(T_W - T_L)$, $\dot{q}_B = \alpha_B(l)\,(T_W - T_{sat})$, and $\alpha_B(l)$ is given in Subchap. H3.4.

Remarks

The method suggested by Chen [39] and adopted by Bergles et al. [40] for convective saturation boiling generally cannot be recommended for subcooled boiling, despite the explicitly worded findings of Gungor and Winterton [41, 42] about its suitability. The method based on an equation derived by Forster and Zuber [43] for saturated pool boiling makes use of a bubble suppression factor S that depends on Reynolds number. The aim of this factor is to allow for the fact that the thermal boundary layer becomes progressively thinner as the Reynolds number increases, with the result that bubble formation is impeded. If the method is applied to the results of experiments performed at high heat fluxes, it can be seen that S must be substantially greater than unity ($S >> 1$, cf. [38]). In addition, heat transfer must be largely independent of Reynolds number. This has been demonstrated by Del Valle and Kenning [44] in more recent measurements on subcooled water at high heat fluxes and at ambient pressure.

Furthermore, in the case of very high supercooling measurements [44] show an explicit improvement of the heat transfer rate. This can only be explained by a further boiling mechanism, which is described in Subchap. H2.2, Eq. (28). This mechanism is active at Ja-numbers >100. It cannot be described with Eq. (60) in Subchap. H3.4. Bergles and Rohsenow [10] found massive hydrodynamic instabilities for slowly flowing water at 2.6 bar and subcoolings $60\ \mathrm{K} < (T - T_{sat}) < 90\ \mathrm{K}$. These instabilities must be attributed to the above-mentioned further boiling mechanism.

4.1.4 Determination of Wall Temperature Profile

The wall temperature has to be determined by iteration. The first step is to determine the wall superheat on the assumption that the entire heat flux $\dot{q}$ is still transferred barely by convection, that is,

$$\left(T_W - \overline{T}_L\right)_i = \frac{\dot{q}}{\alpha_i}. \tag{23}$$

(The subscript i has been inserted because the equation corresponds to the conditions at the initial point.)

Afterward, the wall superheat is calculated on the assumption that the entire heat flux is transferred by saturation boiling, that is,

$$\left(T_W - \overline{T}_L\right)_i = \frac{\dot{q}}{\alpha_B(\dot{q})}. \tag{24}$$

Thus, the wall temperature corresponding to T_L, is

$$1 - \left[\frac{T_W - T_{sat}}{(T_W - T_{sat})_B}\right]^{1/(1-n)} = \frac{T_W - \overline{T}_L}{\left(T_W - \overline{T}_L\right)_i}. \tag{25}$$

The value to be chosen for the term n in the exponent is the same which describes the relationship between the heat transfer coefficient and the heat flux as given in Subchap. H3.4.

4.2 Constant Wall Temperature

It can be assumed as a first approximation that the heat is linearly related to the residual subcooling between the initial point Ph_i and the point at which the saturation enthalpy is reached. In this case, the length of the heated section required to transfer heat from Ph_i to $\mathrm{Ph} = 0$ can be calculated from Eq. (7).

The average heat flux is taken for the determination of the boiling number N_{bm} and is given by

$$\dot{q}_m = \frac{\dot{q}_{\max} - \dot{q}_{\min}}{\ln(\dot{q}_{\max}/\dot{q}_{\min})}, \tag{26}$$

where $\dot{q}_{\max} = (\alpha_i + \alpha_B)\,(T_W - T_{sat})$, $\dot{q}_{\min} = \alpha\left(T_W - \overline{T}_{L,it}\right)$, and α_B is a function of $(T_W - T_{sat})$ as described in Sect. 4.1.2.

5 Void Fraction

Rouhani [45] has proved by experiment that the void fraction ε increases only slightly after the initial point (cf. Part C in Fig. 1). It does not commence to increase rapidly until bubbles are generated in large numbers within the bulk of the flow at a point that is characteristic for the onset of net vapor generation. The development of the void fraction has been described in the form of semiempirical equations by Rouhani [46] for water at elevated pressure.

5.1 Approximation for $\varepsilon < \varepsilon_n$

An equation for interpolation in this range has been derived by Jain et al. [31] from their measurements on R 113, that is,

$$\varepsilon = \varepsilon_n \left(\frac{\mathrm{Ph} - \mathrm{Ph}_i}{\mathrm{Ph}_n - \mathrm{Ph}_i}\right)^{0.6} \left[1 - \exp\left(\frac{1}{4}\left(\frac{\Delta L_n}{D_b} - \frac{\Delta L_i}{D_b}\right)\right)\right], \tag{27}$$

$$\mathrm{Ph}_i < \mathrm{Ph} < \mathrm{Ph}_n.$$

The following applies for water [46]

$$\varepsilon_n = 9.74 \frac{10^{-3}}{D_b}\, p^{-0.237}, \tag{28}$$

where D_b is in meters and p is in $\mathrm{N/m^2}$.

The following figures apply for refrigerants: $\varepsilon_n = 0.005 - 0.01$ [31].

5.2 Approximation for $\varepsilon > \varepsilon_n$

The further development of the void fraction, with an allowance for buoyancy in vertical tubes, can be estimated from an equation derived by Zuber and Findlay [33], that is,

$$\varepsilon - \varepsilon_n = \frac{\dot{x}}{\rho''}\left\{C\left(\frac{\dot{x}}{\rho''} + \frac{1-\dot{x}}{\rho'}\right) + \frac{1.18}{\dot{m}}\left[\frac{\sigma g(\rho' - \rho'')}{\rho'^2}\right]^{1/4}\right\}^{-1}. \tag{29}$$

Rouhani [46] determined the following numerical values for C by comparing the figures calculated from the above equation with the results of his measurements: $C = 1.54$ for almost laminar flow and $C = 1.12$ for turbulent flow.

6 Vapor Mass Fraction

In the light of experimental data, Levy [27] demonstrated that the vapor mass fraction $\dot{x}$ (Part D in Fig. 1) can be adequately represented in almost all cases by a simplified model, that is,

$$\dot{x} = \mathrm{Ph} - \mathrm{Ph}_n \exp\left(\frac{\mathrm{Ph}}{\mathrm{Ph}_n} - 1\right). \tag{30}$$

The case of $\mathrm{Ph} > \mathrm{Ph}_n$ (negative) corresponds to Eq. (5). Firstly, $\dot{x}$ is calculated from Eq. (30); and, secondly, $\varepsilon - \varepsilon_n$ from Eq. (29).

7 Pressure Drop

An improvement of heat transfer in subcooled boiling along a given heated surface is accompanied by an increase in the total pressure drop (Part E in Fig. 1). As is shown in Subchap. H3.2, a momentum balance in the form of a separated flow model for an element $\mathrm{d}L$ of the flow path is given by

$$-\frac{\mathrm{d}p}{\mathrm{d}L} = \frac{\tau_W U}{f} + \dot{m}^2 \frac{\mathrm{d}}{\mathrm{d}L}\left[\frac{\dot{x}^2}{\varepsilon\rho''} + \frac{(1-\dot{x})^2}{1-\varepsilon}\frac{1}{\rho'}\right] + g(\varepsilon\rho'' + (1-\varepsilon)\rho')\sin\gamma. \tag{31}$$

If the flow channel is horizontal, $\gamma = 0°$. Provided that heat transfer is single phase, τ_W can be determined as described in Subchap. H3.2 if due allowance is made for the changes in properties that are caused by heating. Thus,

$$\tau_W = \tau_0\left(\frac{\eta_W}{\eta_F}\right)^m. \tag{32}$$

If the tube and annulus are heated internally, the value for the index $m = 0.14$; and if the annulus is heated externally and internally, $m = 0.25$.

τ_W increases when the first coherent bubbles appear, as denoted by the subscript i. In this case, the second term in Eq. (31) remains comparatively insignificant. When the first bubbles are detached and emerge from the boundary layer (subscript n), τ_W decreases again as the wall becomes more densely covered by bubbles, whereas the second term commences to rise rapidly. In this range, instability and fluctuations in flow may arise.

Very few investigations have been made on pressure drop in subcooled boiling, and they have mainly been restricted to water [24, 44, and 47]. For the development of a computer code, Hoffmann and Wong [48] subdivide the heated pipe into sections according to their respective boiling phenomena. Bartolomei and Kovrizhnykh [49] give an overall equation which takes into account data by Tarasova et al. [50]:

$$\frac{\bar{\tau}}{\tau_{Wi}} = 1 + 170 N_b^{0.7}\left(\frac{\rho'}{\rho''}\right)^{0.3}\left(\frac{w^2}{g\cdot l_0}\right)^{-0.15}\left(1 - \frac{\mathrm{Ph}(L)}{\mathrm{Ph}_i}\right)^{1.5}, \tag{33}$$

with $\mathrm{Ph}_i < \mathrm{Ph}(L)$, where $\mathrm{Ph}(L)$ can be positive as well as negative. The characteristic length

$$l_0 = \sqrt{\frac{\sigma}{g(\rho' - \rho'')}}$$

is proportional to the size of bubble detachment. Thus, it can be seen that, since $\tau_{Wi} < \tau_0$, the total pressure drop may, in practice, be less than the pressure drop that would occur if the liquid were to continue to flow adiabatically under the conditions at the evaporator tube inlet (inlet condition τ_0). This would be the case if the liquid were still strongly undercooled at the outlet, although subcooled boiling had already taken place [51] and Fig. 5.

At high system pressures, the relationship between the pressure drop, the mass flow rate, and the boiling number N_b is not so pronounced as it is at ambient pressure. This is because the difference in density between steam and water, and the resultant forces of acceleration are less. The factor $(\rho'/\rho'')^{0.3} N_b^{0.7}$ makes due allowance for the great significance that is attached at low total pressures to the amount of heat transferred to the stream of subcooled liquid and the ratio of the liquid to the vapor density.

On the basis of experimental data for various refrigerants and for water, Hahne et al. [52] give a correlation for the pressure loss as a function of boiling number and subcooling.

Example 2

Water flows at a rate of $\dot{m} = 3 \times 10^3$ kg/(m^{2}s) and an average pressure of $p = 10.05$ bar($T_{sat} = 180°$C) through a vertical, electrically heated tube ($\dot{q} = 2 \times 10^6$ W/m^2; D = D_b = 7 × 10^{-3} m; L = 0.6 m). The subcooling at the inlet is $(\overline{T}_L - T_{sat})_0 = -60$ K. (The inlet is indicated by the subscript 0.)

(a) Where is the initial point located?
(b) At which point does the onset of net steam generation occur?
(c) What is the magnitude of $\dot{x}(L)$?
(d) What is the magnitude of $\varepsilon(L)$?
(e) What is the wall temperature profile or how great is $\alpha(l)$?
(f) How much is the pressure drop $\Delta p/\Delta p_0$ greater than if the tube were unheated?

Properties at $T = 120°$C:

$$\eta = 0.232 \times 10^{-3}\,\mathrm{kg/ms};\ c_p = 4245\ \mathrm{J/kg\,K};$$
$$\lambda = 0.683\,\mathrm{W/m\,K};\ \rho = 943\,\mathrm{kg/m^3}.$$

Properties at $T = 180°C$:

$$\Delta h_v = 2014\ \text{kJ/kg};\ \rho' = 887\ \text{kg/m}^3;\ \rho'' = 5.16\ \text{kg/m}^3;$$
$$Pr' = 0.976.$$

(a) Location of the initial point:

$$\text{Re} = \dot{m}D_b/\eta = 91{,}300\ \text{(turbulent flow)};\ \text{Pr} = \eta c_p/\lambda = 1.44;$$
$$\text{Pe} = \text{Re Pr} = 1.31 \times 10^5;$$

$$N_b = \dot{q}/\dot{m}\Delta h_v = 0.331 \times 10^{-3};$$
$$\text{Ph}_0 = c_{pi}/\Delta h_v \cdot (T_\text{L} - T_\text{sat})_0 = -0.126;$$

$$\frac{\Delta L_0}{D_b} = -\frac{\text{Ph}_0}{4 \cdot N_b} = 95 \rightarrow \Delta L_0 = 0.665\ \text{m};\ \text{Ph}_i = -0.114;$$
$$\frac{\Delta L_i}{D_b} = -\frac{\text{Ph}_i}{4 \cdot N_b} = 86 \rightarrow \Delta L_i = 0.60\ \text{m};$$
$$l_i = \Delta L_0 - \Delta L_i = 0.065\ \text{m}.$$

(b) Location of onset of net steam generation:

$$\frac{1}{C_2} = 0.0074;\ Ph_n = -0.045;\ \frac{\Delta L_n}{D_b} = 34 \rightarrow \Delta L_n = 0.24\ \text{m};$$
$$l_n = \Delta L_0 - \Delta L_n = 0.425\text{m}.$$

(c) Vapor mass fraction $\dot{x}$ at pipe length L:

$$\text{Ph}(L) = -0.0123 \rightarrow \dot{x}(L) = 0.0094.$$

(d) Vapor void fraction at pipe length L

$$\varepsilon_n = 0.053;\ \varepsilon(L) - \varepsilon_n = 0.544 \rightarrow \varepsilon(L) \approx 0.6.$$

(e) Heat transfer at initial point:

$$\text{Re}_{120} = 91{,}300;\ \text{Pr}_{120} = 1.44;\ \text{Pr}_{180} = 0.976;\ l_i/D = 9.3;$$
$$\xi = 0.0183;$$

$$\text{Nu}(l_i) = \alpha_i D/\lambda = 327 \rightarrow \alpha_i = 32.1\ \text{kW/m}^2\,\text{K};$$
$$\Delta T_i = 62.3\ \text{K}.$$

Indirectly follows:

$$(T_\text{W} - T_\text{S})_i = (T_\text{W} - T_\text{L})_i - (T_\text{L} - T_\text{S})_i$$
$$= \Delta T_i + \text{Ph}_i \Delta h_v/c_p$$
$$= 62.3\ \text{K} - 54.4\ \text{K} = 7.8\ \text{K}.$$

Directly with Eq. (15), it follows:

$$(T_\text{W} - T_\text{S})_i = 5.9\ \text{K}.$$

Using Eq. (XX) in Chap. H2, it follows:

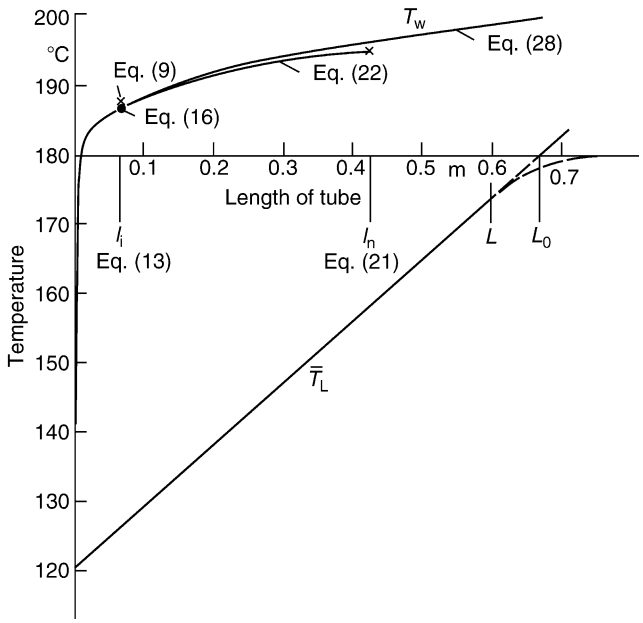
$$(T_\text{W} - T_\text{S})_i = 6.8\ \text{K}$$

between initial point i and point n of net vapor generation

$$\frac{\alpha_i}{\alpha} = \frac{T_\text{W} - \overline{T}_\text{L}}{(T_\text{W} - T_\text{L})_i} = \left(\frac{\Delta L/D_b}{\Delta L_i/D_b}\right)^{0.55}$$

in particular can be estimated

$$\left(T_\text{W} - \overline{T}_\text{L}\right)_n = 0.6\left(T_\text{W} - \overline{T}_\text{L}\right)_i = 37.4\ \text{K}$$



H3.3. Fig. 6. Wall pressure determined in Example 2f.

From there, it follows directly, that

$$(T_\text{W} - T_\text{S})_n = (T_\text{W} - T_\text{L})_i + \text{Ph}_n \Delta h_v/c_p = 15.4\ \text{K}$$

between point n of net vapor generation and Ph = 0.

Using Subchap. H3.4, the following can be estimated

$$\dot{q} = 2 \times 10^6\ \text{W/m}^2;\ \alpha(L)_B = 88{,}090\ \text{W/m}^2\,\text{K} \text{ and } n = 0.69,$$
$$\text{and } \left(T_\text{W} - \overline{T}_\text{L}\right)_i = 62.3\ \text{K},\ \text{and } (T_\text{W} - T_\text{S})_0 = 22.7\ \text{K}.$$

With this, it follows:

$$1 - ((\vartheta_\text{W} - 180)/22.7)^{3.25} = \left(\vartheta_\text{W} - \bar{\vartheta}_\text{L}\right)/62.3.$$

For given $\bar{\vartheta}_\text{F} = 180°C$ or Ph = 0, it can be found by iteration, that

$$\vartheta_\text{W} = 200°C.$$

With this information, the wall temperature profile between i and Ph = 0 can be sketched, as is shown in Fig. 6 as expected, water shows on technical surfaces no particular superheating to commence boiling (as is shown in the general sketch, Fig. 1). Vapor mass fraction $\dot{x}$ has no influence.

(f) Pressure drop in comparison to the unheated pipe:

Up to the initial point, the shear stress at the wall can be estimated using the wall temperature profile, estimated above.

Furthermore, is $\bar{\tau}/\tau_{\text{W}i} = 1.98$, and

$$\frac{\Delta p}{\Delta p_0} = \frac{(\Delta L_0 - \Delta L_i)\bar{\tau}_{1\text{ph}} + (L - (\Delta L_0 - \Delta L_i))\bar{\tau}}{L\tau_0} \approx 1.27.$$

H3.4 Saturated Flow Boiling

Matthias Kind[1] · *Yasushi Saito*[2]
[1]Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany
[2]Kyoto University, Osaka, Japan

1 Convective Flow Boiling of Pure Liquids

Two-phase forced convective boiling, which has also been referred to as convective flow boiling [G1] (for literature and special symbols, see Subchap. H3.8), occurs if the thermal resistance of the boundary layer is less than that in nucleate boiling. In this case, superheat in the liquid on the wall no longer suffices to meet the conditions for the activation of nucleation sites and for bubble formation. Evaporation, thus, results at the liquid–vapor phase boundary.

If the tube walls are wetted, the thermal resistance in the boundary layer is governed by the mechanisms that take place in the liquid phase (cf. *Dukler* [G2], *Hewitt* [G3], and *Steiner* [G4]). Owing to the extent to which the cross-section is occupied and the drag effect exerted by the vapor, the average liquid velocity w' in the two-phase flow is generally higher than that in the single-phase flow at the same mass velocity of the liquid itself. Likewise, the hydraulic diameter d_h is less than the tube inner diameter.

1.1 Convective Flow Boiling in Vertical Tubes

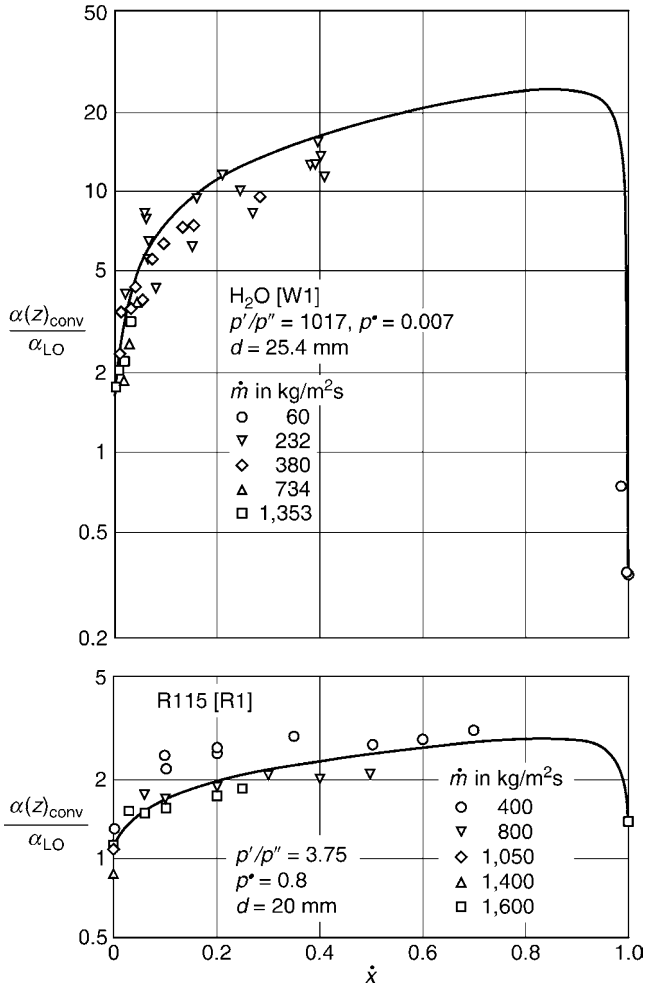
In all flow patterns below the critical boiling state (cf. Subchap. H3.5) in vertical tubes (Fig. 1 in Subchap. H3.1), the heated wall is completely wetted. The following (The term $(1-\dot{x})^{0.01}$ and $\dot{x}^{0.01}$ have been introduced in order to obtain a value of unity for $\dot{x}=0$ and a value of α_{GO}/α_{LO} for $\dot{x}=1$ in Eq. (1).) applies for the vapor mass fraction over the entire range from $\dot{x}=0$ to $\dot{x}=1$:

$$\frac{\alpha(z)_{conv}}{\alpha_{LO}} = \left\{(1-\dot{x})^{0.01}\left[(1-\dot{x})^{1.5}+1.9\dot{x}^{0.6}\left(\frac{\rho'}{\rho''}\right)^{0.35}\right]^{-2.2} + \dot{x}^{0.01}\left[\frac{\alpha_{GO}}{\alpha_{LO}}\left(1+8(1-\dot{x})^{0.7}\left(\frac{\rho'}{\rho''}\right)^{0.67}\right)\right]^{-2}\right\}^{-0.5}. \quad (1)$$

In Eq. (1), α_{LO} and α_{GO} are the local single-phase heat transfer coefficients to be determined at a point z. They are based on a mass velocity $\dot{m}$ that represents the total flow for the liquid (L) or the vapor (G), respectively. They can be determined from the equations given in Sect. 4 (Appendix) or in Chap. G1, for the corresponding hydrodynamic conditions (flow at the inlet or fully developed flow), the thermal boundary conditions ($\dot{q}$ = constant; T_w = constant), and the following values for the Reynolds number:

$$Re_{LO} = \frac{\dot{m}d_h}{\eta_L} \text{ and } Re_{GO} = \frac{\dot{m}d_h}{\eta_G}. \quad (2)$$

The equations to be selected depend on the shape of the cross-section. Thus, the results of measurements on rectangular tubes [W6] and concentric annuli [W7, W8] indicate that the value to be inserted for the hydraulic diameter d_h is that determined by Eq. (37) in Subchap. H3.1.



H3.4. Fig. 1. Relative heat transfer coefficient as a function of the vapor mass fraction in a vertical tube.

1.1.1 Values for the Properties

All the values required for calculation are those for the properties at saturation, for example, $\eta_L = \eta'$ and $\eta_G = \eta''$.

The range of validity is $3.5 \leq \rho'/\rho'' \leq 5000$.
The range of reduced pressures ($p^* = p/p_c$) for the liquids investigated is $10^{-3} \leq p^* \leq 0.8$.

The studies were performed on tubes and annuli of $3 \leq d_h/mm \leq 25.4$. The results of the measurements at low and high values of reduced pressure are shown in Fig. 1. No systematic relationship could be determined between the $\alpha(z)_{conv}/\alpha_{LO}$ ratio and the mass velocity [W1–W6, R1–R4, H2].

1.1.2 Effect of Bends and Elbows

The equations submitted in Sect. 1.1 of this chapter apply solely to straight tubes. They do not embrace disturbances in the two-phase flow, such as secondary currents brought about by gravity and centrifugal forces in bends and elbows. The magnitude of the centrifugal forces depends on the radius of curvature and the velocities of the two phases in the main direction of flow. Together with the force of gravity, they are responsible for some degree of stratification in the liquid phase, with the consequence that partial dryout may occur downstream in vertical tubes of l/d = 5–10 relative length. In other words, the heat transfer coefficient may be reduced in this region.

Measurements were performed by *Pujol* [R3] on R 113 in hairpin rows of vertical tubes at mass velocities of $\dot{m} = 200$–1800 kg/m²s, vapor mass fraction of $\dot{x} = 0$–1, and reduced pressures of $p^* = 0.03$–0.13. They revealed that heat transfer is no longer disturbed if the relative length exceeds l/d = 20. The figures for the heat transfer coefficient on the outer surfaces of the heated bends ($R/d \approx 4.1$) were always higher than those on the inside. Nevertheless, the inner surfaces did not dryout, even at the bend outlets, that is, no significant decrease in the local heat transfer coefficients was observed.

1.2 Convective Flow Boiling in Horizontal Tubes

The liquid phase may be stratified by gravity (cf. Subchap. H3.1) with the result that the heated wall is not completely wetted and that heat transfer to the vapor phase is generally poor. Hence, if the heat flux applied at the circumference $\dot{q}$ is kept constant, the temperatures at the upper surfaces of the tube are considerably higher than those at the lower surfaces. The effects of stratification on the wall temperature distribution over the circumference of tubes has been demonstrated in studies by *Styrikovich* et al. [W11, W12] on water and in measurements by *Chaddock* and *Noerager* [R10] on R 12.

Accordingly, the average heat transfer coefficient around the circumference depends on the degree of wetting and heat conduction $\lambda_w s$ of the tube wall, and attention to these relationships has been drawn by various authors [G5, G6, W15, W17, R14].

Another aspect has been brought up in heat transfer measurements performed by *Chawla* [R11], *Bandel* [R6], *Naganagoudar* and *Steiner* [R23], *Iwicki* and *Steiner* [R18], *Müller-Steinhagen* [C13], and *Schmidt* [R26]. They demonstrated that the only case of convective boiling in which incomplete wetting has a significant effect on the perimeter-averaged heat transfer coefficient is that in which according to Fig. 3 in Subchap. H3.1, there is a stratified or a stratified-wavy flow pattern (Stratified-wavy flow is the name given to the range of wavy flow in which $\left(\mathrm{Re}_L \mathrm{Fr}'_G\right)^{0.5} \leq 2\left(\mathrm{Re}_L \mathrm{Fr}'_G\right)^{0.5}_{\mathrm{tt,lim}}$ is approximately valid.). In all the other flow patterns, the mass velocity does not have a systematic effect on the $\alpha(z)_{conv}/\alpha_{LO}$ ratio. The following applies over the entire range of vapor mass fractions (The term $(1-\dot{x})^{0.01}$ and $\dot{x}^{0.01}$ have been introduced in order to obtain a value of unity for $\dot{x}$ = 0 and a value of α_{GO}/α_{LO} for $\dot{x}$ = 1 in Eq. (1)):

$$\frac{\alpha(z)_{conv}}{\alpha_{LO}} = \left\{ (1-\dot{x})^{0.01} \left[(1-\dot{x}) + 1.2\dot{x}^{0.4} \left(\frac{\rho'}{\rho''} \right)^{0.37} \right]^{-2.2} + \dot{x}^{0.01} \left[\frac{\alpha_{GO}}{\alpha_{LO}} \left(1 + 8(1-\dot{x})^{0.7} \left(\frac{\rho'}{\rho''} \right)^{0.67} \right) \right]^{-2} \right\}^{-0.5} . \quad (3)$$

In Eq. (3), α_{LO} and α_{GO} are the local single-phase heat transfer coefficients to be determined at a point z. They are based on a mass velocity $\dot{m}$ that represents the total flow for either the liquid (L) or the vapor (G), respectively. The pertinent Reynolds numbers for the liquid and the vapor are given by

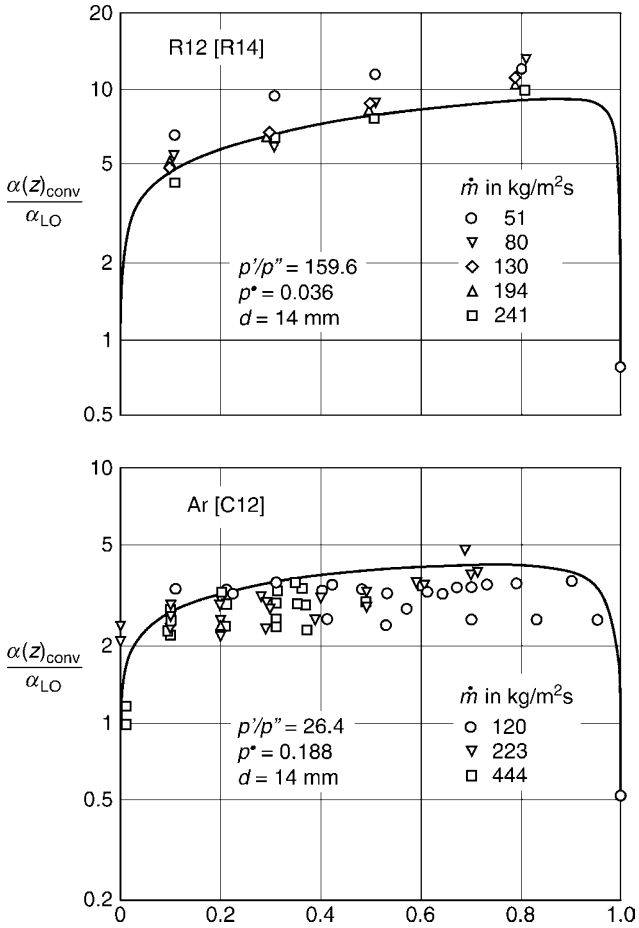
$$\mathrm{Re}_{LO,GO} = \frac{\dot{m} d_h}{\eta_{L,G}}.$$

According to measurements by *Davis* and *David* [W13], the value to be inserted for d_h is that determined from Eq. (37) in Subchap. H3.1. Equations for the determination of α_{LO} and α_{GO} under given hydrodynamic and boundary conditions are presented in Sect. 4 (Appendix), and in Chap. G2. They depend on the shape of the cross-section. The values to be taken for the properties of the pure substances are those for the liquid and the vapor at saturation.

The range of validity is $3.5 \leq \rho'/\rho'' \leq 1500$.
These density ratios correspond to reduced pressures of $5{\cdot}10^{-5} \leq p^* \leq 0.8$.

Up to $p^* = 0.8$, the values determined by this method agree well with those obtained by the measurements of *Niederkrüger* [G7].

The measurements [W9, W10, R2, R4, R6, R8, R11, R18, R23, C13] adopted to fit the parameters in Eq. (3) were performed in tubes of $6 \leq d_h/\mathrm{mm} \leq 25$ diameter. The results obtained at a low and a moderate reduced pressure are shown in Fig. 2. A striking feature is that the slope of the curve for $\alpha(z)_{conv}/\alpha_{LO}$ in the 0–0.2 range of values for the vapor mass fraction is much steeper than that for vertical tubes (cf. Fig. 1). It is in this range that the difference between flow patterns in vertical tubes and those in horizontal tubes is most pronounced. At even higher vapor mass fractions, annular and transition flow patterns also occur in horizontal tubes. However, the thickness of the layer at the crest differs from that at the base of the tube.



H3.4. Fig. 2. Relative heat transfer coefficient as a function of the vapor mass fraction in a horizontal tube.

1.2.1 Effects of Incomplete Wetting

The perimeter-averaged heat transfer coefficient in *stratified* and *stratified-wavy flow* is reduced by incomplete wetting. As is shown in Fig. 4 in Subchap. H3.1, φ is the angle subtended at the center by the unwetted arc. The coefficient α_G for the heat transferred from this arc to the vapor is usually lower than the coefficient α_{Lb} for the wetted arc, which is equal to the value for $\alpha(z)_{conv}$ determined from Eq. (3), that is, $\alpha_{Lb} = \alpha(z)_{conv}$.

The reference length of the unwetted arc is given by

$$\Phi = \varphi/2\pi. \tag{4}$$

The ratio a of the local heat transfer coefficient in the unwetted to that in the wetted section at the point z is given by

$$a = \alpha_G/\alpha_{Lb}. \tag{5}$$

M is a characteristic that defines the fins and is given by

$$M = \frac{\alpha_{Lb} d}{\lambda_w} \cdot \frac{\pi^2 d_m}{4s}, \tag{6}$$

where $d_m = d + s$, s is the wall thickness, and λ_w is the thermal conductivity of the tube.

According to *Martin* [G8], the perimeter-averaged heat transfer coefficient for the *boundary condition of* $\dot{q}$*= constant* is given by

$$\frac{\alpha(z)_{conv}}{\alpha_{Lb}} = \frac{1-(1-a)\Phi}{\psi}, \tag{7}$$

where

$$\psi = 1 + \Phi(1-\Phi)\frac{(1-a)^2}{a}\left[1 - \frac{1-(1-a)\Phi}{f_1+f_2}\right], \tag{8}$$

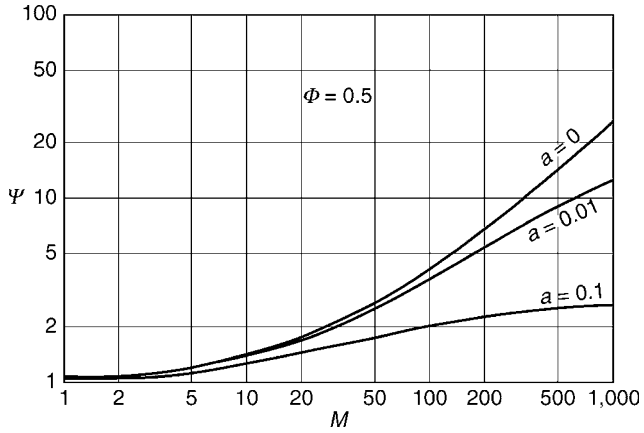
where

$$f_1 = a\sqrt{M}\Phi(1-\Phi)\coth\left(\sqrt{M}(1-\Phi)\right),$$
$$f_2 = a\sqrt{M}\Phi(1-\Phi)\coth\left(\sqrt{aM}\Phi\right).$$

The factor ψ is shown as a function of M for $\Phi = 0.5$, that is, for a half-wetted tube, in Fig. 3. A point to note is that M is large, particularly if the tubes have poor thermal conductivity and thin walls, with the consequence that the decrease in the perimeter-averaged heat transfer coefficient may not be neglected.

If the *boundary condition* is T_w = *constant* or $\dot{q}$ = *constant* and the tubes have good thermal conductivity ($\lambda_w s \geq 1$W/K; or, to be more precise, $M \leq 1$) and if $\psi = 1$, Eq. (7) becomes

$$\alpha(z)_{conv} = \alpha_{Lb}(1-\Phi) + \alpha_G\Phi. \tag{9}$$



H3.4. Fig. 3. Relationship between ψ and the fin characteristic M.

The heat transfer coefficient α_G is obtained from the equations given in Sect. 4 (Appendix), in which case the value for the hydraulic diameter d_{hG} of the gas phase to be inserted in the expression for the Nusselt and Reynolds numbers is

$$d_{hG} = d\left(\frac{\varphi - \sin\left(\frac{180}{\pi}\varphi\right)}{\varphi + 2\sin\left(\frac{90}{\pi}\varphi\right)}\right). \tag{10}$$

The Reynolds number at the point z is given by

$$\mathrm{Re}_G = \frac{\dot{m}\,\dot{x}\,d_{hG}}{\eta''\,\varepsilon}, \tag{11}$$

where ε is the void fraction as determined from Eq. (26) in Subchap. H3.1.

1.2.2 Determination of the Length of the Unwetted Arc φ

The relationship of the flow parameters to the length of the unwetted arc in stratified flow is unknown. The longest unwetted arc is obtained by assuming a flat phase boundary layer, that is, by neglecting the contact angle and the interfacial tension. It can be determined by iteration from Eq. (26) in Subchap. H3.1, and the relationship between ε and φ given by Eq. (27) in Subchap. H3.1, that is,

$$\varphi_g = 2\pi\varepsilon + \sin\left(\varphi_g 180/\pi\right). \tag{12}$$

The heat transfer coefficient corresponding to the boundary condition of $\dot{q} = constant$ or $T_w = constant$ can then be obtained from Eq. (7) or (9). It is the smallest value possible, because interfacial tension and the effect of the contact angle in the two-phase flow cause the tube to be wetted much more effectively, as has been verified by observations [R18, R26, R29].

With organic and inorganic fluids and with mixtures *Niederkrüger* et al. [G7, G9] proved acceptable agreement between experiment and calculation, if the unwetted arc is approximated by

$$\varphi = 0.5\varphi_g. \tag{13}$$

In addition, it was shown that the flow patterns and wetting limits in heated tubes may differ from those in unheated tubes. Studies by *Zahn* [R29] on R22 in heated glass tubes (T_w approximately constant) and by *Schmidt* [R26] on R12 in copper and nickel tubes have revealed by using γ-ray densitometry that some of the flow patterns observed no longer agree with the values predicted for adiabatic vapor–liquid flow from the flow pattern maps.

Consequently, the conclusion may not be drawn that the flow patterns obtained from maps for unheated tubes (Fig. 3 in Subchap. H3.1) remain unchanged when the tube is heated. The additional patterns indicated by the foregoing equations serve as criteria on how $\alpha(z)_{conv}$ should be calculated. The figures, thus, determined agree to within about ±30% with the results of the experiments that have been mentioned [W9, W10, R2, R4, R6, R8, R11, R18, R23, R26, C13, G7, G9].

1.2.3 Improvement in Wetting

Certain measures exist for counteracting, either entirely or partially, the substantial reduction in the perimeter-averaged heat transfer coefficient that is brought about by incomplete wetting. They include tubes with internal fins, for example, integral internal fins or twisted-tape inserts [R17, R25]. Smooth tube walls can be completely wetted by inducing helical flow, for example, by fitting internal coiled strips or machining helical grooves in the inner surface. This has been demonstrated by *Brendeng* [R7], who fitted a coiled strip into a tube through which R12 flowed with a mass velocity of $\dot{m}$ = 86 kg/m^{2}s (The ratio of the coil pitch to the tube inner diameter was 6.3.). The heat transfer coefficient was, thus, increased, under otherwise identical conditions, by a factor of 2.2. The disadvantage of improving heat transfer by these methods is that they involve a higher pressure drop.

Another possibility to improve wetttablity of the inner tube wall is the installation of a displacement tube, to produce a ring gap flow. In studies of *Geskes* [W35] with water, air, and water vapor, it has been found that by the eccentric arrangement of a displacement tube, the wettability effect can be optimized. At the same time, the pressure drop was not so greatly increased.

1.2.4 Effect of Bends and Elbows

The equations submitted in Sect. 1.2 for the determination of the heat transfer coefficient do not embrace the effects of disturbances in two-phase flow brought about by bends, elbows, branches, etc. An example of these effects arose in studies by *Lis* and *Strickland* [W15] on the flow of water in annular flow pattern through a horizontal tube. It was observed that the crest of the tube became dry when a *vertical* assembled bend of R/d = 3 was installed upstream. The relative horizontal length within which dryout occurred depended on the applied heat flux $\dot{q}$, which gave rise to convective boiling, and lay between l/d = 15 and l/d = 65. The relative length of this zone of disturbance l/d was greatly decreased when the bend radius was reduced to R/d = 1.4. When the obstruction was replaced

by a *horizontal* assembled bend of $R/d = 3$ in an otherwise identical experimental layout, hardly any dryout could be observed. The values of reduced pressure under which the experiments were performed, lay between $p^* = 0.068$ and $p^* = 0.3$.

Zahn [R29] studied flow through hairpin rows of horizontal tubes connected by bends of $R/d = 2.35$. The medium was R22, the mass velocity was $\dot{m} = 96$–256 kg/m^{2}s, and the vapor mass fraction was $\dot{x} = 0.2$–0.99 at $p^* = 0.13$. The disturbance in the two-phase flow observed at the tube inlets downstream from the bends extended over a relative length of between $l/d = 10$ and $l/d = 20$. This length was roughly the same in both upward and downward flow through the vertical assembled hairpin rows.

1.3 Convective Flow Boiling in Inclined Tubes and Helical Coils

1.3.1 Inclined Tubes

Stratification of the liquid in tubes inclined at an angle Θ to the horizontal is caused by the gravity component $g \cos \Theta$. Studies by *Cumo* et al. [W30] on R12 at $p^* = 0.77$ and by *Kefer* [W34] on water revealed that the critical boiling regime at the crest of the tube continuously depends on the angle of inclination and passed through a minimum at $\Theta = 0$. *Styrikovich* et al. [W12] investigated the effect of the angle of inclination on the boiling of water at reduced pressures of $p^* = 0.15$–0.4 and noted that the crest of the tube was no longer overheated if $\Theta \geq 10°$. In view of the scanty information on the subject, the only suggestions that can be made for the determination of the perimeter-averaged heat transfer coefficient in inclined tubes are as follows:

If the angle of inclination is $\Theta = 0°$–$30°$, the equations to apply are those for horizontal tubes (Sect. 1.2); and if $\Theta > 30°$, the equations for vertical tubes (Sect. 1.1).

1.3.2 Helical Coils

The centrifugal forces that occur in flow through bends give rise to secondary currents in the form of double vortices. In the three-dimensional bends of helical coils, the direction of flow changes continuously, and a twist flow is superimposed on the double vortices. The vapor velocity that results from the high density ratio ρ'/ρ'' at moderate reduced pressures ensures that the double vortex and the twist flow suffice to wet the tube wall entirely in most of the applications that occur in engineering practice.

This has been confirmed in studies by *Bell* and *Owhadi* [W16, W17] on water at $p^* \approx 0.006$, $\dot{m} = 70$–310kg/m^{2}s, and $\dot{x} = 0.13$–0.96 at the outlet in coils described by $d/D_w = 0.024$ and $d/D_w = 0.05$ (cf. Chap. G3). The points at which the greatest threat of burnout arose at applied heat fluxes of up to $\dot{q} = 250{,}000$ W/m^2 were the crests and the bases of the tubes. They were both dry at vapor mass fractions of 0.8–0.95, whereas the inside and the outside of the coil frequently remained wetted at values of up to $\dot{x} = 0.99$.

In the light of these results, it is suggested that perimeter-averaged heat transfer coefficients at $p^* \leq 0.3$ be calculated by Eq. (1). If $p^* > 0.3$, Eq. (1) should not be applied unless the mass velocity is $\dot{m} \geq 500$ kg/m^{2}s, because there is risk of incomplete wetting at lower values of $\dot{m}$. If incomplete wetting is likely, the equations to apply are those for a horizontal tube (Sect. 1.2; Incomplete wetting).

The relationships given for helical coils in Chap. G3, should be inserted in all equations for the single-phase heat transfer coefficients α_{LO} and α_{GO}. The values to be inserted for the properties are those for the saturated state of the liquid and the vapor.

1.3.3 Effect of Impurities (Applicable to Sects. 1.1–1.3)

Impurities in the liquid phase are solutions of oils, wetting agents, or other liquids in low concentrations. It must be ensured that the correct values for the properties of the mixture are inserted in the equations for convective flow boiling. If the composition of the liquid is known, the properties of the mixture can be calculated as indicated in Chap. D1. The behavior of the mixtures is dealt with in Subchap. H3.7.

2 Nucleate Flow Boiling of Pure Liquids

Heat transfer during evaporation in the nucleate boiling regime is governed by the activation of nucleation sites, bubble growth, and bubble departure. As has been demonstrated by *Koumoutsos* et al. [G10], superimposed forced convection exerts a direct effect on bubble departure. Allowance must also be made for the change in the temperature profile from that in the nucleate boiling of flowing liquid–vapor mixtures to that in free convection.

By introducing the S-factor, *Chen* [G11] explained this change of the temperature profile in the boundary layer, which affects the bubble growth and the number of the nucleation site.

No theory has yet been formulated that allows the heat transfer coefficient in nucleate boiling of flowing liquid–vapor mixtures to be calculated. For this reason, one will refer here to extensions of the equations that *Borishanskii* et al. [G12] derived by applying thermodynamic similarity in the determination of heat transfer in pool boiling.

2.1 Nucleate Flow Boiling in Vertical Tubes

2.1.1 Upward Flow in a Vertical Tube

As long as the critical boiling regime (cf. Subchap. H3.5) is not transgressed, the heated wall of vertical tubes is completely wetted by the liquid in all flow patterns. The heat transfer coefficient can be obtained from the following equation:

$$\frac{\alpha(z)_B}{\alpha_0} = C_F \left(\frac{\dot{q}}{\dot{q}_0}\right)^n F(p^*) F(d) F(W) F(\dot{m}, \dot{x}), \qquad (14)$$

in which the properties of the liquid are embraced by the factor C_F; the properties of the heated wall, by $F(W)$; the dimensions of the tube, by $F(d)$; the flow parameters, by $F(\dot{m},\dot{x})$; and the effect of pressure, by $F(p^*)$. The relationship to heat flux is defined by the term $\dot{q}^n$. The reference value α_o is the same as in Chap. H2, Eq. (5). For selected systems reference values α_o are given in Table 2.

2.1.2 The Effect of Heat Flux and Pressure in Nucleate Boiling

The characteristic $\alpha - \dot{q}$ curves shown in Fig. 4 can be obtained by plotting measurements on all substances in the nucleate boiling regime. It can be clearly seen that the slope of the curve becomes less as the reduced pressure p^* increases. In other words, the exponent n in Eq. (14) depends on pressure.

Practical considerations in the nucleate boiling of flowing liquid–vapor mixtures necessitate the division of media into four groups: (1) Inorganic substances, (2) Hydrocarbons and halocarbons, (3) Cryogenic substances with boiling point $\leq$180K with the exception of ethane and methane, and (4) Helium as the sole representative of its group (cf. Table 2).

It has also been demonstrated by experiment that the exponent n in Eq. (14) becomes less as the critical heat flux (cf. Subchap. H3.5) is approached. No equation has yet been derived to allow for this effect.

For *inorganic fluids*, for example, water and ammonia; and for *hydrocarbons*, for example, *n*-butanol and *halocarbons*, for example, R22, R134a, and R227 n can be estimated by

$$n = 0.8 - 0.1 \cdot 10^{(0.76\,p^*)}. \qquad (15)$$

With the exception of methane and ethane, *cryogenic fluids* (with boiling points $\leq$ 180 K), for example, nitrogen, hydrogen, and helium, display a less pronounced relationship to pressure. At reduced pressures of $p^* < 0.6$, the values of n are also less than those for the inorganic substances mentioned above. The following correlation is suggested for cryogenic fluids:

$$n = 0.7 - 0.13 \cdot 10^{(0.48p^*)}. \qquad (16)$$

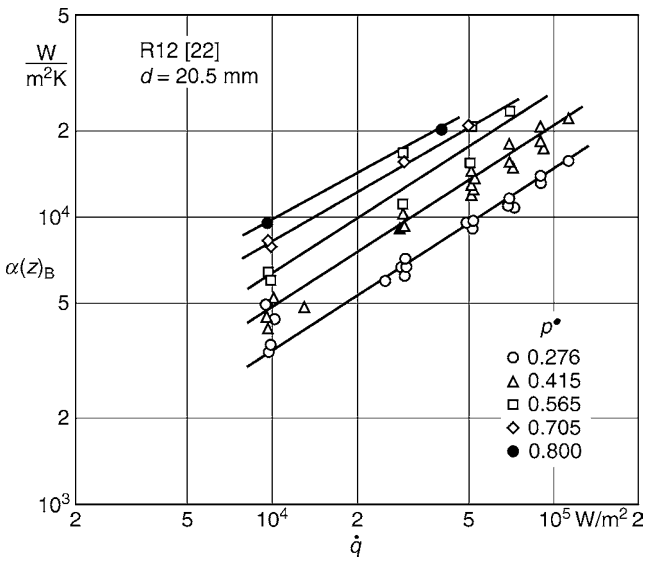
The pressure exerts a significant effect on heat transfer, particularly at the lower and higher values of p^*, and its relationships must be known for the determination of $\alpha(z)_B$. These relationships can be defined by the function $F(p^*)$, which takes into account the allocation into the four groups and the *reference heat flux* $\dot{q}_o$ for the *specific substances* (cf. Table 2). $F(p^*)$ is given by

$$F(p^*) = 2.816p^{*0.45} + \left(3.4 + \frac{1.7}{1 - p^{*7}}\right)p^{*3.7}. \qquad (17)$$

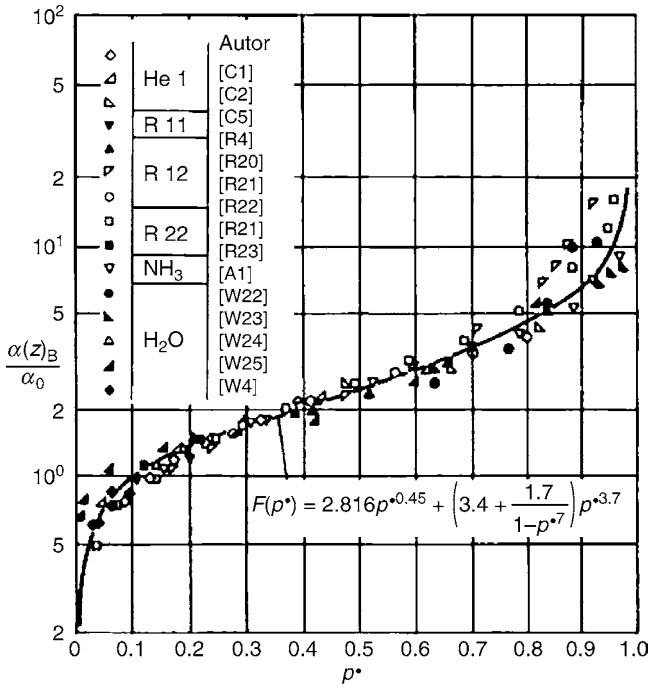
The results of measurements [W4, W23, W26, W27, A1, R4, R30, R31, R33, R34, C1, C2, C5] were taken to determine the pressure function. They are compared in Fig. 5, where it can be seen that the deviation of any one substance, for example, water, from the mean curve, does not differ from that of the other substances. In other words, the deviations are not restricted to specific substances.

2.1.3 Effect of Mass Velocity, the Vapor Mass Fraction, and the Tube Diameter

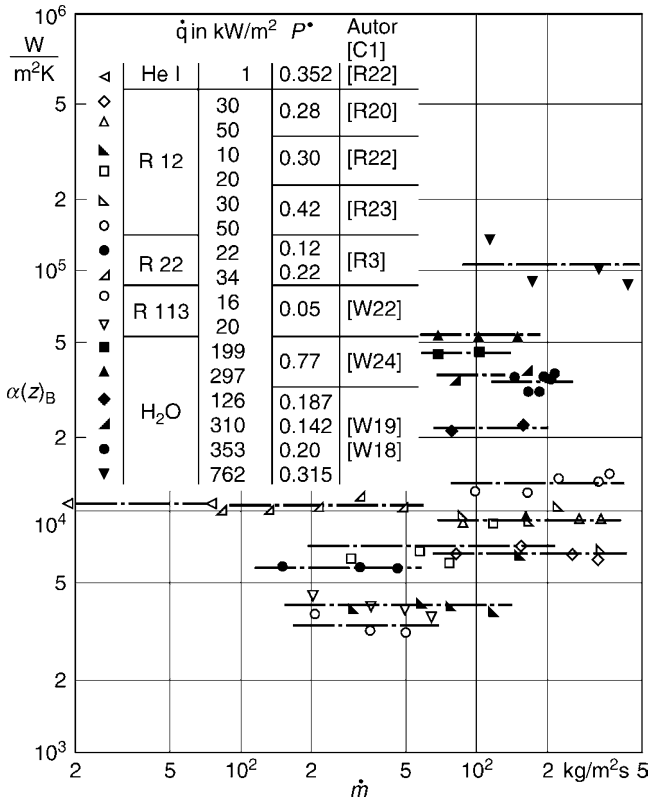
In the literature on flow nucleate boiling in vertical tubes [G1, G11, G13–G17, G25], differences exist in the equations relating



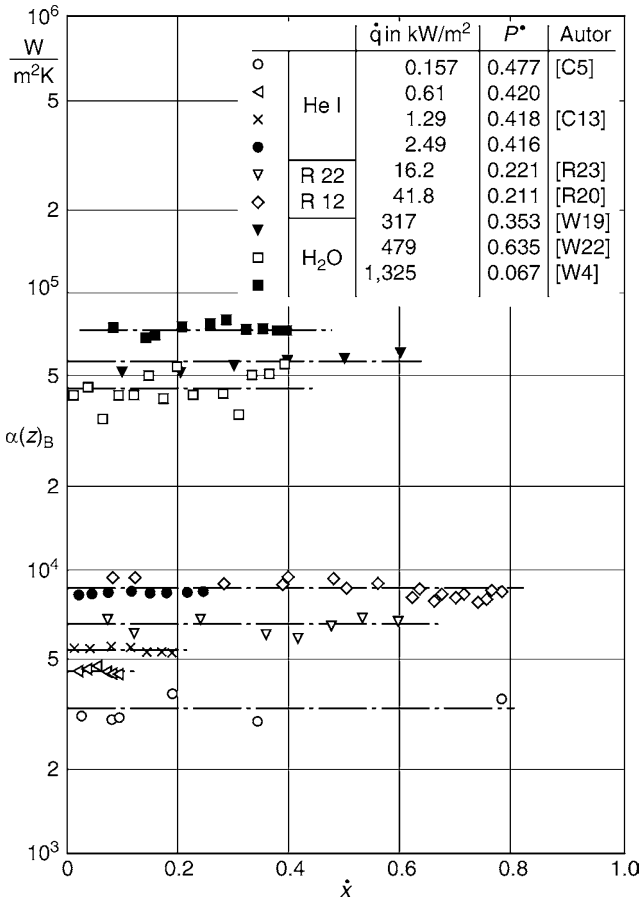
H3.4. Fig. 4. Heat transfer coefficient $\alpha(z)_B$ as a function of the heat flux in a vertical tube.



H3.4. Fig. 5. Relative heat transfer coefficient as a function of the reduced pressure for nucleate boiling in a vertical tube and $\dot{q}_0$ for values of relating to the substances concerned.



H3.4. Fig. 6. Heat transfer coefficient as a function of mass velocity for nucleate boiling in vertical tubes.



H3.4. Fig. 7. Heat transfer coefficient as function of the vapor mass fraction for nucleate boiling in vertical tubes.

the heat transfer coefficient to the flow parameters $\dot{m}$ and $\dot{x}$. In order to find an explanation for these contradictions, the measurements concerned [W18, W20, W23, W24, W26, R3, R30, R33, R34, C1] were evaluated. All the other parameters were the same in each case. The graph thus obtained is reproduced in Fig. 6. According to this, heat transfer during nucleate boiling in vertical tubes is not affected by the mass velocity, even at values as high as 4,500 kg/m^{2}s.

The velocity profile for the liquid is substantially altered by an increase in the vapor mass fraction and drag by the vapor. Figure 7 shows that the vapor mass fraction does not have any effect on the heat transfer coefficient within the range in which it was measured, that is, $\dot{x}$ = 0–0.8.

Hence, the heat transfer coefficient in nucleate flow boiling cannot depend on the flow parameters $\dot{m}$ and $\dot{x}$ or on characteristics that contain them, that is,

$$F(\dot{m}, \dot{x}) = 1. \tag{18}$$

Various authors [W3, W23, W24, R4] have performed experiments on evaporator test units of different internal diameters in the same test loop in order to determine the effect of d on the heat transfer coefficient. Some authors [C1–C5] measured heat transfer coefficients of helium I in tubes with different diameters, while the other parameters were the same. All the results are reproduced in Fig. 8. It can be seen that, if the other parameters are kept constant, the heat transfer coefficient in nucleate boiling decreases with an increase in the tube diameter. The average relationship in the range of validity is

$$F(d) = (d_o/d)^{0.4}, \tag{19}$$

where $d_o = 10^{-2}$ m.

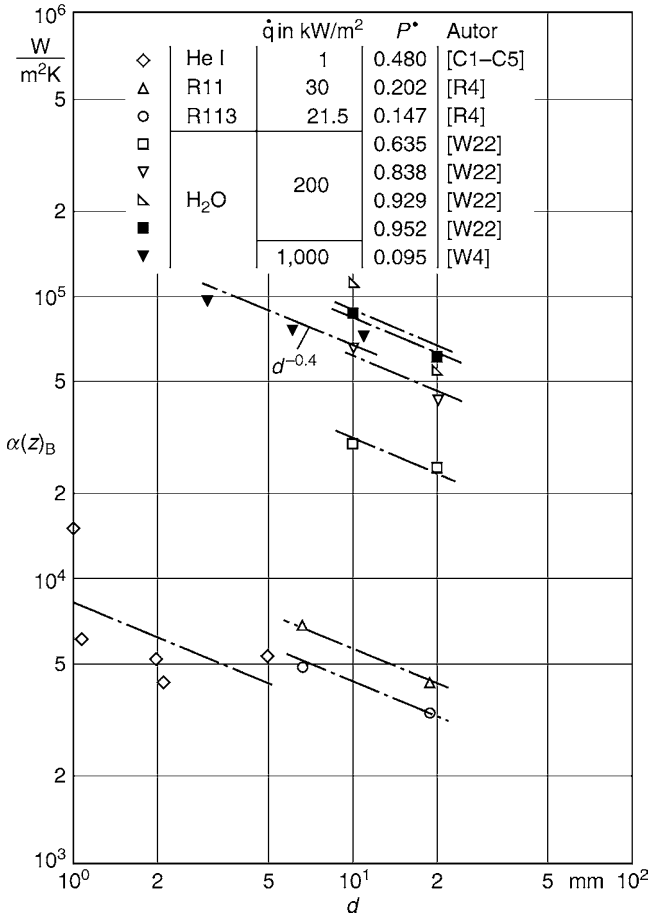
2.1.4 Effect of the Properties of the Heated Wall

Details are not yet known as to which properties of a heated wall govern the heat transfer coefficient. *Stephan* [G18] submitted the following relationship that applies in pool boiling for surfaces finished by turning or drawing:

$$\alpha_{PB} \sim R_p^{0.133},$$

where R_p is the smooth depth as defined in DIN 4762, Part 1/08.60 (cf. Subchap. H2.3).

Systematic measurements were made by *Takagi* [W14] and *Müller* [W27] to determine the effect of roughness on heat transfer in nucleate boiling of flowing liquid–vapor mixtures. *Takagi* used a rectangular horizontal channel in which the lower wall was heated and which was always completely wetted, whereas *Müller* performed his experiments in vertical tubes. The results which are presented in Fig. 9 confirm – on an average – the relationship submitted by *Stephan*.



H3.4. Fig. 8. Heat transfer coefficient as a function of tube diameter for nucleate boiling in vertical tubes.

In Subchap. H2.3, the *arithmetic mean roughness height* R_a was proposed as the reference magnitude in nucleate and flow boiling. Its relationship to the smooth depth R_p for machined and emery-polished surfaces was determined as $R_a = 0.4R_p$ by *Gorenflo* et al. (cf. Subchap. H2.3). A somewhat different correlation, that is, $R_a = 0.6R_p$, was derived from measurements on drawn copper and nickel tubes in the $0.06 \leq R_a \leq 0.7$ range of roughness heights. Consequently, the following equation will be adopted until further results are available:

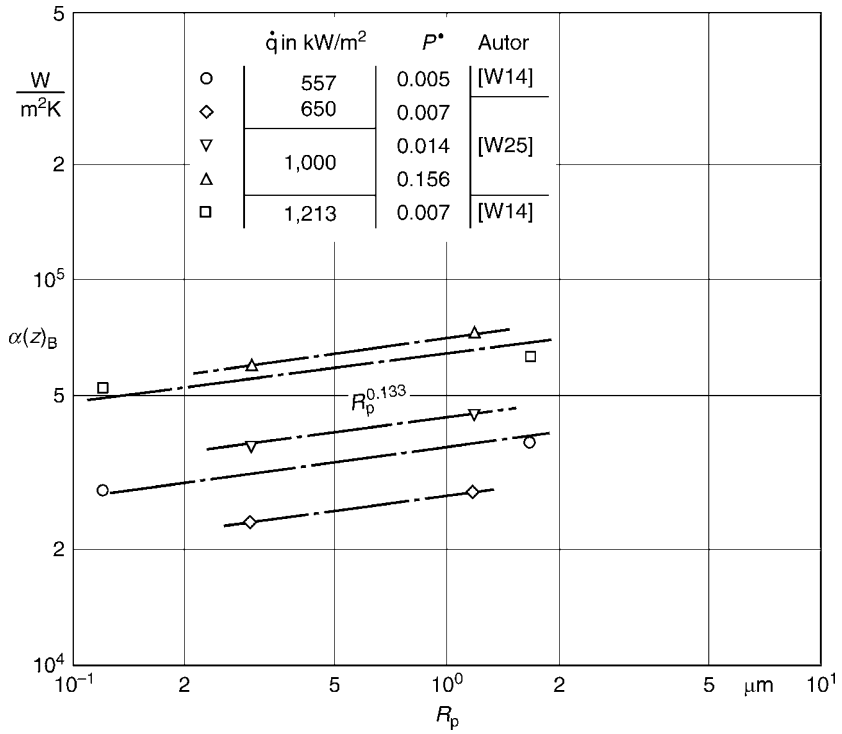
$$F(W) = (R_a/R_{ao})^{0.133}. \tag{20}$$

If $R_{ao} = 1$ µm is taken as the reference value, the choice of R_a in preference to R_p in Eq. (21) entails that the heat transfer coefficient is, purely theoretically, 7% (if $R_a = 0.6\ R_p$) or 13% (if $R_a = 0.4R_p$) higher. This increase was not taken into consideration and, therefore, leads to a conservative design of heat transfer equipment. According to DIN 4766 Part 2/03.81, a value of R_{ao} can be achieved by most finishing techniques.

If the effects discussed are taken into account, the heat transfer coefficient in upward flow through vertical tubes in the subatmospheric to elevated pressure range can be obtained from

$$\frac{\alpha(z)_B}{\alpha_0} = C_F \left(\frac{\dot{q}}{\dot{q}_0}\right)^{n(p^*)} \cdot \left[2.816p^{*0.45} + \left(3.4 + \frac{1.7}{1-p^{*7}}\right)p^{*3.7}\right] \cdot \left(\frac{d_o}{d}\right)^{0.4} \left(\frac{R_a}{R_{ao}}\right)^{0.133}. \tag{21}$$

The exponent $n(p^*)$ is determined from Eq. (15) or (16) according to the nature of the fluid. If the design value is close to that for $\dot{q}_{cr}$ (cf. Subchap. H3.5), account must be taken of the fact that the exponent $n(p^*)$ is smaller than the figure calculated



H3.4. Fig. 9. Effect of the roughness of tube surfaces on the heat transfer coefficient in nucleate boiling.

from Eq. (15) or (16). Thus, the degree of uncertainty in the calculation will become greater.

Symbols with the subscript *o* denote reference values:

$d_o = 1 \cdot 10^{-2}$ m and $R_{ao} = 1 \cdot 10^{-6}$ m; α_o is the reference value at $p_o^* = p/p_c = 0.1$ and $R_{ao} = 1 \cdot 10^{-6}$ m. α_o is listed in Table 2 against the values of $\dot{q}_o$ for *specific substances*.

The factor C_F for various substances has been derived from measurements [W4, W18, W20, W21, W23, W26, A1, R3, R4, R30, R33, R34, C1–C7, G7, G19], and some of the results are listed in Table 1 under the headings "H_2 (Para)" to "R113".

Range of validity of Eq. (21) is:
$0.01 \leq p^* \leq 0.985$; $1 \leq d/\text{mm} \leq 32$; $0.05 \leq R_a/\mu\text{m} \leq 5$.

The roughness values were obtained in measurements on drawn and welded normal and high-precision tubes, including types that were cold-drawn or cold-rolled after welding.

The relationship that can be established between the values of C_F listed in Table 1 and the molar mass $\tilde{M}$ allows the C_F values for other substances to be determined, that is,

$$C_F = 0.435\left(\tilde{M}/\tilde{M}_{H2}\right)^{0.27}. \quad (22)$$

where $\tilde{M}_{H2} = 2.016$g/mol is the molar mass of H_2.

Results that have been obtained up to now indicate that an upper limit of $C_F \leq 2.5$ should be observed.

Equation (22) has been applied to various hydrocarbons [R4, H2, H3, H5, H6], and some of the results obtained are listed in Table 1 in the subcolumns headed "Methanol" to "R11". They are compared with the standard deviation determined for the corresponding measured values. The agreement is good.

Heat transfer data obtained in nucleate boiling experiments in *annular channels* [W7, W8, W18, W22] agreed adequately with calculated values in which d_h, as defined by Eq. (37) in Subchap. H3.1, was substituted for d in Eq. (21).

Heat transfer coefficients for substances not listed in Table 2 can be obtained by determining the reference value α_o ($p_o^* = 0.1$) for $R_a = 1 \cdot 10^{-6}$ m in the following steps, cf. Chap. H2.

(a) Determination of $\alpha_{0.03}$ at the saturation pressure $p^* = 0.03$ with the physical properties at saturation and for a heat flux of $\dot{q} = 20\,000$ W/m^2

(b) Conversion of the value for $\alpha_{0.03}$ ($p^* = 0.03$) to the value $\alpha_{0.03}$ at $p_o^* = 0.1$ by inserting the value of $F(p^*)$ (cf. Example 2, Sect. 4 of this Chapter).

(c) If α_o, corresponding to the specified group of substances in Table 2, has to be determined from a value of $\dot{q}$ that differs from 20,000 W/m^2, the exponent n must be calculated.

2.1.5 Downward Flow in Vertical Tubes

Pujol [R3] studied the effect exerted by the direction of flow on heat transfer to R113 during nucleate boiling in vertical tubes. The bank of tubes in the experiments was designed so that all the measured values for the parameters could be evaluated equally well at an adequate distance from the tube bends. The results are presented in Fig. 10. They reveal that the heat transfer coefficient in downward flow is less than that in upward flow in accordance with the relationship

$$\alpha(z)_{B,\text{down}} = 0.75\alpha(z)_B, \quad (23)$$

where $\alpha(z)_B$ is the value for upward flow as given by Eq. (21).

Kattan et al. [R35] studied flow boiling of R134a in downward and upward flow by using an experimental loop with rotatable test tube. Measurements were performed at mass velocities of $\dot{m}$= 310–1540 kg/m^{2}s and at a reduced pressure of p^* =0.1. Their measurement results showed a significant decrease in the heat transfer coefficients in downward flow at a vapor mass fraction of $\dot{x}$ = 0.07–0.5, which can be fairly calculated by Eq. (23). The effect of upflow and downflow on nucleate boiling of R12 was also investigated by *Hahne* et al. [R36]. The relative lengths of the tubes upstream from the section in which the measurements were made, were $l/d \geq 100$. A significant effect of the flow direction on heat transfer was not observed at $\dot{m}$= 310–1540 kg/m^{2}s, and at $\dot{x}$ = 0–0.17. The results that have been obtained up to now do not permit a definite conclusion to be drawn. For this reason, it is recommended for safety's sake that Eq. (23) also be applied to other substances and other parameters in downward flow.

2.2 Nucleate Flow Boiling in Horizontal Tubes

If the heated wall in horizontal tubes is constantly and completely wetted, the heat transfer coefficient is approximately the same as that in a vertical tube [G20]. This flow pattern

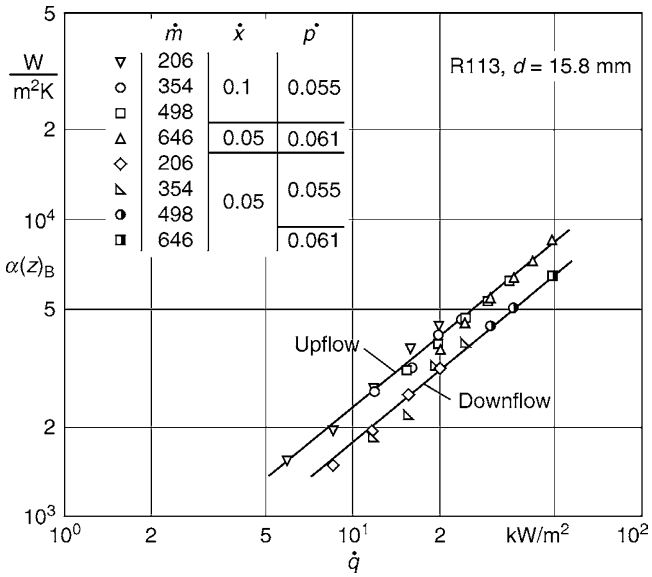
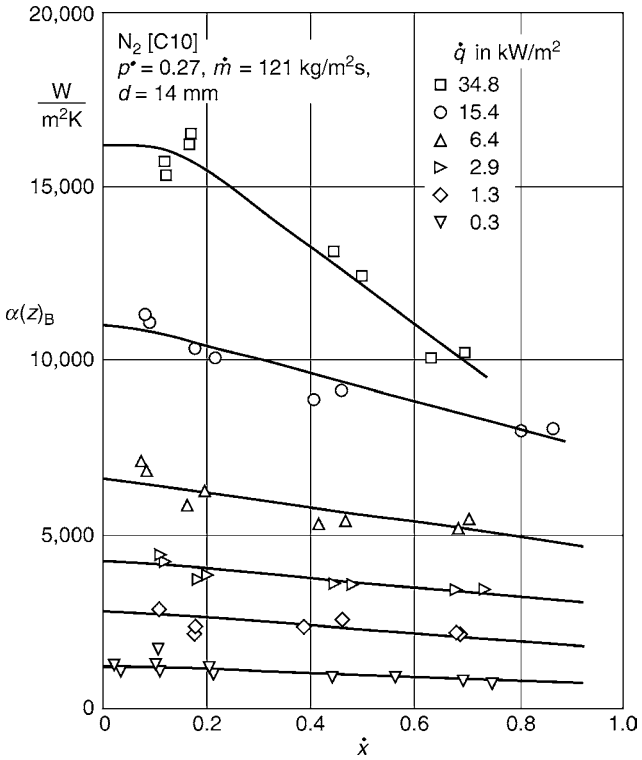
[a]Properties not exactly known in all cases



H3.4. Fig. 10. Heat transfer coefficient during upward and downward flow in a vertical tube (measurements on R 113 [R3]).



H3.4. Fig. 11. Heat transfer coefficient as a function of the vapor mass fraction for nucleate boiling in a horizontal tube.

cannot be achieved frequently, because the thickness of the film is more or less asymmetrical even in annular flow [G26]. One of the consequences is that critical boiling (Subchap. H3.5) sets in at the crest of horizontal tubes at a much earlier stage than it does in vertical tubes under otherwise comparable conditions [W34]. Therefore, this boundary must be taken into account in evaporators with high power density.

Incomplete wetting or the thermally effective wetting limit (Sect. 1.2) is also very pronounced during heat transfer in the nucleate boiling regime. An example is given in Fig. 11, in which the effect of incomplete wetting in a copper tube of $\lambda_w s = 0.95$ W/K is illustrated. It can be seen that the extent to which the perimeter-averaged heat transfer coefficient decreases with the vapor mass fraction becomes greater as the heat flux increases.

Another point in which nucleate boiling in horizontal tubes differs from that in vertical tubes is that measurements have revealed a relationship between the perimeter-averaged heat transfer coefficient and the flow parameters $\dot{m}$ and $\dot{x}$. The perimeter-averaged heat transfer coefficient in nucleate boiling is an approximation. A physically justified prediction ought to be based on local heat transfer coefficients (determined point-by-point) and relative wetting functions similar. These values are not yet available.

This relationship can be ascribed to partial drying. The following function was determined from measurements [R11, R18, R23, C11–C13] in copper tubes with $\lambda_w s \geq 0.7$ W/K:

$$F(\dot{m}, \dot{x}) = \left(\frac{\dot{m}}{\dot{m}_0}\right)^{0.25} \left[1 - p^{*0.1}\left(\frac{\dot{q}}{\dot{q}_{cr,PB}}\right)^{0.3} \dot{x}\right], \qquad (24)$$

where

$$\dot{q}_{cr,PB} = 2.79\dot{q}_{cr;0.1}p^{*0.4}(1 - p^*) \qquad (25)$$

and

$$\dot{q}_{cr;0.1} = 0.13\Delta h_{v0}\left(\rho_0''\right)^{0.5}\left(\sigma_0 g\left(\rho_0' - \rho_0''\right)\right)^{0.25}. \qquad (26)$$

$\dot{m}_o$ is a reference value; in this case, $\dot{m}_o = 100$ kg/m²s. All properties in Eq. (26) must be determined at a reference pressure of $p_o^* = 0.1$.

Equations (25) and (26) are used to determine the maximum heat flux in pool boiling in Chap. H2. The term $\dot{q}_{cr,PB}$ in

Eq. (24) is merely a reference value, and its application does not permit the conclusion that the critical boiling regime in horizontal tubes can be determined from Eqs. (25) and (26).

It has been demonstrated by measurements [W10, R11, R18, R23, R26, C11–C13] that the relationship of $\alpha(z)_B$ to pressure can no longer be described by the equation for vertical tubes, that is, Eq. (17) in Sect. 2.1. The results of the measurements have been plotted in Fig. 12, which also shows the curve for the following function:

$$F(p^*) = 2.692p^{*0.43} + \frac{1.6p^{*6.5}}{1 - p^{*4.4}}. \tag{27}$$

The experiments also reveal an effect of dryout on the relationship between the heat transfer coefficient and the mass velocity. Thus, the exponent n is less than that in vertical tubes, even if the horizontal tubes are thick and have good thermal conductivity ($\lambda_w s > 0.7$ W/K). A point that strikes attention is that, at $p^* \geq 0.1$, the experiments performed by *Riedle* et al. [R4] in stainless steel tubes of ($\lambda_w s < 0.1$ W/K gave rise in several cases to much lower values of n than those obtained in copper tubes. In the experiments on cryogenic fluids, all the sections in which the measurements were performed, consisted of copper with a wall heat conduction of $\lambda_w s > 0.7$ W/K.

If $\lambda_w s \geq 0.7$ W/K, the relationship for *inorganic substances*, *hydrocarbons*, and *halocarbons* is

$$n = 0.9 - 0.36 \cdot p^{*0.13}; \tag{28}$$

and that for *cryogenic fluids*,

$$n = 0.9 - 0.44 \cdot p^{*0.085}. \tag{29}$$

Müller-Steinhagen and *Schlünder* [G21] solved the thermal conductivity equation numerically for given wetting limits and for the heat transfer coefficient at given points. It was, thus, demonstrated that the perimeter-averaged heat transfer coefficient, expressed as a function of the wall heat conduction $\lambda_w s$, decreases with an increase in the diameter of horizontal tubes. In view of the fact that $\alpha(z)_B \sim d^{-0.4}$ in a vertical tube, a closer relationship to the diameter can be expected for a horizontal tube. The following equation has been derived from the experiments concerned [R4, R11], which yielded the results plotted in Fig. 13:

$$F(d) = (d_o/d)^{0.5}, \tag{30}$$

where $d_o = 10^{-2}$ m.

Heat transfer in tubes with a high wall heat conduction ($\lambda_w s \geq 0.7$ W/K)

Boundary condition $\dot{q}_o$*= constant.* A review of all the relationships discussed gives rise to the following equation for nucleate boiling in horizontal tubes for $\lambda_w s \geq 0.7$ W/K

$$\frac{\alpha(z)_B}{\alpha_0} = C_F \left(\frac{\dot{q}}{\dot{q}_0}\right)^{n(p^*)} \left[2.692p^{*0.43} + \frac{1.6p^{*6.5}}{1 - p^{*4.4}}\right] \cdot \left(\frac{d_0}{d}\right)^{0.5} \left(\frac{R_a}{R_{a0}}\right)^{0.133} \left(\frac{\dot{m}}{\dot{m}_0}\right)^{0.25} \cdot \left[1 - p^{*0.1}\left(\frac{\dot{q}}{\dot{q}_{cr,PB}}\right)^{0.3} \dot{x}\right]. \tag{31}$$

Whether $n(p^*)$ is determined from Eq. (28) or (29) depends on the fluid. Equation (25) is taken to calculate $\dot{q}_{cr,PB}$; and $\dot{q}_{cr,01}$ is obtained from Table 3 or Eq. (26). The reference values normally indicated by the subscript o are $d_o = 1 \cdot 10^{-2}$ m, $\dot{m}_o = 100$ kg/m^{2}s, and $R_{ao} = 1 \cdot 10^{-6}$ m. The reference values $\dot{q}_o$ and α_o (at $p_o^* = p/p_c = 0.1$) and $R_{ao} = 1 \cdot 10^{-6}$ m are taken from Table 2. The factor C_F was determined from measurements [W10, W14, R2, R4, R6, R8–R11, R18, R23, R26, C9–C13, G7, G9], and the C_F-value for $\lambda_w s \geq 0.7$ W/K is given in Table 3.

Boundary condition T_w *= constant.* The correction ψ for stratified and wavy flow can be obtained from Fig. 14 up to the limit $\lambda_w s \to \infty$ ($\psi = 0.86$). This value has to be inserted in Eqs. (31) and (35). All the other equations remain unchanged, and no correction is required for other flow patterns.

Range of validity for Eq. (31):

$0.03 \leq p^* \leq 0.93$ (cryogenic fluids)

H3.4. Fig. 12. Relative heat transfer coefficient as a function of the reduced pressure p^* for nucleate boiling in horizontal tubes and for values of $\dot{q}_0$ relating to the substances concerned.

$0.005 \leq p^* \leq 0.85$ (all other liquids)
$4 \leq d/\text{mm} \leq 25$
$0.05 \leq R_a/\mu\text{m} \leq 5$.

The range of roughness values is valid for drawn tubes and precision tubes, welded tubes, and welded precision tubes that have been cold-drawn or cold-rolled after welding.

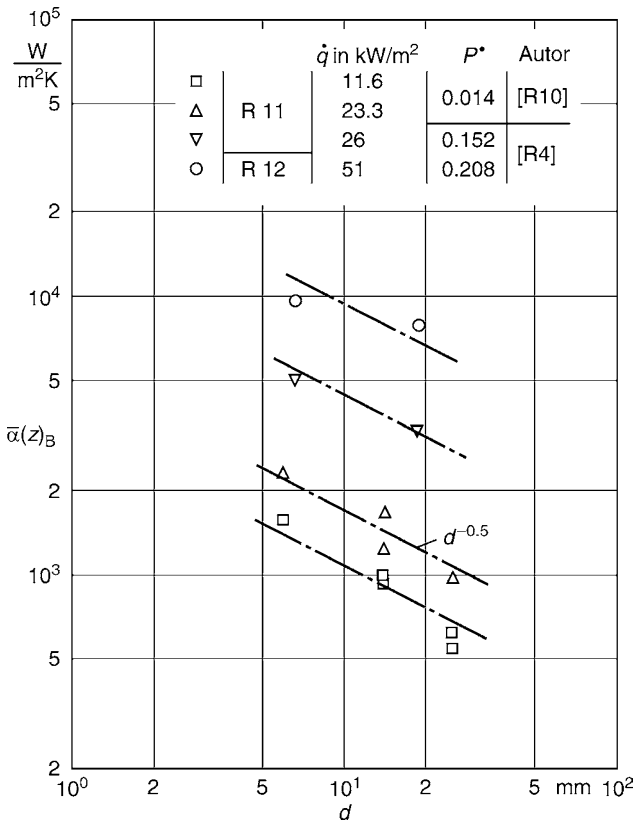
A relationship exists between the molar mass $\widetilde{M}$ and C_F within the range of scattering. Thus, C_F for substances that are not listed in Table 3, can be obtained approximately from the following correlation:

$$C_F = 0.789\left(\widetilde{M}/\widetilde{M}_{H2}\right)^{0.11}, \tag{32}$$

where $\widetilde{M}_{H2} = 2.016$ g/mol is the molar mass of H_2.

Results that have been obtained up to now indicate that an upper limit of $C_F \leq 2.5$ should be observed.

Heat transfer in tubes with low wall heat conduction ($\lambda_w s < 0.7$ W/K).



H3.4. Fig. 13. Heat transfer coefficient as a function of tube diameter for nucleate boiling in horizontal tubes.

Boundary condition $\dot{q}$ = *constant.* Incomplete wetting has an even greater effect in tubes with thin walls and poor wall heat conduction $\lambda_w s$. The following amendments in the correlations have been derived from the few measurements that are available [R4, R6, R18, R26] for evaluation.

(a) The exponent n in the term for the heat flux decreases almost independently of the flow pattern. Allowance for this change is made by the factor κ, a plot of which is shown in Fig. 14.
(b) The heat transfer coefficient is less than that relating to $\lambda_w s \geq 0.7$ W/K under otherwise identical conditions. The extent of the decrease depends on the flow pattern observed in the unheated sight glass. The requisite correction is made by the factor ψ, which is shown as a function of $\lambda_w s$ in Fig. 14.

The dependency shown in Fig. 14 can be formulated as follows:
For all flow patterns, the factor κ can be written by

$$\kappa = 0.675 + 0.325\tanh\left(3.711\left(\lambda_w s - 3.24\cdot 10^{-2}\right)\right). \tag{33a}$$

The value of ψ to be taken as an approximation depends on the flow pattern.

Stratified and wavy flow

$$\psi = 0.46 + 0.4\tanh\left(3.387\left(\lambda_w s - 8.62\cdot 10^{-3}\right)\right) \tag{33b}$$

Slug flow

$$\psi = 0.671 + 0.329\tanh\left(3.691\left(\lambda_w s - 8.42\cdot 10^{-3}\right)\right) \tag{33c}$$

Annular flow

$$\psi = 0.755 + 0.245\tanh\left(3.702\left(\lambda_w s - 1.25\cdot 10^{-2}\right)\right) \tag{33d}$$

Thus, if $\lambda_w s < 0.7$ W/K, the value of n to be taken as an approximation instead of Eq. (28),

$$n = \kappa\left(0.9 - 0.36\cdot p^{*0.13}\right); \tag{34a}$$

and instead of Eq. (29),

$$n = \kappa\left(0.9 - 0.44\cdot p^{*0.085}\right). \tag{34b}$$

C_F in this case, is given by

$$C_F = \psi C_F(\lambda_w s \geq 0.7 W/K). \tag{35}$$

C_F ($\lambda_w s \geq 0.7$ W/K) can be obtained from Table 3 or Eq. (32).

Boundary condition T_w = *constant.* The correction ψ for stratified and wavy flow can be obtained from Fig. 14 up to the limit $\lambda_w s \to \infty$ ($\psi = 0.86$). This value has to be inserted in Eq. (35). All the other equations remain unchanged, and no correction is required for other flow patterns.

H3.4. Table 3. Factor C_F, standard deviation α, and reference value $\dot{q}_{cr,0.1}$

Substance	H_2 (Para)	H_2O[a]	Ne	N_2	Ar	R 22	R 12	R 11
C_F	0.79	0.72	0.95	1.67	0.93	1.23	1.06	1.87
α	0.17	0.29	0.09	0.30	0.34	0.18	0.30	0.32
$\frac{\dot{q}_{cr,0.1}}{W/m^2}$	79,410	3,293,350	126,870	230,000	295,220	429,580	324,150	363,400

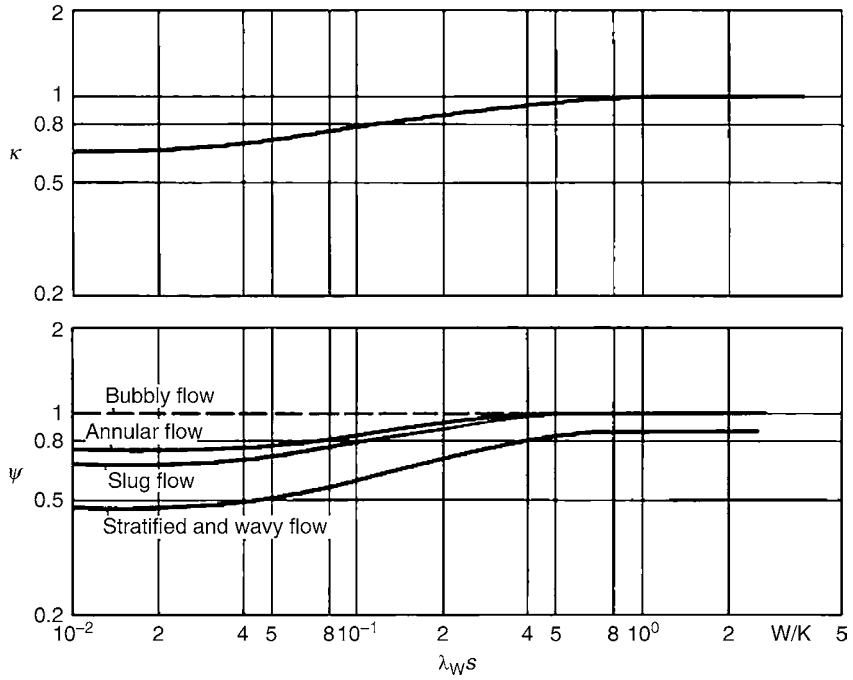
[a]Some of the values measured for water have been taken from Mumm [W10], in which $\lambda_w s = 0.01$ W/K. The corrections are $\kappa = 1$ and $\psi = 1$ [Eqs. (33) and (34)]



H3.4. Fig. 14. Correlation factors κ and ψ as functions of the heat conduction $\lambda_W s$ of the tube wall.

2.2.1 Limit for the Effect of Mass Velocity

From a given mass velocity upward, the value for $\alpha(z)_B$ determined from Eq. (31) no longer depends on the term $(\dot{m}/\dot{m}_0)$. This case arises if the value for $\alpha(z)_B$ determined from Eq. (31) is higher than that calculated from Eq. (21). If the limiting value of $(\dot{m}/\dot{m}_0)^{0.25}$ is expressed as $Y = (\dot{m}/\dot{m}_0)^{0.25}_{lim}$ and calculated on condition that Eq. (31) is equal to that determined from Eq. (21), the following equations are obtained:

$$Y = \frac{\left[\alpha(z)_B\right]_{Eq.(21)}}{\left[\alpha(z)_B \text{ at } (\dot{m}/\dot{m}_0) = 1\right]_{Eq.(31)}}. \quad (36)$$

and if $\left(\alpha(z)_B\right)_{Eq.(31)} > \left(\alpha(z)_B\right)_{Eq.(21)}$,,

$$\alpha(z)_B = \left(\alpha(z)_B\right)_{Eq.(21)}. \quad (37)$$

$n(p^*)$ is determined for the fluid concerned, and $\dot{q}_{cr,PB}$ is calculated as before.

2.2.2 Effects of Bends and Elbows (Sects. 2.1 and 2.2)

The equations given for the determination of $\alpha(z)_B$ in vertical and horizontal tubes do not allow for the disturbances in two-phase flow that are caused by bends, elbows, etc. *Pujol's* measurements [R3] on R 113 in hairpin rows of vertical tubes also embraced nucleate boiling. No disturbances were detected after a relative length $l/d = 20$ had been traversed downstream from a bend with a curvature of $R/d \approx 4.1$ (Sect. 1.1). It can generally be expected that asymmetric film thickness at high heat fluxes causes a partial dryout, that is, a reduction in the heat transfer coefficient over a relative length of $l/d = 5$ to $l/d = 10$, behind conventional bends.

No investigations have been made on the effect of bends, elbows, etc. in horizontal tubes on the heat transfer coefficient in the nucleate boiling regime. It can be concluded from the results discussed in Sect. 1.2, that the phase distribution changes over a relative length of $l/d = 5$–10 behind conventional bends with a curvature of $R/d = 2$–10. Since it is not yet known whether this type of disturbance intensifies the effect of already existent dryout, further reductions in the heat transfer coefficient should not be taken into account.

2.2.3 Effect of Surface Treatment (Sects. 2.1 and 2.2)

Additional roughness caused by sintered coatings or sandblasting cannot be embraced by the function $F(W)$ defined by Eq. (20). The inner surface of the tube used by *Haffner* [R31] in studies on nucleate boiling was sandblasted with aluminaoxide and had an average roughness height of $R_a = 0.33$ µm. The heat transfer coefficients determined for R12 and R22 in this tube were, on an average, higher by a factor of 1.7 than those calculated from Eq. (21) for $R_a = 0.33$. However, the relationships to $\dot{q}$ and p^* agreed satisfactorily with those given by Eq. (21).

2.2.4 Effect of Impurities (Sects. 2.1 and 2.2)

Impurities are solutions of wetting agents, oils, or other liquids that are present in low concentrations in the liquid phase. In nucleate boiling, they exert a considerable effect on heat

transfer. Thus, the presence of oils in refrigerants either increases or decreases the heat transfer coefficient to an extent that depends on the concentration [R22]. The fouling caused by the deposition of the dissolved substances onto the heated surfaces may give rise to great difficulties (cf. Chap. C4). In an example that occurred, the heat transfer coefficient in a horizontal tube during nucleate boiling of argon containing 40 ppm of residual components of air, was reduced in the course of time to one-third of its original value [C13].

2.2.5 Determination of C_F from Measurements

Values of C_F more accurate than those read off from Tables 1 and 3 or calculated from Eqs. (22) and (32) can be derived by inserting values measured on the given liquid/tube wall system in Eqs. (21), (31), or (37) and solving for C_F. Equations (22) and (32) may then be resorted to for extrapolating to other conditions, because the relationships to $\dot{q}$, p, d, $\dot{m}$, and $\dot{x}$ can be regarded as verified by measurements [G7, G9].

2.3 Nucleate Flow Boiling in Inclined Tubes and Helical Coils

2.3.1 Inclined Tubes

Only a few measurements on water are available for the analysis of nucleate boiling in inclined tubes. The parameters in *Bogdanov's* study [W28] on a tube inclined at an angle of 45° were d = 20 mm, $\dot{m}$= 200–3000 kg/m^{2}s, and p^* = 0.045–0.55. *Gilli*'s measurements [W29] in tubes inclined at an angle of 15° to the horizontal were performed at mass velocities of $\dot{m}$ = 200–860 kg/m^{2}s and reduced pressures of p^* = 0.07 and p^* = 0.13. The data, thus, obtained were too scanty to permit any correlations to be established for inclined tubes. Therefore, until further measurements become available, it is suggested that the perimeter-averaged heat transfer coefficient for tubes inclined at an angle of Θ = 0–30° to the horizontal be calculated from the equations for horizontal tubes (Sect. 2.2); and that for tubes inclined at an angle of $\Theta > 30°$, from the equations for vertical tubes (Sect. 2.1).

2.3.2 Helical Coils

Studies on nucleate boiling in helical tubes have been reported in the literature [W16, W17, W31–W33]. *Carver* et al. [W31] performed most of their measurements under conditions of critical boiling. *Gilli* et al. [W32] suggested that the perimeter-averaged heat transfer coefficient for water at $\dot{m}$ = 300–3300 kg/m^{2}s and for reduced pressures of p^* = 0.3–0.86 be calculated from the following equation:

$$\alpha(z)_B = 26 \cdot 10^3 \left(\frac{h_{cr}}{h_{cr} + \Delta h_v}\right)^5 \cdot \left(0.86 \cdot 10^{-3}\dot{q}\right)^{0.57(\Delta h_v/h_{cr})^{0.16}} \left(1 - \frac{d}{D_w}\right)^{-2.4}, \quad (38)$$

where D_w is the average coil diameter, Δh_v is the specific enthalpy of vaporization corresponding to the boiling pressure p, and for water h_{cr} = 2107. 4 kJ/kg.

Very few or no experiments at all have been carried out on water under conditions other than those outlined above or on other liquids. According to *Steiner* [G4], the equation for nucleate boiling in vertical tubes can also be applied to helical coils. It can be deduced from Sect. 1.3 that this approximation is valid only as long as the tube wall is completely wetted. If observation of the phase distribution reveals that flow is already stratified in unheated coils, the equations for horizontal tubes (Sect. 2.2) should be resorted to for the determination of $\alpha(z)_B$.

3 Summary of Heat Transfer in Flow Boiling of Pure Substances

The methods for determining the perimeter-averaged heat transfer coefficient in convective and nucleate boiling during the flow of liquid/vapor mixtures through tubes have been described in Sects. 1 and 2. They were based on measurements on various pure substances under various conditions, and different correlations are required to describe the heat transfer coefficient in each of the two boiling regimes [G22]. Inclusion of the transition boiling regime was avoided, as far as possible, in evaluating the experimental results. Observations by *Gouse* and *Coumou* [R15] and *Gouse* and *Dickson* [R16] on heated glass tubes demonstrated that both convective and nucleate boiling, that is, a definite number of activated nucleation sites, occurred in the transition regime. Results of measurements in transition boiling have been published by many authors [W4, R6, R11, R18, R23, R26].

If the criteria for the onset of nucleate or convective boiling are left out of consideration and if transition boiling is taken into account, the perimeter-averaged heat transfer coefficient, which depends on the inclination of the tubes, is given by

$$\alpha(z) = \sqrt[3]{\alpha(z)_{conv}^3 + \alpha(z)_B^3}, \quad (39)$$

where $\alpha(z)_{conv}$ is defined in Sects. 1.1–1.3, and $\alpha(z)_B$ is defined in Sects. 2.1–2.3. If the heat flux is very small, $\alpha(z)_B$ cannot be determined by the method described in Sect. 2 and inserted into Eq. (39). A certain superheat, that is, heat flux $\dot{q}_{onb}$ is required for the onset of boiling in the liquid near the wall. If it is not attained, only convective boiling should be taken into account in Eq. (39). Particular attention must be devoted to this point in the $\dot{x}$ = 0–0.3 range of vapor mass fractions.

The heat flux at the onset of nucleate boiling can be estimated from

$$\dot{q}_{onb} = \frac{2\sigma T_{sat}\alpha_{LO}}{r_{cr}\rho'' \Delta h_v}, \quad (40)$$

where $r_{cr} = 0.3 \cdot 10^{-6}$ m for all heated surfaces with a permissible roughness as defined in Sect. 2; α_{LO} is the local single-phase heat transfer coefficient at the point z = 0 and for a liquid mass velocity of $\dot{m}$. If the Reynolds number, the hydrodynamic conditions, and the thermal boundary conditions

($\dot{q}$ = constant; T_w = constant) are known, α_{LO} for a given tube cross-section can be calculated from the equations presented in Sect. 4 (Appendix) or in Chap. G4. The value to insert for the Reynolds number in this case is

$$\mathrm{Re}_{LO} = \frac{\dot{m} d_h}{\eta_L}. \tag{41}$$

The value for α_{LO} for helical coils can be determined by the method described in Chap. G3.

The values to be taken for the properties are those corresponding to saturation at the pressure p.

4 Appendix – Local Heat Transfer Coefficient in Forced Single-Phase Flow

The local heat transfer coefficient at the point z in the direction of flow is defined by

$$\alpha(z) = \frac{\dot{q}(z)}{(T_W - T_{sat}(p))_z}. \tag{A1}$$

Flow in the tube is always laminar below the critical Reynolds number of Re = 2300, and becomes turbulent above this value. In the $2300 \le \mathrm{Re} \le 5{\cdot}10^4$ transition range, the equations for laminar heat transfer in a short length of tube, that is, $d/z > 0.01$, may yield higher values of the Nusselt number Nu_z than those obtained from turbulent flow equations. This depends on the Prandtl number. In such cases, it must always be ensured that the highest value obtained for Nu_z is taken.

According to *Gnielinski* [G23], the following equations apply.

Laminar flow:
Boundary condition T_w=constant
Hydrodynamic inflow:

$$\mathrm{Nu}_z = 0.332 \sqrt[3]{\mathrm{Pr}} \sqrt{\mathrm{Re} \cdot d/z} \tag{A2}$$

Hydrodynamically developed flow:

$$\mathrm{Nu}_z = \sqrt[3]{3.66^3 + 1.077^3 \mathrm{Re}\,\mathrm{Pr} \cdot d/z} \tag{A3}$$

If $d/z \ge 1$, the numerical value to insert in Eqs. (A2) and (A3) is $d/z = 1$.

Boundary condition $\dot{q}$ = constant

According to *Shah* and *London* [G24], the following approximations apply.
Hydrodynamic inflow:

$$\mathrm{Nu}_z = 0.455 \sqrt[3]{\mathrm{Pr}} \sqrt{\mathrm{Re} \cdot d/z} \tag{A4}$$

Hydrodynamically developed flow:

$$\mathrm{Nu}_z = \sqrt[3]{4.36^3 + 1.302^3 \mathrm{Re}\,\mathrm{Pr} \cdot d/z} \tag{A5}$$

If $d/z \ge 1$, the numerical value to insert in Eqs. (A4) and (A5) is $d/z = 1$.

Turbulent flow:

According to *Gnielinski* [G23], the equations for turbulent flow under the boundary condition T_w = constant or $\dot{q}$ = constant do not differ significantly from each other.
Hydrodynamic inflow (sharp edges)

If $d/z \ge 1$, Nu_z can be obtained approximately from the following equation:

$$\mathrm{Nu}_z = \frac{4}{3} \mathrm{Nu}_\infty. \tag{A6}$$

If $d/z < 1$,

$$\mathrm{Nu}_z = \mathrm{Nu}_\infty \left[1 + \frac{1}{3} (d/z)^{2/3} \right], \tag{A7}$$

where

$$\mathrm{Nu}_\infty = \frac{(\xi/8)(\mathrm{Re} - 1000)\,\mathrm{Pr}}{1 + 12.7\sqrt{(\xi/8)}\left(\mathrm{Pr}^{2/3} - 1\right)} \tag{A8}$$

Hydrodynamically developed flow

$$\mathrm{Nu}_z = \mathrm{Nu}_\infty \tag{A9}$$

Explanations

$$\mathrm{Nu}_z = \frac{\alpha(z) d}{\lambda} \tag{A10}$$

$$\mathrm{Pr} = \frac{\eta c_p}{\lambda} \tag{A11}$$

$$\xi = \left(1.82 \log_{10} \mathrm{Re} - 1.64\right)^{-2}. \tag{A12}$$

The Reynolds numbers are obtained from Eq. (39) in Sect. 1.1 or from Sect. 1.2. If the tube cross-section is not circular, the hydraulic diameter d_h must be substituted for the diameter d in the equations for the Nusselt and Reynolds numbers.

The values to be inserted for the properties have to be determined in accordance with the instructions given in Sects. 1.1 and 1.2. The same applies to the determination of the local heat transfer coefficient for a liquid, in which case the properties of the liquid concerned must be inserted in Eqs. (A10) and (A11). The corresponding procedure is adopted in calculating $\alpha(z)$ for a vapor.

Example 1

n-Butanol is to be evaporated at an average pressure of $p = 4.82$ bar in a natural-circulation evaporator with vertical copper tubes (d_o = 30 mm, s = 1.5 mm, R_a = 2 µm). The average heat flux is $\dot{q}$= 60 kW/m^2, and the mass velocity in the tubes is $\dot{m}$= 250 kg/m^2 s. The *n*-butanol enters the tubes at saturation, and the vapor mass fraction at the outlet is $\dot{x}_{out}$= 0.3. The heat transfer coefficient has to be determined step by step, and $\Delta\dot{x}$= 0.05 is given.

Properties at $p = 4.82$ bar $T_w = 446.5$ K

$\rho' = 640$ kg/m^3; $\eta' = 2.308 \cdot 10^{-4}$ kg/m s;
$\lambda' = 1.126 \cdot 10^{-1}$ W/m K; $\rho'' = 12.5$ kg/m^3;
$\eta = 1.14 \cdot 10^{-5}$ kg/m s; $\lambda' = 2.82 \cdot 10^{-2}$ W/m K;
$c'_p = 4420$ J/kg K; $\Delta h_v = 509\,700$ J/kg;
$c''_p = 2140$ J/kg K; $\sigma = 1.23 \cdot 10^{-2}$ kg/s^2.

The inlet to the tube bundle has sharp edges. The heat transfer coefficients in single-phase flow are to be determined for the case of hydrodynamic inflow under the boundary condition $\dot{q}$ = constant. The equations concerned are given by Eqs. (A4), (A6–A8), and (A10–A 12).

At $z = 0$, $\alpha_{LO} = 1271$ W/m^2 K.

The heat flux at the onset of nucleate boiling [Eq. (40)] is

$$\dot{q}_{onb} = \frac{2\sigma T_{sat}\alpha_{LO}}{r_{cr}\rho''\Delta h_v}$$
$$= \frac{2 \cdot 1.23 \cdot 10^{-2}\text{kg/s}^2 \cdot 446.5\text{K} \cdot 1271\text{W/m}^2\text{K}}{0.3 \cdot 10^{-6}\text{m} \cdot 12.5\text{kg/m}^3 \cdot 509700\text{Ws/kg}} = 7304\text{W/m}^2.$$

In accordance with the remarks in Sect. 3, both convective and nucleate boiling occur because $\dot{q} > \dot{q}_{onb}$.

α_0 for *n*-butanol in nucleate boiling is taken from Table 2.

The heat transfer coefficient in nucleate boiling $\alpha(z)_B$ is determined by the method described in Sect. 2; and the coefficient in convective flow boiling is determined by the method described in Sect. 1. The figures thus obtained are listed in Table 4.

Determination of the length of tube required to evaporate *n*-butanol from $\dot{x}_{in} = 0$ to $\dot{x}_{out} = 0.3$:

The energy balance yields

$$\dot{m}f\,\Delta\dot{x}\,\Delta h_v = \dot{q}\,\pi\,d\,l, l = \frac{\dot{m}f\Delta\dot{x}\Delta h_v}{\dot{q}\pi d}$$
$$= \frac{250\text{kg/m}^2\text{s} \cdot 5.73 \cdot 10^{-4}\text{m}^2 \cdot 0.3 \cdot 509,700\text{Ws/kg}}{60,000\text{W/m}^2 \cdot \pi \cdot 2.7 \cdot 10^{-2}\text{m}} = 4.3\text{m}.$$

Thus, a section of length $\Delta l = 0.717$ m is required for each change in the vapor fraction by an amount $\Delta\dot{x} = 0.05$.

Example 2

Refrigerant R12 is to be completely evaporated at $\theta_{sat} = -20°C$ in a single-pass injection evaporator designed for cooling brine.

The mass velocity in each tube is 80 kg/m^2 s, and the inlet vapor mass fraction behind the expansion valve is $\dot{x}_{in} = 0.1$. The dimensions of the horizontal tube are $d_o = 18$ mm and $s = 2$ mm, and the roughness is $R_a = 1.5$ µm. The average heat flux to be transferred is $\dot{q} = 9$ kW/m^2. The heat transfer coefficient has to be determined step by step, and $\Delta\dot{x} = 0.1$ is given.

Properties at $p = 1.51$ bar and $\theta_{sat} = -20°C$

$\rho' = 1459.9$ kg/m^3; $\eta' = 3.249 \cdot 10^{-4}$ kg/m s;
$\lambda' = 8.562 \cdot 10^{-2}$ W/m K; $\rho'' = 9.15$ kg/m^3;
$\eta'' = 1.08 \cdot 10^{-5}$ kg/m s; $\lambda'' = 7.34 \cdot 10^{-3}$ W/m K;
$c'_p = 904.9$ J/kg K; $\Delta h_v = 161\,780$ J/kg;
$c''_p = 600.1$ J/kg K; $\sigma = 1.43 \cdot 10^{-2}$ kg/s^2.

Flow is hydrodynamically undeveloped at the inlet to the evaporator tube, that is, downstream from the expansion valve and the refrigerant distributor. The values for α_{LO}, α_{GO}, and α_G have to be determined for hydrodynamic inflow at $\dot{q}$ = constant from Eqs. (A4), (A6–A8), and (Al0–A12).

At $z = 0$, $\alpha_{LO} = 246.5$ W/m^2 K. Hence, the heat flux at the onset of nucleate boiling [Eq. (40)] is $\dot{q}_{onb} = 4019$ W/m^2. Since $\dot{q} = 9000$ W/m^2 $> \dot{q}_{onb}$, both convective and nucleate boiling occur.

Convective Flow Boiling

According to the criterion given in Sect. 1 and to the flow pattern map, stratified or stratified-wavy flow exists at $\dot{x} = 0.1$ and $\dot{x} = 0.2$ (Table 5). The angle subtended at the center by the unwetted surface φ is obtained from H3.1, Eqs. (26) and (27) in Subchap. H3.1; and the hydraulic diameter for the vapor phase d_{hG}, from Eq. (10). The value to be inserted for the thermally effective unwetted arc in the determination of $\alpha(z)_{conv}$ need only be half as much as the figure determined from Eq. (13).

The values for $\alpha(z)_{conv}$ and the fin characteristic M are as follows:

$\dot{x}$	M	$\alpha(z)_{conv}$ W/m^2 K
0.1	0.98	779
0.2	0.65	503

Since $M < 1$, the above figures for $\alpha(z)_{conv}$ are approximations, as determined from Eq. (9). The values obtained from Eq. (8) are listed in Table 5. A comparison reveals that the values

H3.4. Table 4. Calculation results for the natural-convective evaporator (Example 1)

0.8	3.523	Wavy flow	128	112			8.994						1153	0.849	746	1249
0.9	4.027	Wavy flow	128	112			9.215						1181	0.849	720	1264
1	4.53		128	112			0.875						112		–	112

[a] At $z = 0$ m the value $z = 10^{-5}$ m is assumed
[b] At $\dot{x} = 0.2$ the condition $Re_L Fr'_G \leq 4\left(Re_L Fr'_G\right)_{lim}$ is fulfilled. Therefore, the convective heat transfer coefficient is to be calculated as if it were stratified flow with partial wetting

obtained from Eq. (9) are sufficiently accurate for the boundary condition $\dot{q}$=constant and for $M \leq 1$.

Nucleate Boiling in the Horizontal Tube

At $\theta_{sat} = -20°C$, $\lambda_w = 320$ W/m K. The correction factors for the change in n and C_F for stratified and wavy flow can be read off from Fig. 14: thus, $\kappa = 0.993$ and $\psi = 0.849$.

The heat transfer coefficient for vertical tubes [Eq. (21)] is $\alpha(z)_B = 1337$ W/m² K. It is higher than the corresponding value calculated for horizontal tubes at all values of $\dot{x}$. Consequently, the limit defined by Eq. (36) is not reached at which heat transfer no longer depends on the mass velocity.

The energy balance yields $\dot{m} f \, \Delta\dot{x} \, \Delta h_v = \pi \, d \, l \, \dot{q}$. Hence, the length of the tube is

$$l = \frac{80\text{kg/m}^2\text{s} \cdot 1.54 \cdot 10^{-4}\text{m}^2 \cdot 0.9 \cdot 161780\text{J/kg}}{9000\text{W/m}^2 \cdot \pi \cdot 1.4 \cdot 10^{-2}\text{m}} = 4.53\text{m}.$$

In other words, the one pass suffices. The length of the section of tube required to effect a change of $\Delta\dot{x}$= 0.1 in the vapor mass fraction is $\Delta l = 0.503$.

The values obtained are listed in Table 5.

Example 3

Determine the rate of heat transfer into the water in the evaporation tubes of a forced-circulation boiler. The evaporation section consists of seamless steel (13 CrMo 44) tubes of $d_o = 31.8$ mm and $s = 4.5$ mm. The length of a straight section in the string of tubes is 3.5 m, and the spacing is 64 mm. The tubes are horizontal and are welded to the wall formed by the fins.

In view of the layer of magnetite formed during operation, the average roughness height that can be anticipated is $R_a = 5$ µm. The boiler is operated at a pressure of $p = 160$ bar and a mass velocity of $\dot{m}$= 800 kg/m² s. The furnace is designed to allow a heat flux of $\dot{q}$= 200 kW/m² to be applied uniformly over the circumference of the tubes. The water is heated to saturation in the economizer, that is,it enters the evaporator tubes at $\dot{x}_{in} = 0$.

H3.4. Table 6. Flow pattern in horizontal evaporator tubes acc. to Subchap. H3.1 (Example 3)

$\dot{x}$	z m	Flow pattern
0.01	0	Plug flow
0.1	2.12	Slug flow
0.2	4.23	Slug flow
0.3	6.35	Slug flow
0.4	8.47	Slug flow
0.5	10.59	Slug flow
0.6	12.7	Annular mist flow
0.7	14.82	Mist flow
0.8	16.94	Mist flow
0.9	19.06	Mist flow

The heat transfer coefficients and the wall superheat are to be determined in steps of $\Delta\dot{x} = 1$. The steps are continued up to the state of critical boiling if it has not already been reached, or to complete evaporation.

Properties at $p = 160$ bar and $\theta_{sat} = 347.34°C$:

$\rho' = 584$ kg/m³; $\eta' = 6.69 \cdot 10^{-5}$ kg/m s;
$\lambda' = 4.427 \cdot 10^{-1}$ W/m K; $\rho'' = 107.87$ kg/m³;
$\eta'' = 2.34 \cdot 10^{-5}$ kg/m s; $\lambda'' = 1.282 \cdot 10^{-1}$ W/m K;
$c'_p = 9597.1$ J/kg K; $\Delta h_v = 928\,644$ J/kg;
$c''_p = 14\,878.8$ J/kg K; $\sigma = 4.2 \cdot 10^{-3}$ kg/s².

The length of the tubes derived from the energy balance $\dot{m} f \, \Delta\dot{x} \, \Delta h_v = \dot{q} \, \pi \, d \, l$ is

$$l = \frac{800\text{kg/m}^2\text{s} \cdot 4.083 \cdot 10^{-4}\text{m}^2 \cdot 928,664\text{J/kg}}{200,000\text{W/m}^2 \cdot \pi \cdot 2.28 \cdot 10^{-2}\text{m}} = 21.17\text{m}.$$

A section of length Δl= 2.12 m is required to cause a change of $\Delta\dot{x}$= 0.1 in the vapor mass fraction. The number of the tube rows is n = 21.17 m/3.5 m ≈ 6.

H3.4. Table 7. Calculation results for the evaporator tube (Example 3)

$\dot{x}$	z m	α_{LO} W/m² K	α_{GO} W/m² K	$\frac{\alpha(z)_{conv}}{\alpha_{LO}}$	$\alpha(z)_{conv}$ W/m² K	ψ	$\alpha(z)_B$ W/m² K	$\alpha(z)$ W/m² K	ΔT K

0.5	10.59	12,176	12,270	2.363	28,768	0.825	49,385	52,446	3.81
1	21.17	12,176	12,270	1.008	12,270	–	–	12,270	16.3

No allowance is made for evaporation in the bends, which have a curvature of $R/d = 1.4$ and an average length of about 0.1 m. Since the relative length of the economizer tubes is $l/d \geq 20$, flow is hydrodynamically developed. The equations for the determination of the heat transfer coefficient in single-phase flow are Eqs. (A8) and (A9– A12).

At $\alpha_{LO} = 12\,176$ W/m² K, the minimum heat flux required for the onset of nucleate boiling is $\dot{q}_{onb} = 2112$ W/m². Since a value of $\dot{q} = 200$ kW/m² is given, both convective and nucleate boiling must be taken into account.

Convective Boiling

The flow patterns determined by the method described in Subchap. H3.1 are entered in Table 6. The likelihood of a reduction in $\alpha(z)_{conv}$ in the convective boiling regime can be ignored, because stratified or stratified-wavy flow does not occur throughout the entire $\dot{x}$ range. The disturbance in the two-phase flow that is caused by the bends with a curvature of $R/d = 1.4$ within a length of $l/d \approx 25$, can be ignored in the case of slug and mist flow.

Nucleate Boiling in Horizontal Tubes

$\lambda_w = 30$ W/m K and $\lambda_w s = 0.135$ W/K apply if $\theta = 350°$C. The correction factor obtained from Eq. (33a) is $\kappa = 0.792$, and the values for ψ have been entered in Table 7.

If the tubes are horizontal, no allowance need be made for the effect of bends in further reducing the heat transfer coefficient in nucleate boiling.

The heat transfer coefficient in nucleate boiling is $\alpha(z)_B = 75{,}523$ W/m² K, as determined by Eq. (60) for vertical tubes. The figure or $\alpha(z)_B$ determined by Eq. (31) for the horizontal tube is less than 75,523 W/m² K at all vapor mass fractions $\dot{x}$. Consequently, the limit at which $\alpha(z)_B$ no longer depends on the mass velocity, is not reached.

Critical Boiling State

According to the method described in Subchap. H3.5, the critical heat flux should first be determined for upward flow in a vertical tube. A figure of $\dot{x}_{cr} = 0.405$ at dryout is obtained from H3.5, Eq. (3).

The values at which the critical state occurs in a horizontal tube ($\cos\varphi = 1$) can then be determined from H3.5, Eqs. (5–7). Thus,

$$\mathrm{Fr} = \frac{\frac{\dot{x}_{cr}\dot{m}}{\rho''}}{\sqrt{\frac{gd\cos\varphi(\rho'-\rho'')}{\rho''}}} = \frac{\frac{0.405 \cdot 800\,\mathrm{kg/m^2 s}}{107.87\,\mathrm{kg/m^3}}}{\sqrt{\frac{9.81\,\mathrm{m/s^2} \cdot 2.28 \cdot 10^{-2}\,\mathrm{m}(584-107.87)}{107.87}}} = 3.02.$$

In other words, a critical state will arise. The crisis in boiling at the upper ($\dot{x}_{cr,up}$) or lower ($\dot{x}_{cr,low}$) side of the tube can be expected to occur at the following vapor mass fractions:

$$\dot{x}_{cr,up} = \dot{x}_{cr} - \Delta\dot{x}_{cr}/2 = 0.405 - 0.63/2 = 0.09,$$
$$\dot{x}_{cr,low} = \dot{x}_{cr} + \Delta\dot{x}_{cr}/2 = 0.405 + 0.63/2 = 0.72,$$

$\Delta\dot{x}_{cr}$ is obtained from H3.5, Eq. (6), that is,

$$\Delta\dot{x}_{cr} = 16/(2 + \mathrm{Fr})^2 = 0.63.$$

The flow patterns in the unheated tubes can be determined as described in Subchap. H3.1. It can be seen from Table 6 that slug flow occurs at $\dot{x} = 0.1$–0.5, that is, the two-phase flow is stratified. As a result of the heat applied, slug flow is thermally suppressed, and the stratification effect is intensified [R26]. For the purpose of the calculation, it is, therefore, assumed that the critical state is reached from $\dot{x}_{cr,low} = \dot{x} = 0.5$ onward. Values for $\dot{x} = 0$ to $\dot{x} = 0.5$ are listed in Table 7.

H3.5 Critical Boiling States in Flowing Liquids

Hein Auracher[1] · *Oliver Herbst*[2]
[1]Stuttgart, Germany
[2]AREVA NP GmbH, Erlangen, Germany

1 Introduction

Boiling allows large heat fluxes to be transferred at small temperature differences from a wetted wall to a liquid, but an upper limit is imposed on the flow rate of the heat thus transferred. If certain boundary conditions are transgressed, the heat transfer mechanism undergoes a change, referred to as the boiling crisis. This critical state in boiling can be recognized by one of the following characteristics:

- If the heat flux is applied to the system by electric heaters, radiators, nuclear energy, or other independent sources, a critical value $\dot{q}_{cr}$ exists at which a slight increase in $\dot{q}$ gives rise to a sudden leap in the wall temperature.
- A slight increase in the set temperature of a wall heated by an exchanger, condenser, or similar system causes a pronounced decrease in the heat flux.

The reason for the deterioration in heat transport in these cases is that the liquid loses direct contact with the wall. As a consequence, heat is transferred to the vapor and no longer to the liquid phase.

The boiling curve for a heated surface/liquid system is shown in Fig. 1. Its shape and thus the value for the critical heat flux depend on

- The nature of the liquid.
- The flow pattern (liquid pool or flowing liquid).
- The thermodynamic state of the liquid, for example, subcooling and the void fraction.
- The geometry of the heated surface.
- The material from which the heated wall has been constructed.
- The finish on the heated surface.

Two different physical mechanisms lead to the boiling crisis. They are described below.

- Film boiling

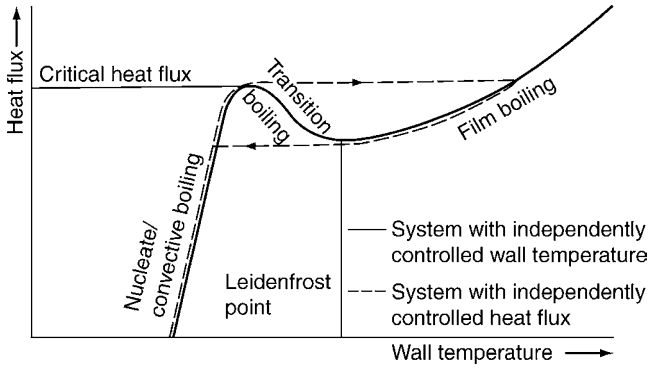
  If the void fraction in the stream is low, that is, if the liquid is the continuous phase, a vapor film is formed at the point where the boiling crisis occurs, and it separates the liquid from the heated surface. Owing to the poor thermal conductivity of the vapor, heat transfer is greatly impaired, and heat is imparted to the liquid by film boiling. The mechanism, which is illustrated in Fig. 2a, is referred to as departure from nucleate boiling (DNB). An increase in heat flux in this case shifts the initiation of the boiling crisis in the direction of lower vapor mass fractions.

- Dryout of the heated surfaces

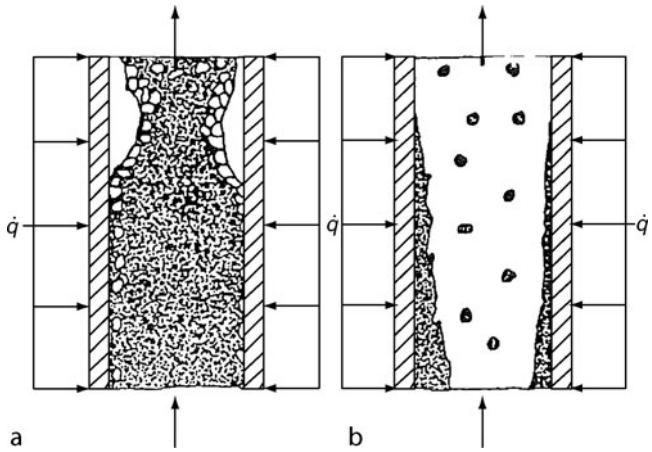
  If the void fraction is high enough to cause annular flow, the liquid film is torn off or dries out at the point where the boiling crisis occurs. This case is illustrated in Fig. 2b. Under these circumstances, the deterioration in heat transfer is less than that in film boiling, because the high vapor mass fraction is responsible for convective cooling of the heated surface. The critical mass fraction of vapor is almost independent of the heat flux. In the range of low heat fluxes, however, the number of entrained liquid droplets that are redeposited on the heated surface may increase. In this case, the boiling crisis is referred to as deposition-controlled burnout.

The attention that must be paid to the following factors in the boiling crisis depends on the application:

- The (critical) vapor mass fraction.
- The (critical) heat flux.



H3.5. Fig. 1. Heat transfer mechanisms in two-phase flow.



H3.5. Fig. 2. Boiling crisis mechanisms. (**a**) Film boiling (DNB). (**b**) Dryout.

The curve obtained by plotting the critical heat flux against the vapor mass fraction can be divided into three characteristic sections [1], as is shown in Fig. 3.

The effect of the boiling crisis depends on the interplay between the liquid and the heated surface as well as on the thermodynamic parameters. It is represented schematically in Fig. 4 for a water–steel system. Burnout or physical damage of the heated surface can be anticipated if the heat flux lies within the hatched section above the full-line curve in the diagram. It is also evident that a boiling crisis need not necessarily lead to damage if the vapor mass fraction is high, particularly if the medium is a refrigerant.

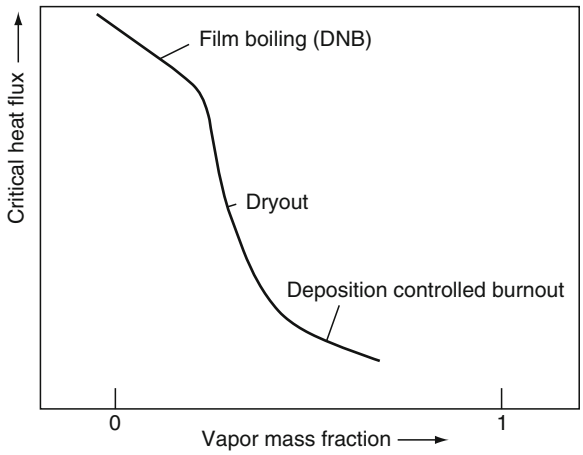
2 Flow of Water

2.1 Flow through Tubes

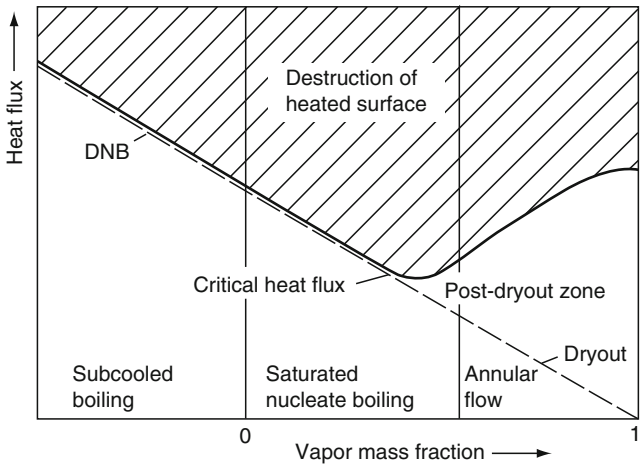
2.1.1 Upward Flow through Vertical Tubes

Two fundamental difficulties are encountered in determining the critical heat flux:

- In deciding the form of boiling crisis that can be anticipated, that is, film boiling or dryout.



H3.5. Fig. 3. Typical relationship between the critical heat flux and the vapor mass fraction or "quality" [1].



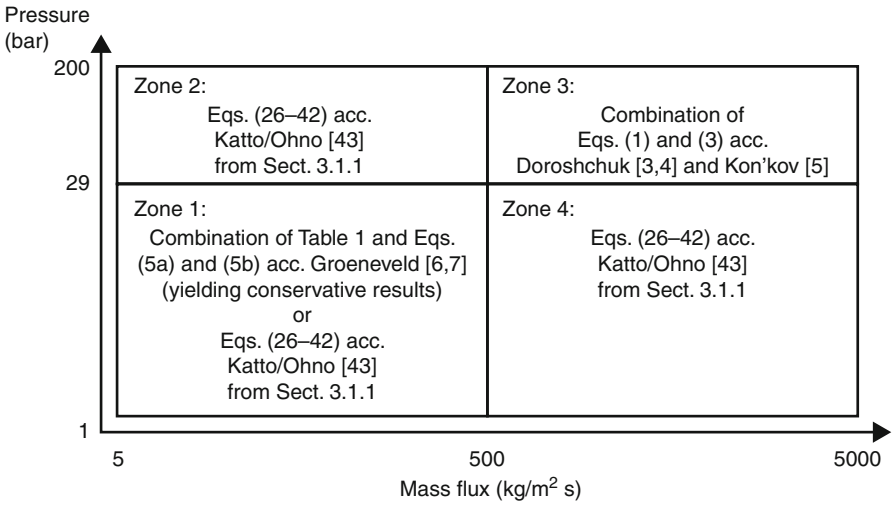
H3.5. Fig. 4. Effect of the boiling crisis on the heated surface for a water–steel system.

- In selecting the equation applicable to a particular case from the numerous empirical correlations, most of which are valid only within narrow ranges of the parameters concerned.

Figure 5 may serve as a guide for the recommended calculation procedure within the respective limits of validity, collectively covering a very large range of parameters.

The case for which high pressure parameters are coupled with large mass fluxes (Zone 3 in Fig. 5) is accounted for in the following method. It largely disregards the physical mechanisms involved, instead utilizing equations that are valid over a wide range of parameters for film boiling and dryout.

In the light of a comparison of about 3,000 measured values, Drescher and Köhler [2] demonstrated that the tables compiled by Doroshchuk et al. [3,4] are superior to the correlations extant. In practice, however, it is simpler to use the empirical equation for water that *Doroshchuk* derived *for film boiling* from the tables. The loss in accuracy that it entails can be reasonably accepted. The equation is



H3.5. Fig. 5. Parameter domains and their respective calculation procedures.

$$\dot{q}_{cr} = 10^3 \left[10.3 - 17.5\left(\frac{p}{p_c}\right) + 8\left(\frac{p}{p_c}\right)^2\right]\left(\frac{8\cdot 10^{-3}}{d}\right)^{0.5} \cdot \left(\frac{\dot{m}}{1000}\right)^{0.68\left(\frac{p}{p_c}\right)-1.2\dot{x}-0.3} \cdot e^{-1.5\dot{x}}. \quad (1)$$

The ranges within which the equation is valid are

$$29 \text{ bar} \le p \le 200 \text{ bar},$$
$$500 \text{ kg/m}^2\text{s} \le \dot{m} \le 5000 \text{ kg/m}^2\text{s},$$
$$0 \text{ K} \le \Delta\vartheta_{sub} \le 75 \text{ K},$$
$$4\cdot 10^{-3} \text{ m} \le d \le 25\cdot 10^{-3} \text{ m}.$$

The critical vapor mass fraction is given by

$$\dot{x}_{cr} = \frac{\ln\left(\frac{\dot{m}}{1000}\right)\left(0.68\frac{p}{p_c} - 0.3\right) - \ln(\dot{q}_{cr}) + \ln(C)}{1.2\ln\left(\frac{\dot{m}}{1000}\right) + 1.5} \quad (2a)$$

where

$$C = 10^3\left[10.3 - 17.5\left(\frac{p}{p_c}\right) + 8\left(\frac{p}{p_c}\right)^2\right]\left(\frac{8\cdot 10^{-3}}{d}\right)^{0.5}. \quad (2b)$$

Equation (1) was checked by taking the quotient of the calculated and measured values of the critical heat flux. The mean was found to be 0.99 with a standard deviation of 16% [2].

The *Kon'kov* equation for water [5] has been recommended for the range in which the heated surface *dries out* [2, *loc. cit.*]. Thus,

$$\begin{aligned} \dot{q}_{cr} &= 1.8447\cdot 10^8 \dot{x}^{-8}\dot{m}^{-2.664} \cdot (d\cdot 1{,}000)^{-0.56} e^{0.1372p} && \text{Range of pressures } p \\ &&& 4.9-29.4 \text{ bar} \\ \dot{q}_{cr} &= 2.0048\cdot 10^{10} \dot{x}^{-8}\dot{m}^{-2.664} \cdot (d\cdot 1{,}000)^{-0.56} e^{-0.0204p} && \\ &&& 29.4-98 \text{ bar} \\ \dot{q}_{cr} &= 1.1853\cdot 10^{12} \dot{x}^{-8}\dot{m}^{-2.664} \cdot (d\cdot 1{,}000)^{-0.56} e^{-0.0636p} && \\ &&& 98-196 \text{ bar}. \end{aligned} \quad (3)$$

Range of parameters covered by the equation

$$200 \text{ kg/m}^2\text{s} \le \dot{m} \le 5{,}000 \text{ kg/m}^2\text{s},$$
$$4\cdot 10^{-3} \text{ m} \le d \le 32\cdot 10^{-3} \text{ m}.$$

The critical vapor mass fraction of water is given by

$$\begin{aligned} \dot{x}_{cr} &= 10.795\, \dot{q}^{-0.125}\dot{m}^{-0.333} \cdot (d\cdot 1{,}000)^{-0.07} e^{0.01715p} && \text{Range of pressures } p \\ &&& 4.9-29.4 \text{ bar} \\ \dot{x}_{cr} &= 19.398\, \dot{q}^{-0.125}\dot{m}^{-0.333} \cdot (d\cdot 1{,}000)^{-0.07} e^{-0.00255p} && \\ &&& 29.4-98 \text{ bar} \\ \dot{x}_{cr} &= 32.302\, \dot{q}^{-0.125}\dot{m}^{-0.333} \cdot (d\cdot 1{,}000)^{-0.07} e^{-0.00795p} && \\ &&& 98-196 \text{ bar}. \end{aligned} \quad (4)$$

Equation (3) was checked by taking the difference between the calculated and the measured values of the critical vapor mass fraction [2]. The mean deviation was found to be −0.04; and the standard deviation, 0.10.

The application of the above equations presumes stable flow. If fluctuations occur in the mass flow rate, the boiling crisis may be triggered off at a much earlier stage.

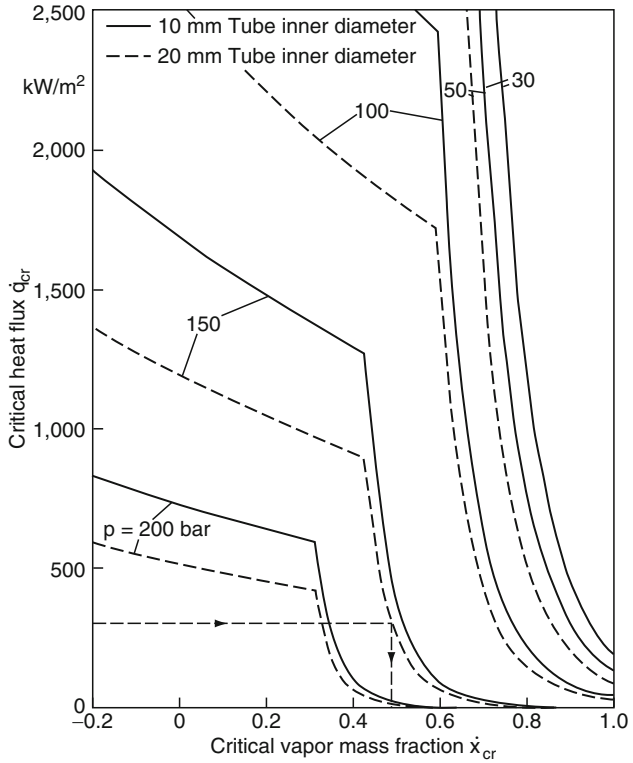
It can be seen in Fig. 3 that the curve obtained by plotting the critical heat flux against the vapor mass fraction has a much greater downward slope in the dryout range than in the range of film boiling. Hence the boundary between the two critical boiling mechanisms is the intersect of Eqs. (1) and (3). This implies that the critical heat flux must be calculated from both equations and that the lower value thus obtained should be taken.

Consequently, the decision can be made which form of boiling crisis – film boiling or dryout – is to be anticipated:

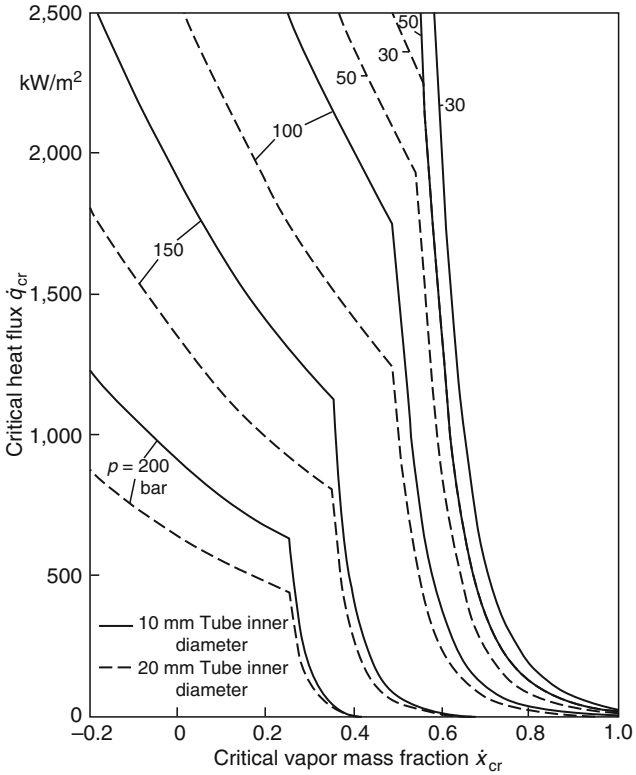
The value to be taken for $\dot{q}_{cr}$ is the lower of that obtained from Eq. (1) and that from Eq. (3).

Likewise, the value to be taken for $\dot{x}_{cr}$ is the lower of that obtained from Eq. (2) and that from Eq. (4).

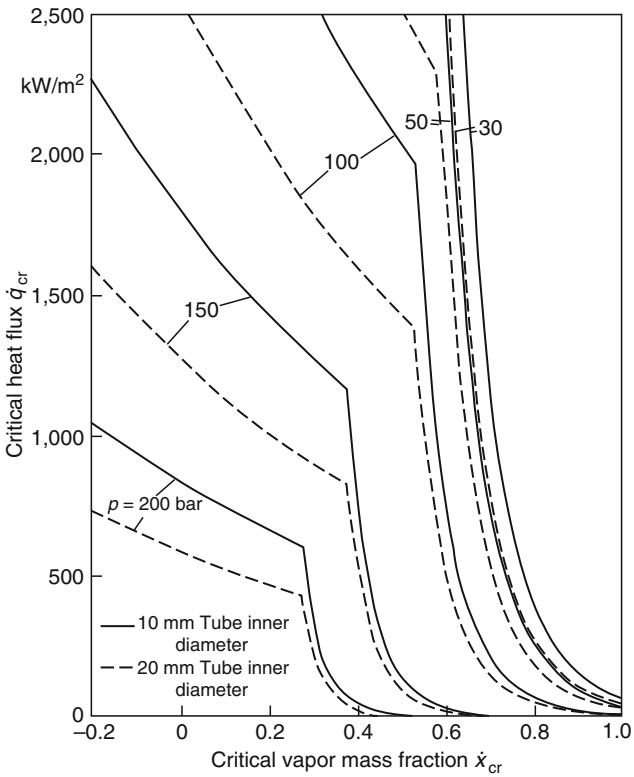
Diagrams are presented in Figs. 6–11 for the determination of the heat flux during the upward flow of water in vertical tubes of 10 and 20 mm diameter. The corresponding values for tubes



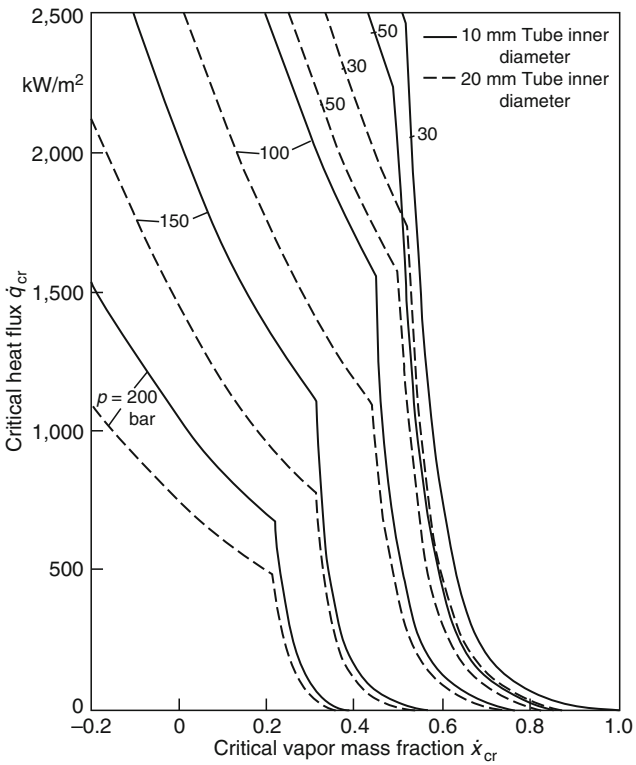
H3.5. Fig. 6. Critical heat flux as a function of the critical vapor mass fraction (mass velocity 500 kg/m^2 s).



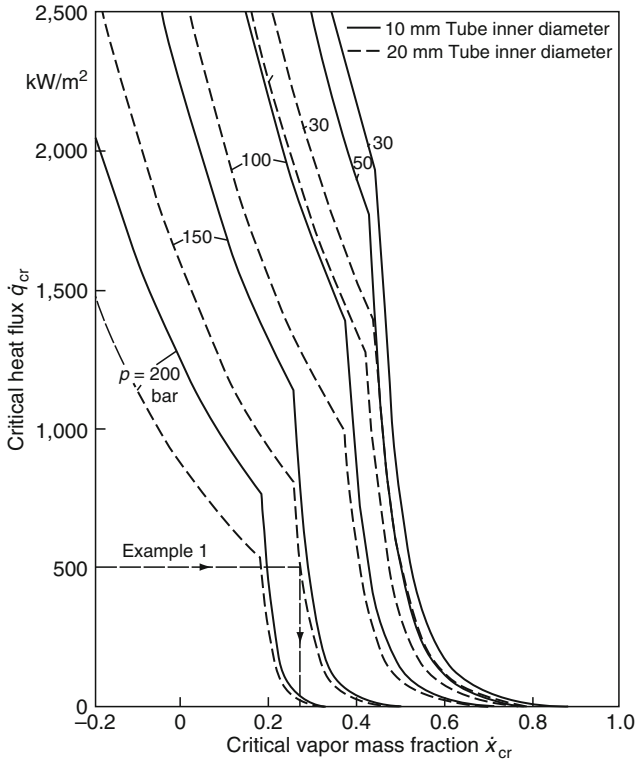
H3.5. Fig. 8. Critical heat flux as a function of the critical vapor mass fraction (mass velocity 1000 kg/m^2 s).



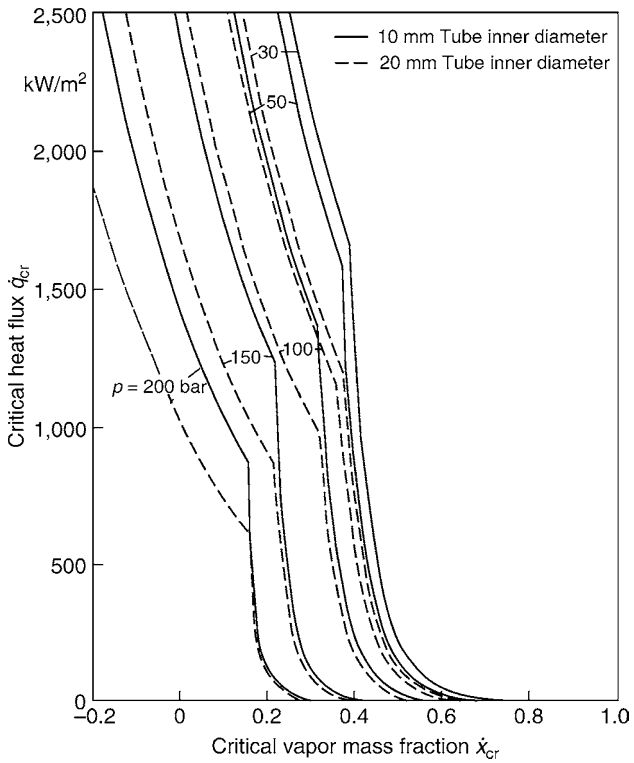
H3.5. Fig. 7. Critical heat flux as a function of the critical vapor mass fraction (mass velocity 750 kg/m^2 s).



H3.5. Fig. 9. Critical heat flux as a function of the critical vapor mass fraction (mass velocity 1,500 kg/m^2 s).



H3.5. Fig. 10. Critical heat flux as a function of the critical vapor mass fraction (mass velocity 2,500 kg/m^2 s).



H3.5. Fig. 11. Critical heat flux as a function of the critical vapor mass fraction (mass velocity 4,000 kg/m^2 s).

in the 4–25 mm diameter range can be obtained by interpolation or extrapolation.

For parameters within the domain

$$p < 29 \text{ bar},$$
$$\dot{m} < 500 \text{ kg/m}^2\text{s},$$

the combination of Eqs. (1) and (3) is not valid (Zone 1 in Fig. 5). In this case, the critical heat flux for $l/d > 80$ and $-0.5 < \dot{x}_{inl} < 0$ can be extracted from Table 1. Table 1 is an excerpt from "1995 Tables of Critical Heat Fluxes" developed by Groeneveld et al. [6]. Table 1 displays the critical heat flux in discrete steps of pressure, mass flux and critical vapor mass fraction for the parameter ranges considered here.

The table developed by Groeneveld et al. [6] is based upon approximately 23,000 values for upwards flow in vertical tubes covering the range of $1 \le p \le 200$ bar, $6 \le \dot{m} \le 8{,}000$ kg/m^{2}s, $-0.5 \le \dot{x}_{cr} \le 1.0$, $3 \cdot 10^{-3} \le d \le 40 \cdot 10^{-3}$ m and $80 \le l/d \le 2{,}485$. The accuracy of the table totaled to a RMS error of 7.8% and an average relative error of 0.69%. Only data incorporating a heated length to diameter ratio of greater than 80 was used to ensure that the underlying "local conditions hypothesis" is valid. This hypotheses assumes that the local values of the proper system parameters (p, $\dot{m}$, $\dot{x}_{cr}$, and d) explicitly determine the critical heat flux.

All of the values in Table 1 are valid for tubes with an inner diameter of 8 mm and can be adjusted to suit alternate diameters by applying Eq. (5a):

$$\frac{\dot{q}_{cr,d}}{\dot{q}_{cr,d=8\text{ mm}}} = \left(\frac{d}{8 \cdot 10^{-3}}\right)^{-0.5} \quad \text{for} \quad 3 \cdot 10^{-3}\text{ m} \le d \le 25 \cdot 10^{-3}\text{ m}$$
$$\frac{\dot{q}_{cr,d}}{\dot{q}_{cr,d=8\text{ mm}}} = 0.6 \quad \text{for} \quad 25 \cdot 10^{-3}\text{ m} < d \le 40 \cdot 10^{-3}\text{ m}. \tag{5a}$$

Parameters which are not explicitly tabulated in Table 1 may be linearly interpolated between the displayed values. Here it must be noted that the empty cells in Table 1 correspond to such highly subcooled fluid enthalpies that their respective values are smaller than at the point of freezing.

For smaller heated tube lengths that are in the range of $5 \le l/d < 80$, the heated length influences the critical heat flux, necessitating the correction of the values in Table 1 using the following method [7]:

$$\frac{\dot{q}_{cr,\,l/d<80}}{\dot{q}_{cr,\,l/d\ge 80}} = K_l \tag{5b}$$

with

$$K_l = \exp\left(\frac{d}{l} \cdot e^{2\cdot\varepsilon_{hom}}\right)$$

and the volumetric vapor fraction according to the homogenous model:

$$\varepsilon_{hom} = \frac{\rho_l \cdot \dot{x}}{\rho_l \cdot \dot{x} + \rho_g \cdot (1 - \dot{x})}. \tag{5c}$$

For very small mass fluxes ($\dot{m} \le 100$ kg/m^{2}s), the critical heat fluxes specified by *Groeneveld* are afflicted with certain uncertainties. This is because they are based upon comparatively smaller numbers of measured data [6]. For this reason, measurements by Köhler et al. [8] on an electrically heated tube at

H3.5. Table 1. Critical heat fluxes $\dot{q}_{kr}$ in (kW/m^2) for smaller pressures and mass fluxes acc. Groeneveld [6] for tubes with an inner diameter of 8 mm, $l/d \geq 80$

[a]Values required for interpolations within the range $0\,\mathrm{kg/m^2\,s} < \dot{m} \leq 50\,\mathrm{kg/m^2\,s}$ made available by [6,7]

pressures of 1 and 1.35 bar, mass fluxes from 5 to 40 kg/m^{2}s and heated length-to-diameter ratios of less than 80 are shown in Fig. 12. They are compared with values extracted from Table 1 and adjusted using Eqs. (5a) and (5b). Virtually all values lie within a tolerance of ±20%, which qualify as excellent on the grounds that the mass fluxes under investigation were extremely small. Hence, the values in Table 1 are verified for $\dot{m} \leq$ 100 kg/m^{2}s.

For practical purposes, it is easier on one hand to work with equations than with Table 1, which in most cases necessitates additional interpolation calculations. On the other hand, no approximation equations were put forward by *Groeneveld*. Therefore, extensive parameter variations for comparison of his tabulations [6] and the method acc. to Katto and Ohno [43] were undertaken. This method is introduced in Sect. 3.1.1. When applying Eqs. (26–42), it is necessary to use the physical properties for water and steam.

In the calculation of the critical heat flux for water, Fig. 13 compares the results of *Katto/Ohno* with those of Table 1 and Eq. (5b). The results are compared over a domain of $1 \leq p \leq 30$ bar, $5 \leq \dot{m} \leq 500$ kg/m^2 s and $38 \leq l/d \leq 700$ for an evaporator tube of $d = 8 \cdot 10^{-3}$ m. Over a wide range of parameters, excellent agreement is observed within a tolerance of −10% to +30%. Therefore, the method acc. to *Katto* and *Ohno* (Eqs. 26–42) can be applied for the approximation of the critical heat fluxes given in Table 1. However, it emerges from Fig. 13 that the values calculated by *Katto/Ohno* for pressures of 1–5 bar are on average higher than those in Table 1. Therefore, for security relevant considerations in the range of smaller pressures and mass fluxes, it is prudent to use the values in Table 1 and adjust the results using Eqs. (5a) and (5b) as necessary.
For parameters within the range

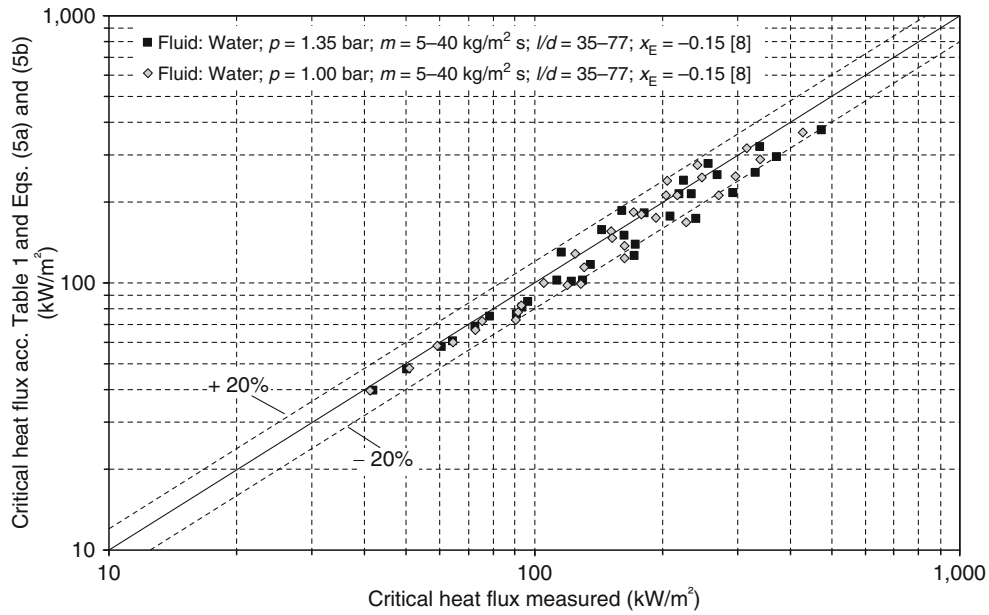
$$29 \leq p \leq 200\,\text{bar},$$
$$\dot{m} < 500\ \text{kg/m}^2\text{s},$$

i.e., for higher pressures coupled with smaller mass fluxes (Zone 2 in Fig. 5) the combination of Eqs. (1) and (3) is not valid. In this case, the procedure developed by *Katto/Ohno* [43] (Eqs. 26–42) can be applied for $l/d > 5$ and $-0.5 < \dot{x}_{\text{inl}} < 0$ to approximate the critical heat fluxes given in the tables developed by Groeneveld [6]. For evaporator tubes with $d = 8 \cdot 10^{-3}$ m, the critical heat fluxes calculated by *Katto/Ohno* and the values given in the *Groeneveld* tables are in very good agreement. Results lie within a tolerance of ±30% over the domain $50 \leq p \leq 200$ bar, $20 \leq \dot{m} \leq 500$ kg/m^2 s and $12 \leq l/d \leq 700$.
For parameters within the range

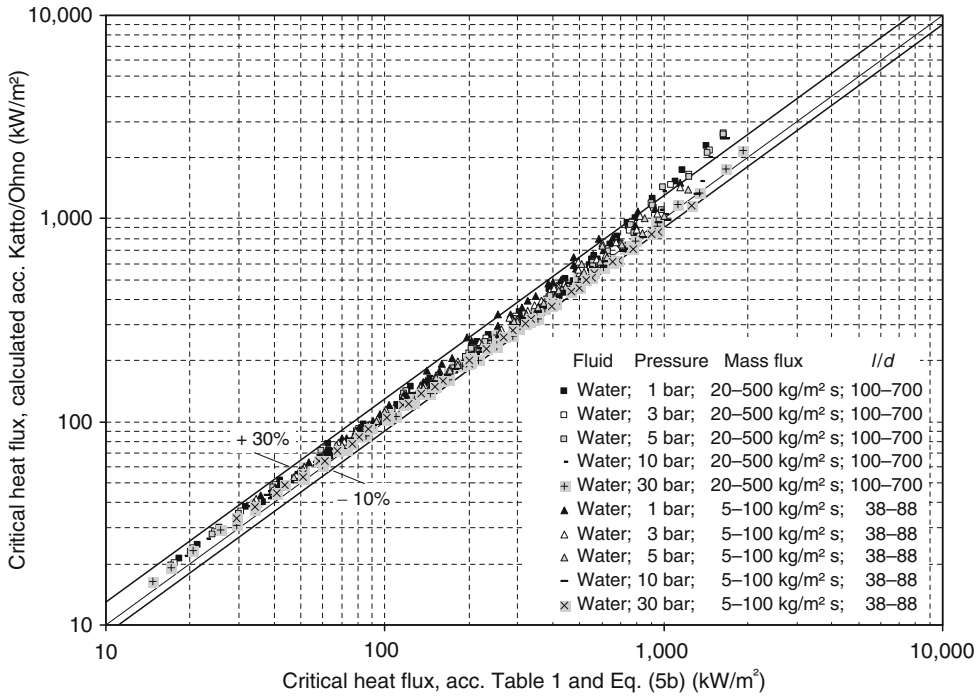
$$p < 29\ \text{bar},$$
$$\dot{m} \geq 500\ \text{kg/m}^2\text{s},$$

i.e., for smaller pressures coupled with higher mass fluxes (Zone 4 in Fig. 5) the combination of Eqs. (1) and (3) is likewise invalid. For $l/d > 100$ und $-0.5 < \dot{x}_{\text{inl}} < 0$, the procedure developed by Katto and Ohno [43] (Eqs. 26–42) can also be applied to approximate the critical heat fluxes given in the tables developed by Groeneveld [6]. For evaporator tubes of $d = 8 \cdot 10^{-3}$ m, the equations developed by *Katto/Ohno* for the critical heat flux and the values in the *Groeneveld* tables are in good agreement. Results lie within a tolerance of ±30% for the parameter range $1 \leq p \leq 30$ bar, $500 \leq \dot{m} \leq 4{,}000$ kg/m^{2}s and $100 \leq l/d \leq 700$. Stronger scattering may develop when water-steam flow of smaller pressures take on higher mass fluxes approaching the speed of sound (at the corresponding critical vapor mass fraction). This makes both the occurrence and therefore the forecasting of a critical heat flux impossible.

Consequently, there exists a complete calculation method for the determination of the critical heat flux for upwards flows through vertical tubes. This is applicable over a wide range of parameters, i.e. pressures from 1 to 200 bar and mass fluxes from 5 to 5,000 kg/m^2 s (refer to Fig. 5).



H3.5. Fig. 12. Comparison of measured critical heat fluxes and the values of Table 1 (acc. *Groeneveld* [6]) for water.



H3.5. Fig. 13. Comparison of critical heat fluxes acc. *Katto/Ohno* [43] and the values of Table 1 (acc. *Groeneveld* [6]) for water.

Figure 14 shows the critical heat fluxes determined from the *Groeneveld* tables [6] and Eqs. (1) and (3) at the transition from Zone 2 to 3 and from 3 to 4. As an example, subcooled-water with an equilibrium vapor mass fraction of −0.20 flows into a 20 mm inner diameter evaporator tube. It is heated over the length of 6 and 10 m (top and bottom diagrams respectively in Fig. 14).

Concerning the transition from Zone 2 to 3 (left diagrams), the heat flux is plotted for pressures of 30, 100, 150, and 200 bar, respectively, at the limiting mass flux of 500 kg/m^2 s. The point of intersection with each straight heat balance line gives the heat flux for which the boiling crisis is initiated exactly at the tube exit. The heat balance lines describe the linear relationship between the heat flux and the vapor mass fraction at the exit of a uniformly heated tube. There are small relative deviations from +1.3% to +16.7%, a larger relative deviation of +27.6% becoming evident only at 200 bar and l/d = 500 where the critical heat fluxes are small. The relative deviations are defined to be between the respective heat fluxes at the points of their intersection with the heat balance lines. Only the values which lie along these lines explicitly correspond to the system defined by the parameters (l, d, $\dot{x}_{\mathrm{inl}}$, p, $\dot{m}$) and the condition (*boiling crisis directly at the tube exit*).

Regarding the transition from Zone 3 to 4 (right diagrams), the heat flux is plotted for 500, 1,500, and 4,000 kg/m^2 s, respectively, at a pressure of 30 bar, together with the heat balance lines. Here also, there are small relative deviations from −10.8% to +10.6%. Additionally, the parameter combination of 200 bar and 4,000 kg/m^2 s is illustrated in these diagrams (bold text in legend; lines with triangle symbols). Large relative deviations of +36.7% and +61.9% becoming evident at the heated length of 6 and 10 m, respectively. This fact shows that when higher pressures are coupled with higher mass fluxes (Zone 3 in Fig. 5) the calculation by *Doroshchuk* and *Kon'kov* produces considerably conservative values and should therefore be retained – especially for security relevant considerations.

Example 1

Water at saturation enters an evaporator tube that is uniformly heated in the axial direction. At what point in the tube does the boiling crisis occur?

Tube inner diameter $d = 20 \cdot 10^{-3}$ m
Length of tube $l = 8$ m
Pressure $p = 150$ bar
Mass flow rate $\dot{M} = 0.8$ kg/s
Heat flow rate $\dot{Q} = 250$ kW

Determination of heat flux

$$\dot{q} = \frac{\dot{Q}}{d\pi l} = \frac{250\ \mathrm{kW}}{\pi \cdot 0.02\ \mathrm{m} \cdot 8\ \mathrm{m}} = 497.4\ \mathrm{kW/m^2}.$$

Determination of mass velocity

$$\dot{m} = \frac{4\dot{M}}{\pi d^2} = \frac{4 \cdot 0.8\ \mathrm{kg/s}}{4 \cdot 10^{-4}\pi\ \mathrm{m^2}} = 2546.5\ \mathrm{kg/m^2\,s}.$$

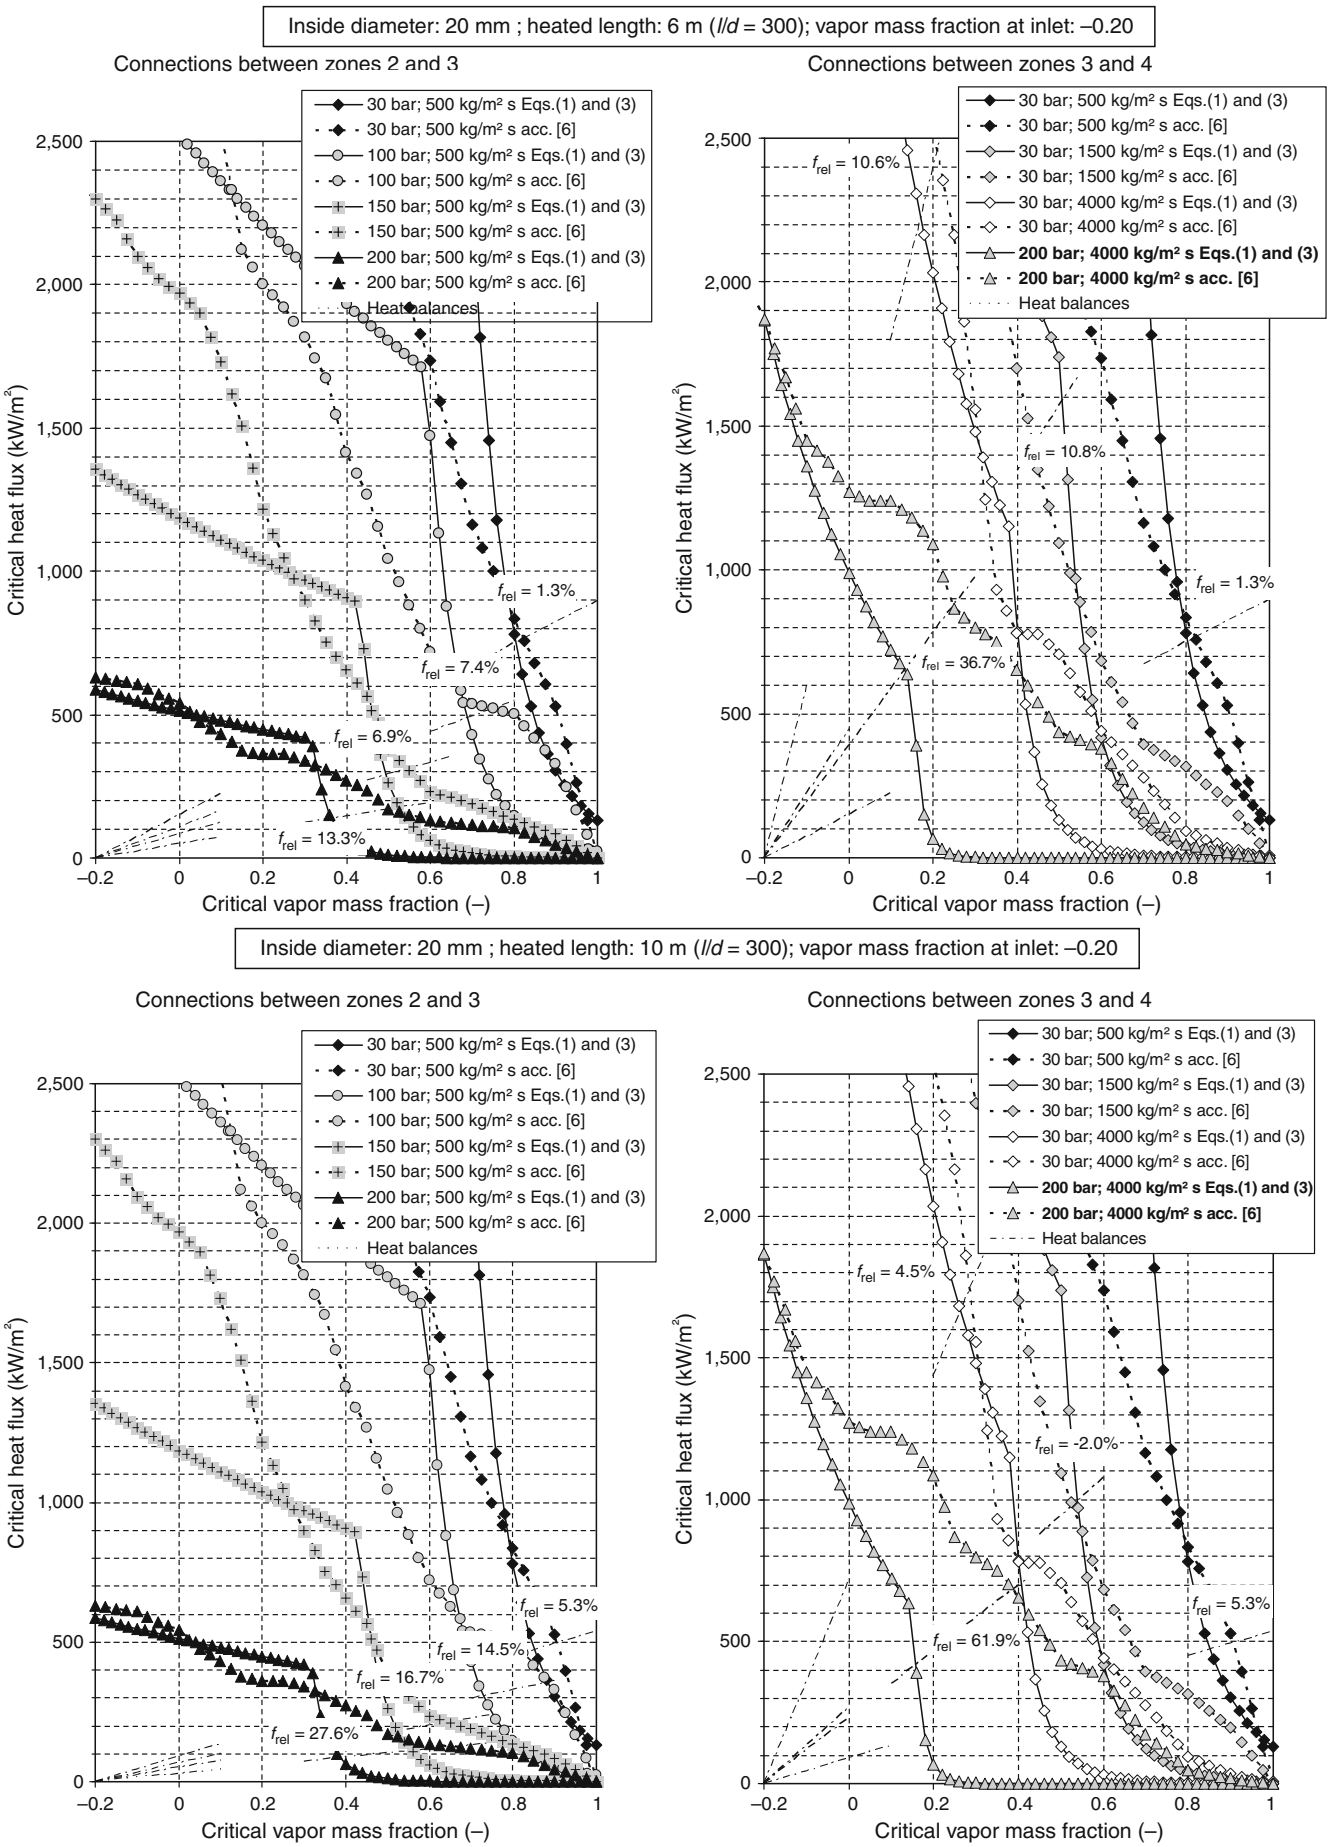
A comparison of Fig. 10 with Fig. 3 reveals that the boiling crisis for these parameters is attained by dryout of the heated surface. Hence, the critical vapor mass fraction should be determined from Eq. (4). The figure thus obtained is $\dot{x}_{\mathrm{cr}} = 0.269$. It must now be checked whether the boiling crisis is actually attained by dryout. Thus, substituting $\dot{x}_{\mathrm{cr}} = 0.269$ for $\dot{x}$ in Eq. (1) gives

$$\dot{q}_{\mathrm{cr}} = 767\ \mathrm{kW/m^2} > 497.4\ \mathrm{kW/m^2}.$$

that is, the assumption is confirmed.

The critical vapor mass fraction is attained at the point z. Since $\pi dzq = M(\dot{x}_{\mathrm{cr}} - \dot{x}_{\mathrm{inl}})$ and $\dot{x}_{\mathrm{inl}} = 0$,

$$z = \frac{\dot{M}\dot{x}_{\mathrm{cr}}\Delta h_{\mathrm{v}}}{d\pi\dot{q}} = \frac{0.8\ \mathrm{kg/s} \cdot 0.269 \cdot 1{,}004\ \mathrm{kJ/kg}}{0.02\pi\ \mathrm{m} \cdot 497.4\ \mathrm{kW/m^2}} = 6.91\ \mathrm{m}.$$



H3.5. Fig. 14. Transition between the individual zones.

Example 2

A straight vertical tube with an inner diameter of 12 mm and a length of 1.0 m is uniformly, electrically heated. Water flows through the tube at 300 kg/m^2 s, 0.3 MPa (3 bar) and $\vartheta_{inl} = 100°C$. At what heat flux does the boiling crisis occur?

The vapor mass fraction at the inlet $\dot{x}_{inl}$ is given by:

$$\dot{x}_{inl} = \frac{h_{inl} - h'}{\Delta h_v} = \frac{419.0 - 561.2}{2161.9} = -0.066.$$

In other words, the water is subcooled when it enters the tube. The critical heat flux at the upper end of the tube is determined below.

The relevant parameters are located in Zone 1 of Fig. 5. Hence, the critical heat flux can be extracted from Table 1 and converted for the actual diameter using Eq. (5a). The heated length to inner diameter ratio is given by:

$$\frac{l}{d} = \frac{1.0}{12 \cdot 10^{-3}} = 83.3 > 80$$

Equation (5b) must not be applied in this case because the ratio is greater than 80.

The critical heat flux is dependant upon the vapor mass fraction, which at the upper end of the tube is in turn dependant on the adjusted heat flux. Therefore, the solution can only be found using iteration. This is completed with the use of an energy balance:

$$\dot{q} \cdot \pi \cdot d \cdot l = \dot{m} \cdot \frac{\pi}{4} \cdot d^2 \cdot (\dot{x}_{out} - \dot{x}_{inl}) \cdot \Delta h_v,$$

solving for $\dot{x}_{out}$:

$$\dot{x}_{out} = \frac{\dot{q} \cdot 4 \cdot l}{\dot{m} \cdot d \cdot \Delta h_v} + \dot{x}_{inl}.$$

The vapor mass fraction at the tube outlet is determined for a range of heat fluxes. Values of the critical heat flux corresponding to these vapor mass fractions are then extracted from Table 1. For 3 bar, 300 kg/m^2 s and a vapor mass fraction of, for example, 0.4, a value of 1,636 kW/m^2 can be read from Table 1. Since $d < 25$ mm, this value is then converted to suit the actual diameter using Eq. (5a):

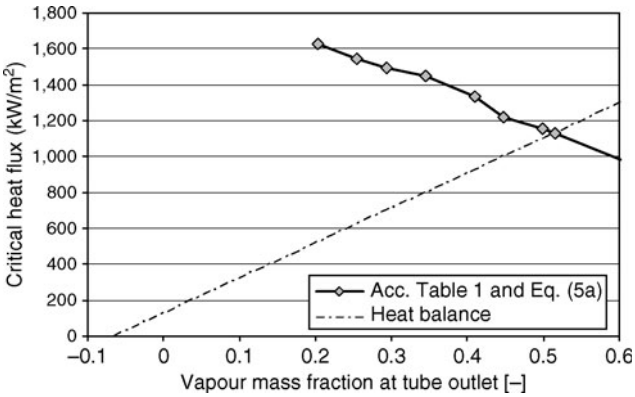
$$\dot{q}_{cr,d=12\text{ mm}} = \dot{q}_{cr,d=8\text{ mm}} \cdot \left(\frac{12}{8}\right)^{-0.5}$$
$$= 1636 \cdot 1.5^{-0.5}\ \text{kW/m}^2 = 1335.8\ \text{kW/m}^2$$

The following table of values is obtained by varying the value of the heat flux:

$\dot{q}$ (kW/m^2)	$\dot{x}_{out}$ (–)	$\dot{q}_{cr,d=8\text{ mm}}$ from Table 1 (kW/m^2)	$\dot{q}_{cr,d=12\text{ mm}}$ using Eq. (5a) (kW/m^2)
525	0.20	1,995	1628.9
625	0.26	1,895	1547.3
700	0.30	1,828	1492.6
800	0.35	1,771	1446.0
925	0.41	1,636	1335.8
1,000	0.45	1,494	1219.8
1,100	0.50	1,418	1157.8
1,131	0.52		1130.6[a]
1,300	0.60	1,203	982.2

[a]Interpolated

Plotted versus $\dot{x}_{out}$, the solution is located at the intersection of the energy balance line with $\dot{q}_{cr,d=12\text{ mm}}$:



The critical heat flux is 1,131 kW/m^2.

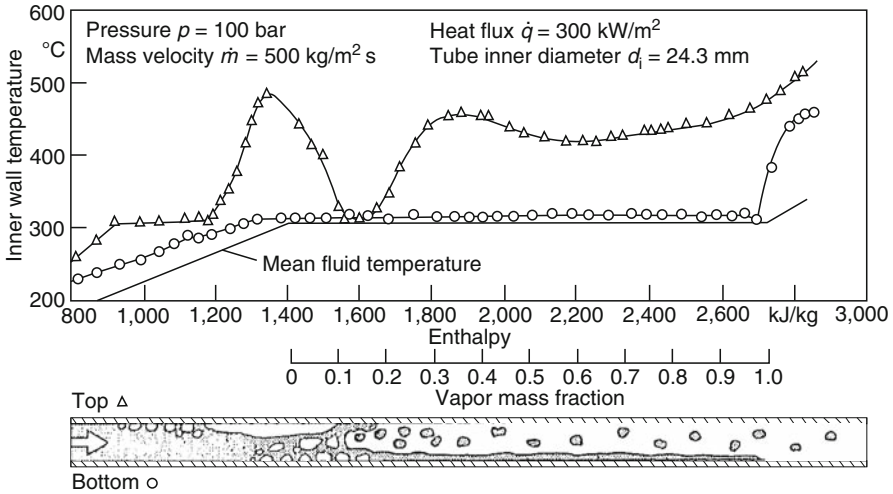
2.1.2 Horizontal and Inclined Tubes

Owing to the phase separation caused by gravity, the vapor mass fractions at which the boiling crisis occurs are lower in horizontal and inclined tubes than they are in vertical tubes. In most cases, the crisis sets in at the crest of the tube while the lower wall remains wetted. An example of a temperature profile in a horizontal, uniformly heated evaporator tube is presented in Fig. 15. It differs from that in a vertical tube uniformly heated in the axial direction. In the vertical tube, the boiling crisis usually commences at the tube outlet and migrates upstream when more heat is applied. In the example shown in Fig. 15 for a horizontal tube, the boiling crisis already occurs at low vapor mass fractions and disappears again downstream. The incipient boiling crisis in this example can be explained by the transition from nucleate to stratified flow, in which case the crest of the tube may dry out.

As the vapor mass fraction and thus the rate of mixing increase, the crest of the tube is rewetted. This can be ascribed to a change from stratified to slug or annular flow. In the latter case, the film on the crest of the tube is thinner than that on the underside. Consequently, the dryout that results when the water film evaporates commences at the crest of the tube. As can be seen in Fig. 15, very large differences may exist between the vapor mass fractions at the first and last occurrences of the boiling crisis. The higher the ratio of the force of gravity to the forces applied during turbulent mixing, the greater the difference between flow in horizontal tubes to that in vertical tubes. The ratio increases if the specific mass flow rate is reduced or the tube diameter is increased. If the mass velocity is higher than 4,000–6,000 kg/m^2 s, the inclination of the tube no longer has any effect on the point at which the boiling crisis occurs.

Published comparisons between vertical and inclined tubes [9–12] are mostly based on measurements performed within a narrow range of parameters. Extensive measurements on evaporator tubes were made by Kefer [13]. The effect of the inclination of the tubes is described qualitatively in Fig. 16.

The following procedure is recommended for estimating the effect of inclination on the occurrence of the boiling crisis.



H3.5. Fig. 15. Effect of gravity on heat transfer in horizontal tubes.

It was derived from a suggestion by Wallis [87] to the effect that stratification during two-phase flow in a horizontal tube could be represented by a dimensionless group, in which the inertia force is the numerator and the buoyancy of the vapor is the denominator. Together with the vapor mass fraction $\dot{x}_{cr}$ at which the boiling crisis would occur in vertical tubes (cf. Sect. 2.1.1), this characteristic forms the following modified Froude number:

$$Fr = \frac{\dot{x}_{cr}\dot{m}}{\sqrt{gd(\varrho' - \varrho'')\cos\varphi}} \qquad (6)$$

where φ is the angle of inclination of the tube to the horizontal.

If the numerical value of Fr obtained from this equation is higher than $Fr = 10$, the angle of inclination of the tube has practically no effect on the boiling occurrence. Very pronounced stratification effects can be anticipated if $Fr < 3$. The boiling crisis occurs on the crest of horizontal tubes at very low vapor mass fractions, whereas the underside remains wetted until the liquid has almost completely evaporated.

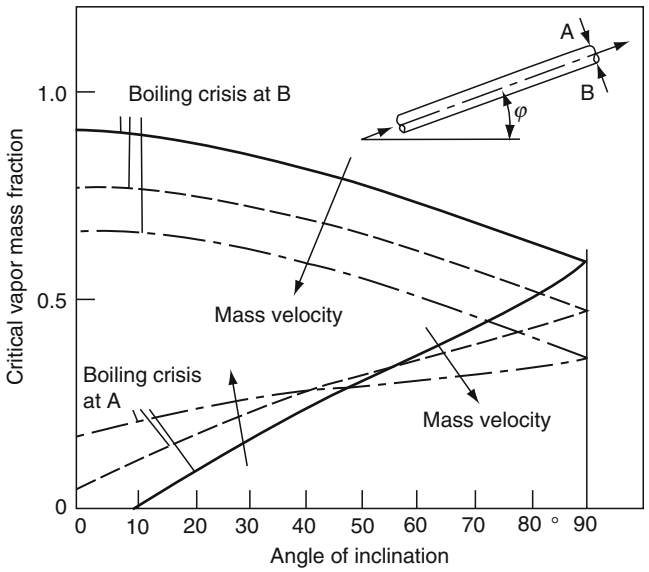
According to Kefer [13], the difference between the critical vapor mass fraction at the crest and that at the underside of horizontal tubes can be determined with the aid of the modified Froude number defined by Eq. (6). The equation that he suggested is

$$\Delta\dot{x}_{cr} = \dot{x}_{cr,low} - \dot{x}_{cr,up} = \frac{16}{(2 + Fr)^2}. \qquad (7)$$

It has been checked that Eq. (7) covers the following ranges of parameters:

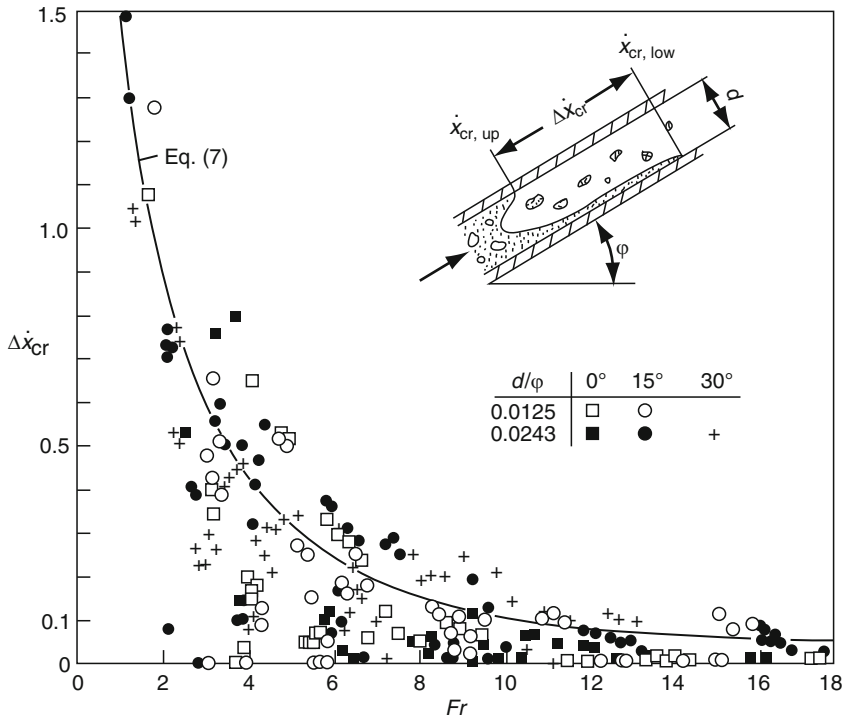
$$25 \le p \le 200 \text{ bar}$$
$$500 \le \dot{m} \le 2{,}500 \text{ kg/m}^2\text{s}$$
$$200 \le \dot{q} \le 600 \text{ kW/m}^2.$$

It can be seen from Fig. 17 that the figures calculated from Eq. (7) for various angles of inclination agree well with measured values. The diagram also shows that stratification effects become much more pronounced and that the measured values are more scattered if the value of Fr is reduced to below 4–5. For this reason, it is recommended that Froude numbers higher than $Fr = 10$ should be selected in order to avoid stratification.

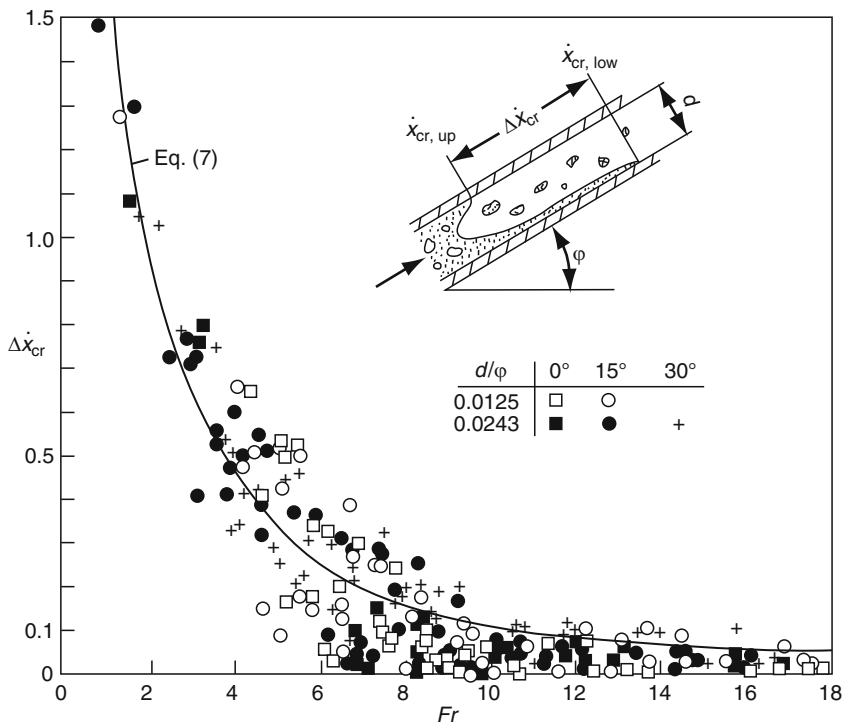


H3.5. Fig. 16. Effect of the angle of inclination on the critical vapor mass fraction.

Figure 18 shows that even better agreement can be obtained between the figures calculated from Eq. (7) and measured values. The improvement is achieved by inserting an average value for $\dot{x}_{cr}$ in Eq. (6) for the determination of the modified Froude number. The average in this case is that derived from the measured values for the critical vapor mass fractions responsible for dryout at the crest and underside respectively of the tube. In other words, the value inserted for $\dot{x}_{cr}$ in Eq. (6) can be regarded as the mean vapor mass fraction at which the crest and underside of the tube dry out. Thus, the critical vapor mass fractions in horizontal and inclined tubes are given by



H3.5. Fig. 17. Difference between the critical vapor mass fraction during dryout on the crest and that during dryout on the underside of a horizontal or inclined tube {*Fr* calculated from Eq. (6) with values of $\dot{x}_{cr}$ obtained as described in Sect. 2.1.1}.



H3.5. Fig. 18. Difference between the critical vapor mass fraction during dryout on the crest and that during dryout on the underside of a horizontal or inclined tube {*Fr* calculated from Eq. (6) with values of $\dot{x}_{cr}$ obtained from measurements}.

$$\dot{x}_{cr,up} = \dot{x}_{cr} - \frac{\Delta\dot{x}_{cr}}{2},$$
$$\dot{x}_{cr,low} = \dot{x}_{cr} + \frac{\Delta\dot{x}_{cr}}{2}. \quad (8)$$

If the value calculated for $\dot{x}_{cr,low}$ is higher than unity, the figure to be taken is $\dot{x}_{cr,low} = 1$.

Initiation of the boiling crisis in horizontal tubes is associated with a slight rise in temperature, which is not the case

during flow through vertical tubes. One of the reasons for this lower increase is the flow of heat in the tube wall from the unwetted crest to the wetted underside.

Example 3

Determine the critical vapor mass fraction at the crest and underside of a horizontal evaporator tube through which water flows.

Parameters

Inner diameter of tube $d = 20 \cdot 10^{-3}$

Pressure $p = 150$ bar

Mass velocity $\dot{m} = 500$ kg/m^2 s

Heat flux $\dot{q} = 300$ kW/m^2

According to Fig. 6, the critical vapor mass fraction for upward flow through a vertical tube is $\dot{x}_{cr} = 0.49$. The densities for the vapor and the water at 150 bar are $\varrho'' = 96.71$ kg/m^3 and $\varrho' = 603.17$ kg/m^3 respectively.

The Froude number determined from Eq. (6) is

$$Fr = \frac{\dot{x}_{cr}\dot{m}/\sqrt{\varrho''}}{\sqrt{gd(\varrho' - \varrho'')\cos\varphi}} = \frac{0.49 \cdot 500/\sqrt{96.71}}{\sqrt{9.81 \cdot 20 \cdot 10^{-3}(603.17 - 96.71)1}} = 2.50.$$

The difference between the critical vapor mass fraction during dryout at the crest and that at the underside is obtained as follows from Eq. (7):

$$\Delta\dot{x}_{cr} = \frac{16}{(2 + Fr)^2} = \frac{16}{(2 + 2.50)^3} = 0.79.$$

Thus the critical vapor mass fractions during dryout at the crest and the underside respectively of the evaporator tube are obtained as follows from Eq. (8):

$$\dot{x}_{cr,up} = \dot{x}_{cr} - \frac{\Delta\dot{x}_{cr}}{2} = 0.49 - \frac{0.79}{2} = 0.095,$$

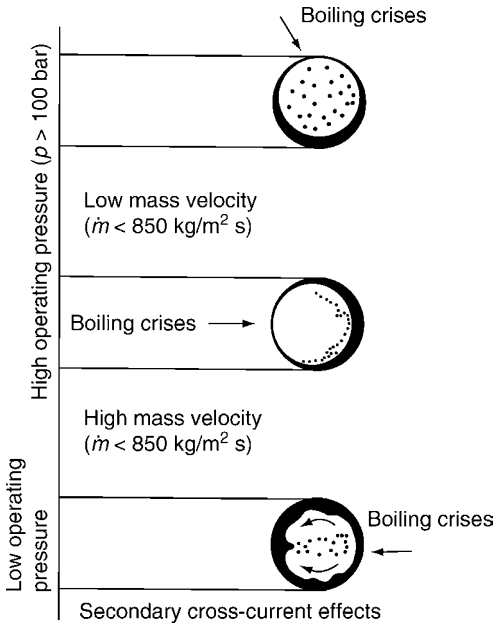
$$\dot{x}_{cr,low} = \dot{x}_{cr} + \frac{\Delta\dot{x}_{cr}}{2} = 0.49 + \frac{0.79}{2} = 0.885.$$

In this case, the boiling crisis at the crest occurs at very low vapor mass fractions, whereas the underside remains wetted until the liquid has almost completely evaporated.

2.1.3 Helical Coils

Flow patterns in coiled or bent tubes are formed by buoyancy, centrifugal forces, and secondary cross-flows caused by pressure gradients perpendicular to the main direction of flow. The boiling crisis is affected by separation effects that depend on the geometry of the helical coil. In analogy to the case in horizontal tubes (cf. Sect. 2.1.2), initial and final boiling crises, that is, first and last occurrences, can be observed.

It is demonstrated schematically in Fig. 19 that, at elevated operating pressures ($p > 100$ bar), the boiling crisis in a helical coil with a vertical axis is mainly influenced by the mass velocity. The centrifugal forces that arise at $\dot{m} > 850$ kg/m^3 s crowd the liquid toward the outside of the coil, and the boiling crisis occurs on the inside [14,60]. At low mass fluxes, the force of



H3.5. Fig. 19. Location of the flow boiling crisis in coiled tubes [60].

gravity predominates, and the boiling crisis thus occurs initially at the upper end of the coil. At low operating pressures and high mass velocity, secondary cross-flows transport the liquid phase from the outside to the inside of the coil; in this case, the initial boiling crisis is mainly observed on the outside of the coil.

The boiling crisis in coiled tubes has not been the subject of many experimental and theoretical studies, and the data that can be found on the subject in the literature are scanty [14–23]. Ünal [14,20] performed experiments with the following operating parameters:

$$0.44 < p/p_c = p_r < 0.92,$$

$$100 \text{ kg/m}^2\text{s} < \dot{m} < 3{,}500 \text{ kg/m}^2\text{s},$$

$$0.08 < \dot{x}_{cr} < 1.0 \text{ and}$$

$$38 < D_w/d < 90.$$

He thus derived the following empirical correlation for the critical vapor mass fraction and the points in the coil at which it occurred:

$$\dot{x}_{cr} = 3.88 K_h K_p K_D K_\delta K_m + \dot{x}_{inl} \quad (9)$$

where

$$K_h = 1 + 3.8(1 - h_{inl}/h')$$

$$K_p = 0.114 - 0.041 \ln(1 - p_r)$$

$$K_D = 1 + 0.44 \exp(-0.056\, D_w/d)$$

(for the first boiling crisis)

$$K_D = 1 + 0.56 \exp(-0.011\, D_w/d)$$

(for the last boiling crisis)

$$K_\delta = \left(\frac{2\delta}{d}\right)^{0.32},$$

$$K_m = \frac{\left(\frac{l_{cr}}{d}\right) + 4.59\left(\frac{l_{cr}}{d}\right)^{-0.2}}{\left(\frac{l_{cr}}{d}\right) + 28 Fr^{0.44}}.$$

The location of the boiling crisis within the coil can be calculated from the heat balance, that is,

$$\frac{l_{cr}}{d} = \frac{\dot{m}\Delta h_v}{4\dot{q}}(\dot{x}_{cr} - \dot{x}_{inl}). \quad (10)$$

By definition, the Froude number is given by $Fr = \dot{m}/(\varrho'\sqrt{gd})$.

The critical vapor mass fraction $\dot{x}_{cr}$ at the point l_{cr} where the boiling crisis occurs is determined by iteration. The first approximations for $\dot{x}_{cr}$ and l_{cr} in the iteration can be obtained from Eqs. (9) and (10). It is evident from Eq. (9) that the effect of the factor D_w/d on $\dot{x}_{cr}$ can be neglected if $D_w/d > 40$.

Equation (9) is not valid for operating parameters in the following ranges:

$$p < 5 \text{ bar}$$
$$\dot{m} < 500 \text{ kg/m}^2\text{s}$$
$$80 < l/d < 250$$
$$10 < D_w/d < 20$$
$$-0.25 < \dot{x}_{inl} < 0,$$

An empirical equation that can be resorted to for calculating the final boiling crisis when these parameters apply is that derived by Babarin [22] and Alad'yev [23], that is,

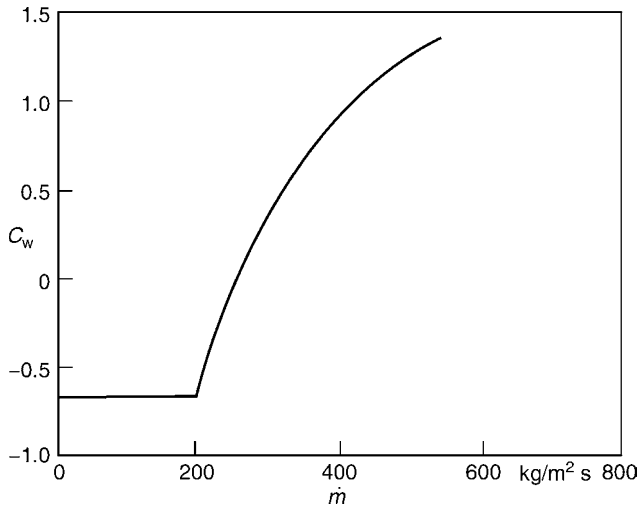
$$\dot{q}_{cr} = k\left(\frac{\dot{m}}{l/d}\right)^{0.9}[1 + C_w(0.75 + \dot{x}_{inl})] \quad (11)$$

The numerical value of the factor k in this equation is 585 for water. The relationship between the factor C_w and the mass velocity $\dot{m}$ is shown in Fig. 20, which was plotted from the following points:

$\dot{m}$ (kg/m^2 s)	50–200	300	400	500
C_w	−0.660	0.395	0.925	1.270

Example 4

Water flows at a rate of 250 kg/m^2 s, a pressure of 0.3 MPa (3 bar), and a temperature of ϑ_{int} = 100°C through an electrically heated, coiled tube of 12 mm inner diameter and 1.0 m length. Determine the heat flux at which the boiling crisis occurs in the tube.



H3.5. Fig. 20. C_w factor in Eq. (11) as a function of the mass velocity $\dot{m}$.

The inlet vapor mass fraction is

$$\dot{x}_{inl} = \frac{h_{inl} - h'}{\Delta h_v} = \frac{419.0 - 561.2}{2161.9} = -0.066.$$

The critical heat flux, as determined from Eq. (11), is

$$\dot{q}_{cr} = 585\left(\frac{250}{83.3}\right)^{0.9}[1 - 0.06(0.75 - 0.066)] \text{ kW/m}^2$$
$$= 1{,}510 \text{ kW/m}^2.$$

Example 5

An evaporator heated by a helical coil is operated at a system pressure of 16.0 MPa (160 bar). The outer diameter of the coil is D_{wo} = 1.8 m; and the inner diameter, D_{wi} = 0.63 m. The outer diameter of the coiled tube is d_o = 0.022 m; and the inner diameter, d = 0.016 m. The water enters at a temperature of ϑ_{in} = 300°C and a mass velocity of $\dot{m}$ = 1,500 kg/m^2 s. It is assumed that the heat flux remains constant at $\dot{q}$ = 600 kW/m^2 over the entire length of the coil. Determine the location of the points at which the first and the last boiling crises occur within the inner and outer coils.

Applying Eq. (9) gives

$$K_h = 1 + 3.8\left(1 - \frac{1336.7}{1648.5}\right) = 1.719;$$

$$K_p = 0.114 - 0.041 \ln\left(1 - \frac{160}{221.3}\right) = 0.166;$$

$$K_\delta = \left(\frac{2 \cdot 0.003}{0.016}\right)^{0.32} = 0.731;$$

$$\dot{x}_{inl} = \frac{1336.7 - 1648.5}{929.9} = -0.335$$

$$Fr = \frac{1500}{583.8\sqrt{9.8065 \cdot 0.016}} = 6.486.$$

(a) Outer coil (D_{wo} = 1.8 m)

The following applies for the first boiling crisis:

$$K_D = 1 + 0.44 \exp\left(-0.056\frac{1.8}{0.016}\right) = 1.0008 \approx 1.0;$$

and the following applies for the last boiling crisis:

$$K_D = 1 + 0.56 \exp\left(-0.011\frac{1.8}{0.016}\right) = 1.162.$$

As a first approximation, $\dot{x}_{cr}$ = 0.4. Applying Eq. (10) gives

$$l_{cr} = \frac{1500 \cdot 929.9}{4 \cdot 600}(0.4 + 0.335) = 427.2.$$

The next step is to determine K_m. Thus

$$K_m = \frac{427.2 + 4.59(427.2)^{-0.2}}{427.2 + 28 \cdot 6.486^{0.44}} = 0.873.$$

It then follows from Eq. (9) that

$$x_{cr} = 3.88 \cdot 1.719 \cdot 0.166 \cdot 1 \cdot 0.731 \cdot 0.873 - 0.335 = 0.372.$$

Repeating the calculation with $\dot{x}_{cr} = 0.37$ gives

$$\dot{x}_{cr} = 0.367; \quad l_{cr} = 6.53 \text{ m}.$$

Determination of the final boiling crisis

A value of $\dot{x}_{cr} = 0.367 \cdot 1.162/1.0 \approx 0.43$ is taken as a first approximation for the iteration, and the calculation then proceeds in the same way as that for the first boiling crisis. Thus

$$\frac{l_{cr}}{d} = \frac{1500 \cdot 929.9}{4 \cdot 600}(0.43 + 0.335) = 444.6;$$

$$K_m = \frac{444.6 + 4.59(444.6)^{-0.2}}{444.6 + 28 \cdot 6.486^{0.44}} = 0.877;$$

$\dot{x}_{cr} = 3.88 \cdot 1.719 \cdot 0.166 \cdot 1.162 \cdot 0.731 \cdot 0.877 - 0.335 = 0.49$. The calculation is repeated with the new value for the critical vapor mass fraction, and the following is obtained after two iteration stages:

$$\dot{x}_{cr} = 0.478; \quad l_{cr} = 7.75 \text{ m}.$$

(b) Inner coil ($D_w = 0.63$ m)

The procedure for determining the first boiling crisis is similar to that adopted under heading (a) for the outer coil. Thus

$$K_D = 1 + 0.44 \exp\left(-0.056 \cdot \frac{0.63}{0.016}\right) = 1.048.$$

Likewise, for the final boiling crisis,

$$K_D = 1 + 0.56 \exp\left(-0.011 \cdot \frac{0.63}{0.016}\right) = 1.363.$$

Determination of the first boiling crisis

In view of the results obtained for the outer coil, the first approximation to be taken for the iteration is $\dot{x}_{cr} = 0.367 \cdot 1.048 = 0.38$, and the desired root is again obtained in two stages, that is,

$$\dot{x}_{cr} = 0.385; \quad l_{cr} = 6.88 \text{ m}.$$

Determination of the final boiling crisis

The first approximation made in this case is

$$\dot{x}_{cr} = 0.478 \cdot \frac{1.363}{1.162} \approx 0.56.$$

The following figures are obtained after three stages in the iteration:

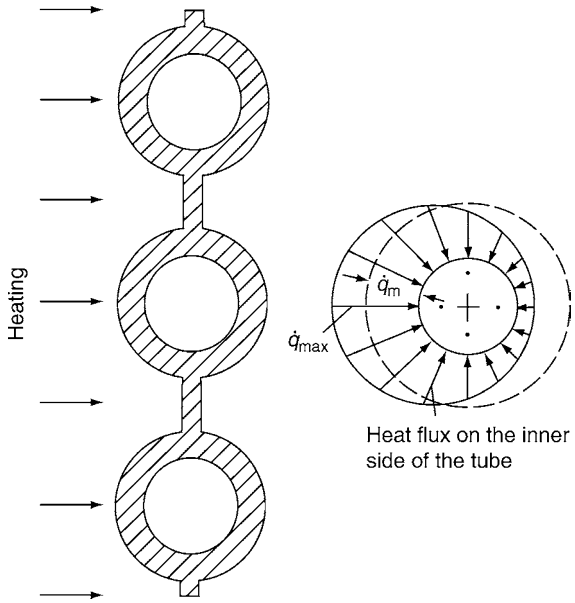
$$\dot{x}_{cr} = 0.640; \quad l_{cr} = 9.25 \text{ m}.$$

For the purpose of the calculation, the pressure drop in the coil is neglected. The values for the properties of the fluid can be referred to the system pressure of 16.0 MPa.

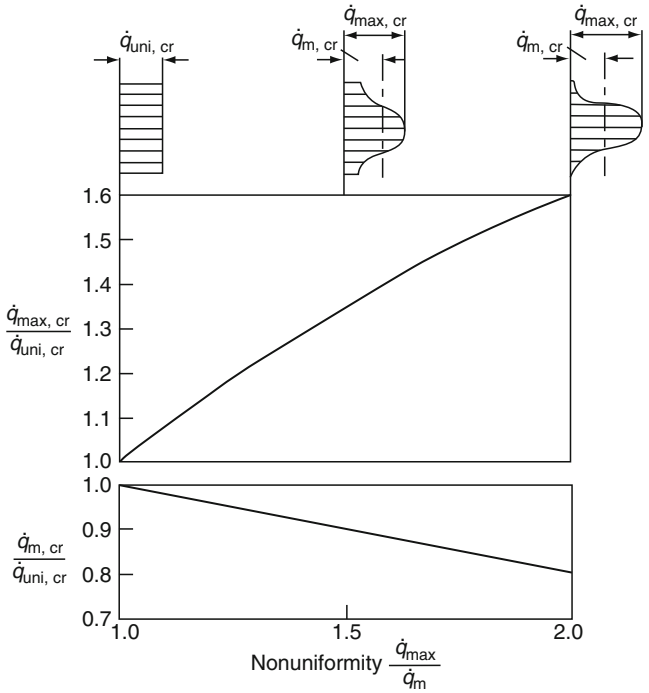
2.1.4 Effect of Nonuniform Heating

Nonuniform Heating in the Circumferential Direction

If evaporator tubes are heated by radiation on the one side, a roughly cosinusoidal profile can be assumed for the heat flux on the inside of the tube, as is shown in Fig. 21. The maximum heat flux at the commencement of the boiling crisis is greater than that for the case of uniform heating, but the average value, that is, the transmittable heat flux, is less. A model that was devised by Butterworth [24] and is illustrated in Fig. 22 allows the effect of nonuniform heating on the critical heat flux to be determined.



H3.5. Fig. 21. Distribution of heat flux inside a tube heated on the one side.



H3.5. Fig. 22. Effect of nonuniformity on the average and maximum critical heat fluxes expressed as a function of the critical heat flux under conditions of uniform heating.

Nonuniform Axial Heating

The axial heat applied to a cooling medium is often nonuniform. In this case, the occurrence of the boiling crisis may be governed solely by the local parameters (a case referred to as the local conditions hypothesis). An additional factor that is inherent in the heating system is its memory effect, which depends on the nature of the heat applied and on the pressure, the mass flux, and the vapor mass flux fraction.

As a general rule, local parameters suffice for determining the boiling crisis in the subcooled regime, for example, under the conditions in pressurized water reactors, and the memory effect in the heating system is a significant factor in regimes with high vapor mass fractions, for example, steam generators. Nonuniform axial heating causes water droplets to be detached from the film on the wall under conditions that differ from those encountered in uniform heating. As a consequence, dryout of the liquid film on the wall may, in turn, be influenced [25–29].

(a) Local conditions hypothesis

The assumption made in the local conditions hypothesis is that the boiling crisis in tubes with nonuniform axial heating occurs at the same combination of local heat flux and local vapor mass fraction as it does in tubes with uniform axial heating.

A heat flux profile that can be assessed by the local conditions hypothesis is shown in Fig. 23. Here, the critical heat flux at a given point B would be exceeded if the combination of the local heat flux $\dot{q}_B$ and the local vapor mass fraction $\dot{x}_B$ were to give rise to a boiling crisis in a uniformly heated tube, that is, if $\dot{q}_B > \dot{q}_{cr,B}$.

This is not the case in the example shown. Even if the point B were to be placed in other positions, the local heat flux would be less than the value calculated by the method described in Sect. 2.1.1. It is evident from Fig. 23 that the margin of safety against critical boiling depends greatly on the axial position in the flow channel.

(b) Integral power hypothesis

In the integral power hypothesis, it is assumed that the power that must be applied in a tube with nonuniform axial heating before the boiling crisis is reached is the same as that applied in a uniformly heated tube.

Figure 24 shows a heat flux profile that can be assessed by the integral power hypothesis. If the combination of the mean heat flux $\dot{q}_{m,\,AB}$ and the local vapor mass fraction $\dot{x}_B$ were to cause a boiling crisis in a uniformly heated tube, that is, if $\dot{q}_{m,\,AB} > \dot{q}_{cr,\,B}$, the boiling crisis in the nonuniformly heated tube would occur between the points A and B. This is not the case in the example shown. However, the margin of safety against critical boiling is less than that determined by the local conditions hypothesis.

The point of reference A that is frequently selected for the commencement of the regime investigated is that at which the liquid reaches saturation. In this case, the section AB is referred to as the "boiling length."

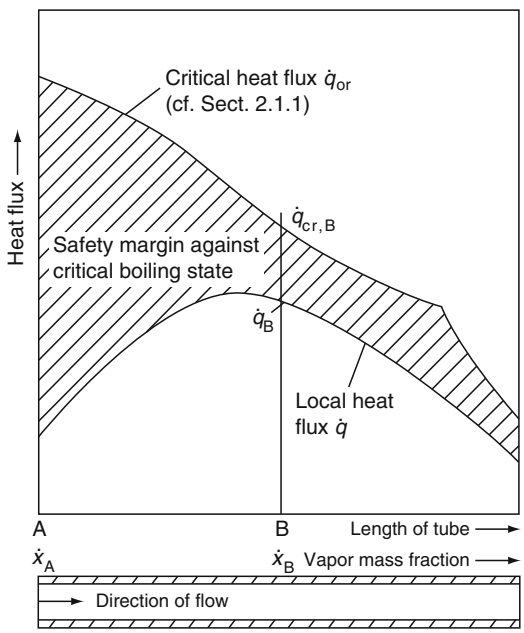
When the critical heat flux is calculated by both methods, the smaller of the two values obtained should be taken. If the maximum power lies within the zone at the commencement of the heated section, the integral power hypothesis should be applied; and if it lies at the end of the heated section, the local conditions hypothesis should be applied.

2.2 Complex Geometries

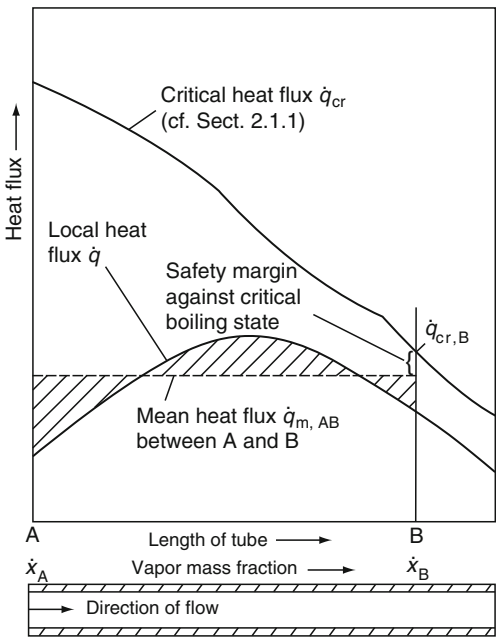
2.2.1 Annular Channels

A cross section through an annular channel is shown in Fig. 25. Heat may be applied in three different ways, that is,

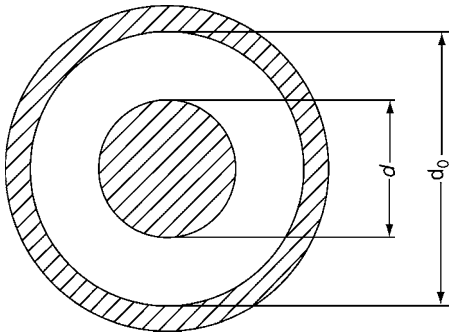
- Through the wall of the outer tube (inner diameter d_o).
- Through the wall of the inner tube (inner diameter d).
- Through the walls of both tubes.



H3.5. Fig. 23. Determination of the boiling crisis by the local conditions hypothesis.



H3.5. Fig. 24. Determination of the boiling crisis by the integral power hypothesis.



H3.5. Fig. 25. Cross section through annular channel.

Heat Applied through the Wall of the Outer Tube

In this case, the critical heat flux $\dot{q}_{cr}$ or the critical vapor mass fraction $\dot{x}_{cr,o}$ can be determined as a first approximation by inserting the diameter of the outer tube in the equations given in Sect. 2.1.1.

Example 6

Water flows at a pressure of 70 bar and a mass velocity $\dot{m}$ = 1,000 kg/m^2 s through an annular gap ($d_o = 21.3 \cdot 10^{-3}$ m, $d = 12 \cdot 10^{-3}$ m and a heated length of 3 m). If the inlet temperature ϑ_{inl} = 275.8°C and the outer tube is uniformly heated axially, what is the maximum rate at which heat can be fed $\dot{Q}_{act}$ without the occurrence of critical boiling? What would happen if the mass velocity were to be increased to $\dot{m}$ = 4,000 kg/m^2 s?

The following figures can be read off against 70 bar in steam tables:

$$h' = 1267.4 \text{ kJ/kg}$$
$$\Delta h_v = 1506.0 \text{ kJ/kg}$$
$$h_{inl} = 1217.4 \text{ kJ/kg}.$$

The heat flux is obtained from the energy balance, that is,

$$\dot{q} = \frac{(d_o^2 - d^2)\dot{m}\Delta h_v}{4 d_o l}\left(\dot{x}_{cr,o} - \dot{x}_{inl}\right),$$
$$\dot{x}_{inl} = (h_{inl} - h')/\Delta h_v = -0.035.$$

If d_o is substituted for d in Eq. (4) and if $\dot{x}_{cr,o}$ = 0.5 (from Fig. 8) is taken as the first approximation in the iteration, the following will be obtained in a few stages:

$$\dot{q}_{cr} = 1{,}066 \text{ kW/m}^2 \quad \text{and} \quad \dot{x}_{cr,o} = 0.549.$$

It can be seen from Fig. 8 that the value to be determined from Eq. (1) is $\dot{q}_{cr} > 1{,}066$ kW/m^2 and thus that the conditions for critical boiling are not reached.

If a standard deviation of $\Delta x = 0.1$ for the measured values is laid down as a safety measure [2], the figures finally obtained are

$$\dot{x}_{max} = 0.549 - 0.1 = 0.449 \quad \text{and} \quad \dot{q}_{max} = 883.1 \text{ kW/m}^2.$$

The maximum rate of heat flow through the annulus is

$$\dot{Q}_{act} = 883.1 \cdot 21.3 \cdot 10^{-3}\pi \cdot 3 \text{ kW} = 177.3 \text{ kW}.$$

Inserting $\dot{m}$ = 4,000 kg/m^{2}s for the mass velocity in Eq. (4) gives

$$\dot{q}_{cr} = 2{,}524 \text{ kW/m}^2 \quad \text{and} \quad \dot{x}_{cr,o} = 0.311.$$

As can be seen from Fig. 11, $\dot{q}_{cr} < 2{,}500$ kW/m^2 if $\dot{x}_{cr,o}$ = 0.311. Therefore, the critical data must be determined from Eq. (1). Since the energy balance and Eq. (1) conform for $\dot{q}_{cr}$ = 1,653 kW/m^2 and $\dot{x}_{cr,o}$ = 0.191, these values represent the conditions for the occurrence of critical boiling.

If a standard deviation of 16% for the measured values is laid down as a safety measure [2], the following figures are obtained:

$$\dot{q}_{max} = 1{,}653(1 - 0.16) = 1{,}388 \text{ kW/m}^2$$
$$\dot{x}_{max} = 0.155.$$

Hence the peak value of the power that can be transmitted through the annular gap is

$$\dot{Q}_{act} = 1{,}388 \cdot 21.3 \cdot 10^{-3}\pi \cdot 3 \text{ kW} = 278.6 \text{ kW}.$$

Heat Applied through the Wall of the Inner Tube

The critical heat fluxes $\dot{q}_{cr}$ that apply if heat is transmitted only through the inner wall of the annulus do not differ from those that occur if the outer wall is heated. Therefore, in the cases in which Eq. (1) or Eq. (2) is valid, the characteristic diameter for the determination of $\dot{q}_{cr}$ is $d = d_o$.

If Eq. (3) or Eq. (4) is adopted, $\dot{x}_{cr,o}$ must also be determined for $d = d_o$ first of all. The critical vapor mass fraction $\dot{x}_{cr,i}$ that applies for the case in which the inner tube of the annulus is heated is then obtained by multiplying $\dot{x}_{cr,o}$ by the diameter ratio d/d_o, that is,

$$\dot{x}_{cr,i} = \dot{x}_{cr,o}\frac{d}{d_o}. \tag{12}$$

In each case, the "poorer" of the results obtained by the two methods is taken.

Example 7

Under the conditions quoted in Example 6, what is the rate of heat flow $\dot{Q}_{act}$ if the inner and not the outer tube is heated?

The energy balance for the heat flux yields

$$\dot{q} = \frac{(d_o^2 - d^2)\dot{m}\Delta h_v}{4dl}\left(\dot{x}_{cr,i} - \dot{x}_{inl}\right),$$
$$\dot{x}_{inl} = \frac{(h_{inl} - h')}{\Delta h_v},$$
$$\dot{x}_{cr,i} = \frac{d}{d_a}\dot{x}_{cr,o},$$

If d_o is substituted for d in Eq. (4) and if $\dot{x}_{cr,o}$ = 0.5 is taken as the first approximation in the iteration (as in Example 6), the following will be obtained in a few stages:

$$\dot{q}_{cr} = 1{,}111 \text{ kW/m}^2, \ \dot{x}_{cr,o} = 0.546, \text{ and } \dot{x}_{cr,i} = 0.308.$$

It is immediately evident from Fig. 8 that critical boiling, as defined by Eq. (1), does not occur under these conditions. If a standard deviation of Δx = 0.1 for the measured values is laid down as a safety measure [2], the following values are obtained:

$$\dot{x}_{max,o} = 0.546 - 0.1 = 0.446$$
$$\dot{x}_{max,i} = 12/21.3 \cdot 0.046 = 0.251$$
$$\dot{q}_{max} = 927.2 \text{ kW/m}^2.$$

The peak value of the power that can be transmitted through the annular gap is

$$\dot{Q}_{act} = 927.2 \cdot 12 \cdot 10^{-3}\pi \cdot 3 \text{ kW} = 104.9 \text{ kW}.$$

The method indicated by Eqs. (4) and (12) initially yields the following results for a mass velocity of $\dot{m} = 4{,}000$ kg/m^2 s:

$$\dot{q}_{cr} = 2{,}703 \text{ kW/m}^2,\ \dot{x}_{cr,o} = 0.308, \text{ and } \dot{x}_{cr,i} = 0.174.$$

These figures are higher than those calculated from Eq. (1), namely,

$$\dot{q}_{cr} = 2{,}502 \text{ kW/m}^2 \text{ and } \dot{x}_{cr,i} = 0.123.$$

If a standard deviation of 16% is laid down for the measured values as a safeguard [2], the following values are obtained:

$$\dot{q}_{max} = 2{,}052(1 - 0.16) \text{ kW/m}^2 = 1{,}724 \text{ kW/m}^2$$
$$\dot{x}_{max,i} = 0.098.$$

Thus the maximum rate at which heat can be transmitted through the annular gap is

$$\dot{Q}_{act} = 1724 \cdot 12 \cdot 10^{-3}\pi \cdot 3 \text{ kW} = 195 \text{ kW}.$$

Heat Applied through Both Walls

In Fig. 26, the critical vapor mass fraction $\dot{x}_{cr}$, as determined from measurements by Becker and Letzter [30], has been plotted against the ratio y of the power fed through the wall of the outer tube to the total power fed, that is, $y = \dot{Q}_o/(\dot{Q}_o + \dot{Q}_i)$. Values for $\dot{x}_{cr}$ determined in the previous sections have been included in the diagram, namely, those for heat fed solely through the wall of the outer tube ($y = 1$; symbol ▲) and those for heat fed solely through the wall of the inner tube ($y = 0$; symbol •). The agreement with the measured values for the boundary case is good.

If heat is applied through the walls of both the inner and outer tubes, the experimental results (Fig. 26) can be closely approximated by considering the critical vapor mass fraction to be constant in the $0.8 < y \leq 1.0$ range and by equating $\dot{x}_{cr} = \dot{x}_{cr,o}$. In the $0 < y \leq 0.8$ range, $\dot{x}_{cr}$ can be obtained by linear interpolation from $\dot{x}_{cr,i}$ and $\dot{x}_{cr,o}$.

The power peak that can be fed to the annular channel is given by

$$\dot{Q}_{act} = (\dot{x}_{cr} - \dot{x}_{inl})\Delta h_v \dot{m} f. \tag{13}$$

The heat flux transferred from the outer tube is

$$\dot{q}_o = \frac{y\dot{Q}_{act}}{\pi d_o l}; \tag{14}$$

and that transferred from the inner tube is

$$\dot{q}_i = \frac{(1.0 - y)\dot{Q}_{act}}{\pi d l}. \tag{15}$$

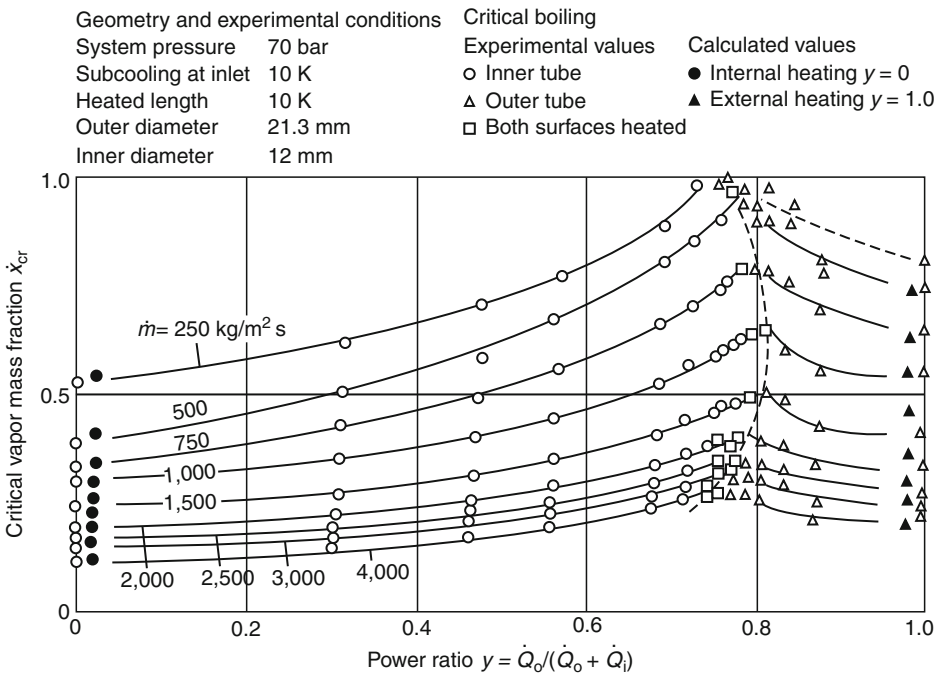
Example 8

Under the conditions quoted in Example 6, what is the maximum power $\dot{Q}_{act}$ that can be fed to the annulus if both tube walls are heated? The outer tube supplies 60% of the power.

If the selected safeguards are taken into consideration, the critical vapor mass fractions corresponding to $\dot{m} = 1{,}000$ kg/m^{2}s are

in Example 6, $\dot{x}_{cr,o} = 0.449$

in Example 7, $\dot{x}_{cr,i} = 0.251$.



H3.5. Fig. 26. Critical vapor mass fraction in an annular channel as a function of the ratio of the power applied to the outer tube to the total power [30].

The cross sectional area of the annulus is

$$A = \pi/4(d_o^2 - d^2) = \pi(21.3^2 - 12^2)10^{-6}\ \mathrm{m}^2 = 2.43 \cdot 10^{-4}\ \mathrm{m}^2.$$

Since $y < 0.8$, $\dot{x}_{cr}$ is obtained by interpolation, that is,

$$\dot{x}_{cr} = \left(\frac{\dot{x}_{cr,o} - \dot{x}_{cr.i}}{0.8}\right)0.6 + \dot{x}_{cr,i} = 0.400$$

The power peak that can be transmitted is given by Eq. (13), that is,

$$\dot{Q}_{act} = (0.400 + 0.035)1506 \cdot 1{,}000 \cdot 2.43 \cdot 10^{-4}\ \mathrm{kW} = 159.3\ \mathrm{kW}.$$

The heat flux from the outer tube is given by Eq. (14), that is,

$$\dot{q}_o = \frac{0.6 \cdot 159.3}{\pi \cdot 21.3 \cdot 10^{-3} \cdot 3}\ \mathrm{kW/m^2} = 476\ \mathrm{kW/m^2}.$$

The heat flux from the inner tube is given by Eq. (15), that is,

$$\dot{q}_i = \frac{0.4 \cdot 159.3}{\pi \cdot 12 \cdot 10^{-3} \cdot 3}\ \mathrm{kW/m^2} = 563\ \mathrm{kW/m^2}.$$

If the selected safeguards are taken into consideration, the critical vapor mass fractions corresponding to $\dot{m} = 4{,}000\ \mathrm{kg/m^2 s}$ are

in Example 6, $\dot{x}_{cr,o} = 0.155$

in Example 7, $\dot{x}_{cr,i} = 0.098$.

$$\dot{x}_{cr} = \left(\frac{\dot{x}_{cr,o} - \dot{x}_{cr,i}}{0.8}\right)0.6 + \dot{x}_{cr.i} = 0.141.$$

The power peak that can be transmitted is given by Eq. (13), that is,

$$\dot{Q}_{act} = (0.141 + 0.035) \cdot 1506 \cdot 4{,}000 \cdot 2.43 \cdot 10^{-4}\ \mathrm{kW} = 257.6\ \mathrm{kW}.$$

The heat flux from the outer tube is given by Eq. (14), that is,

$$\dot{q}_o = \frac{0.6 \cdot 257.6}{\pi \cdot 21.3 \cdot 10^{-3} \cdot 3}\ \mathrm{kW/m^2} = 770\ \mathrm{kW/m^2}.$$

The heat flux from the inner tube is given by Eq. (15), that is,

$$\dot{q}_1 = \frac{0.4 \cdot 257.6}{\pi \cdot 12 \cdot 10^{-3} \cdot 3}\ \mathrm{kW/m^2} = 911\ \mathrm{kW/m^2}.$$

2.2.2 Axial Rod Bundles

General

The thermohydraulic conditions that relate to axial flow within multirod clusters permit a greater degree of freedom in the geometry and the heating system than the conditions that apply to flow through tubes. Cheng and Müller have conducted a review of the relevant effects [31]. In the first place, the cross-sectional area available for flow between the heated rods may vary; and, in the second place, the heat flux may differ from the one rod to another. As a result, there will always be a zone within rod clusters that is particularly threatened by the occurrence of critical boiling.

These threatened zones can generally occur at high heat and low mass fluxes. The conditions in the cooling medium are often determined by subchannel analysis with the aid of a computer program [32–40]. These methods, in common with those adopted for flow through tubes, are mostly based on the local conditions hypothesis, but resort is occasionally taken to the integral power hypothesis (cf. Sect. 2.1.4).

The procedure described below permits safety margins for boiling crises to be approximately determined without a computer [41].

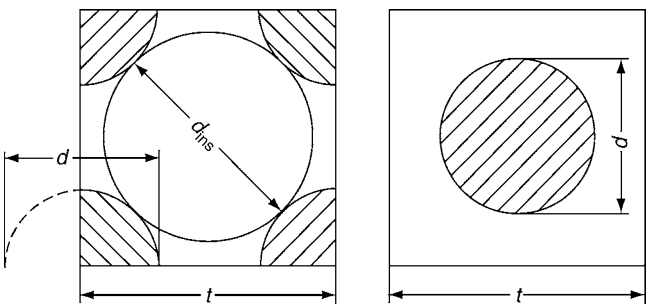
The first point to note is that the occurrence of the critical boiling state depends on local conditions in the cooling medium, for example, the local vapor mass fraction $\dot{x}$ or degree of subcooling, the local mass velocity $\dot{m}$, and the pressure p. It does not depend on the system variables, for example, the temperature at the inlet to the rod cluster or the length l of the cluster. If the ratio of the distance between spacers t and the wetted hydraulic diameter d_h is sufficiently large, that is, $t/d_h > 20$, the experimental determination can be regarded as reliable, or at least for the film-boiling regime. Controversy still exists on the application of this method to the dryout of heater surfaces.

Another requirement is to express axial flow through the bundle in terms of flow through an equivalent tube. For this purpose, it is assumed that the rods are arranged in groups of four so that the lines drawn through their centers form a rectangular grid. The flow channels can then be regarded as the circles inscribed within the individual squares of the grid, as is illustrated in Fig. 27; and the equivalent tube consists of the four rod quadrants that form the corners of each square and are pieced together as is shown in the diagram.

The critical heat flux can also be influenced by the spacers within the rod bundle. The pressure drop caused by the spacers must be as small as possible, and the following requirements are imposed on the rectangular grid formed by the rods in order to obviate critical boiling.

- The ratio of the flow cross section to the area of the surface of the heated tube must remain constant.
- The rods must be uniformly arranged, and protuberant fittings such as spring attachments must be as small as possible.
- Springs and protuberances should preferably be located in the narrow gap between the heated tubes.

Uniform design of the rod bundle cross section and spacers is of great importance in avoiding boiling crises, because weak points will adversely affect the performance of the entire assembly.



H3.5. Fig. 27. Basic element in flow around the outside of a multirod cluster. t, spacing in square grid; d, outer diameter of the equivalent tube; d_{ins}, diameter of the inscribed circle.

If spacers are sufficiently well designed to have no influence on the occurrence of the critical boiling state, the equations and diagrams presented in Sect. 2.1.1 for upward flow through vertical tubes can also be applied to flow along the vertical axis of a multirod cluster assembly. For this purpose, the inlet parameters must be modified as described below.

Inlet Parameters

Mass velocity $\dot{m}_j$

(a) Equation (16) applies if all the subchannels (subscript j) consist of identical elements and conform to Fig. 27:

$$\dot{m}_j = \dot{m}_m = \frac{\dot{M}}{A} \tag{16}$$

where

$\dot{M}$ is the total mass flow rate through the tube bundle

A is the total cross sectional area through which the medium flows

(b) If the bundle is nonuniformly heated in the radial direction, for example, if the heater rating for each tube differs or if the cooling channels have different hydraulic diameters, the assumption of equal pressure drops in parallel channels gives rise to the following equation:

$$\dot{m}_j = \dot{m}_m \frac{\sqrt{\frac{d_{h,j}}{\Phi_j^2}}}{\sum_{j=1}^{n} \sqrt{\frac{d_{h,j}}{\Phi_j^2}} \frac{A_j}{A}} \tag{17}$$

where

A_j is the cross sectional area of the subchannel

$U_{wet,\,j}$ is the wetted periphery of the subchannel

$d_{h,\,j}$ is the wetted hydraulic diameter $= 4A_j/U_{wet,\,j}$

Φ_j^2 is the two-phase multiplier expressed as the average over the heated length of tube (cf. Subchap. H3.2)

n is the number of parallel channels

The vapor mass fraction $\dot{x}$ is given by

$$\dot{x}_j = \frac{h_{inl} - h' + \Delta h_j}{\Delta h_v}. \tag{18}$$

(a) If the heating is the same in all the tubes and the hydraulic diameters are the same in all the subchannels j, the enthalpy difference is given by

$$\Delta h_j = \Delta h_m = \frac{\dot{q}_m U_{htd} l}{\dot{m}_m f}. \tag{19}$$

(b) Equation (20) applies for tube bundles that are nonuniformly heated in the radial direction and/or have different hydraulic diameters:

$$\Delta h_j = \Delta h_m \left[\left(\frac{\dot{q}_j}{\dot{q}_m} \frac{(U_{htd}/f)_j}{(U_{htd}/f)_m} \frac{\dot{m}_m}{\dot{m}_j} - 1 \right) \psi + 1 \right]. \tag{20}$$

The term $\dot{m}_m/\dot{m}_j$ is calculated from Eq. (17).

The geometry of the system ($U_{htd}/A; \dot{m}_m/\dot{m}_j$) and the heating parameters ($\dot{q}_j/\dot{q}_m; \dot{m}_m/\dot{m}_j$) give rise to differences in the rate at which the medium is heated up. The extent to which these differences are phased out by admixture with the coolant is expressed by the factor ψ, which depends on the design of the spacers. Under normal conditions, values in the $0.65 < \psi < 0.75$ range can be taken for spacers in tube bundles with a ratio $t/d \approx 1.3$ (where t is the bar spacing as illustrated in Fig. 27). Values of down to $\psi = 0.35$ at $t/d \approx 1.3$ can also be reached in unsaturated bulk flow ($\dot{x}_j < 0$) by fitting the spacers with devices that promote turbulence. If the vapor mass fraction is positive, that is, $\dot{x}_j > 0$, these devices must be designed so that they do not interfere with the film of water on the heated surfaces and thus give rise to a premature boiling crisis. Otherwise, the gain that could be anticipated from better mixing ($\dot{x}_j < 0$) would be annulled by the increased accumulation of liquid droplets ($\dot{x}_j > 0$).

Tube Diameter *d*

The characteristic length that is mostly suggested in the literature is similar to that adopted in the determination of pressure drop, that is, the wetted hydraulic diameter d_h. In some instances, the only means of calculating the recommended hydraulic diameter is based on the heated peripheries, but this assumption could lead to errors, as in the case of annular gaps. If the rods are arranged to form a regular square grid, much better results are obtained by selecting the diameter of the largest inscribed circle d_{ins} (cf. Fig. 27) as the reference magnitude in the $8 \cdot 10^{-3} \le d_{ins} \le 30 \cdot 10^{-3}$ range. The diameter d_{ins} of the circle inscribed in a square grid is obtained from the rod spacing t and the rod diameter d, that is,

$$d_{ins} = t\sqrt{2} - d. \tag{21}$$

If the rods are very closely spaced or arranged to form a hexagonal grid or if the pressure is less than 100 bar, Eq. (21) should be treated with reserve.

Uniform Axial Heating

Avoidance of film boiling

The method for determining the critical heat flux $\dot{q}_{cr,j}$ for each subchannel j in a cluster with uniform axial heating is that described in Sect. 2.1.1:

$$\dot{q}_{cr,j} = \dot{q}_{cr}(p, \dot{m}_j, d_j, \dot{x}_j). \tag{22}$$

The factor that decides whether or not film boiling will occur is the minimum ratio of the critical heat flux $q_{cr,j}$ to the maximum heat flux $\dot{q}_j$ on the heated surface of channel K, that is,

$$\left(\frac{\dot{q}_{cr}}{\dot{q}}\right)_K = \min\left(\frac{\dot{q}_{cr,j}}{\dot{q}_j}\right). \tag{23}$$

The term $(\dot{q}_{cr}/\dot{q})_K$ must be substantially higher than 1.0 if film boiling is to be avoided.

According to Drescher and Köhler [2], the standard deviation of figures determined by Eq. (1) from the values measured in flow through tubes is 16%.

Avoidance of dryout

The critical vapor mass fraction $\dot{x}_{cr,j}$ in each subchannel j is determined by the method described in Sect. 2.1.1:

$$\dot{x}_{\mathrm{cr,j}} = \dot{x}_{\mathrm{cr}}(p, \dot{m}_{\mathrm{j}}, \dot{q}_{\mathrm{j}}). \tag{24}$$

The limiting value that decides whether or not the heated surfaces will dry out is the minimum difference between the critical vapor mass fraction and the actual vapor mass fraction in the channel K, that is,

$$\Delta\dot{x}_{\mathrm{K}} = \min(\dot{x}_{\mathrm{cr,j}} - \dot{x}_{\mathrm{j}}). \tag{25}$$

If dryout is to be prevented, the term $\Delta\dot{x}_{\mathrm{K}}$ must be significantly greater than zero. Drescher and Köhler [2] submitted a figure of 0.10 for the standard deviation from the difference between calculated and measured values of the vapor mass fraction in flow through tubes. For this reason, $\Delta\dot{x}_{\mathrm{K}} > 0.10$ is recommended.

Nonuniform Axial Heating

The method that has been described for nonuniform axial heating is to divide the tube bundle up into sections, in each of which the heating is constant. The minima defined by Eqs. (23) and (25) indicate the margins that separate the conditions from those in critical boiling.

Special Cases

If no measurements are available for the grid selected, care must be exercised in evaluating the results obtained by the above methods. This applies particularly if

- Great differences exist in the spacing within the bundle.
- The nonuniformity of the axial power distribution is very pronounced.
- The surfaces in the subchannel illustrated in Fig. 27 are unheated or are heated to very different extents (cf. Sect. 2.2.1).
- The system pressure is low, that is, $p < 50$ bar, and the vapor mass fraction is positive. In this case, the likelihood of unstable flow within the bundle cannot always be excluded, even if acceptable results are obtained from Eqs. (23) and (25). As a consequence of the instability, the boiling crisis may occur [42].
- If the design of the spacers leaves room for doubt (cf. Sect. 2.2.1).

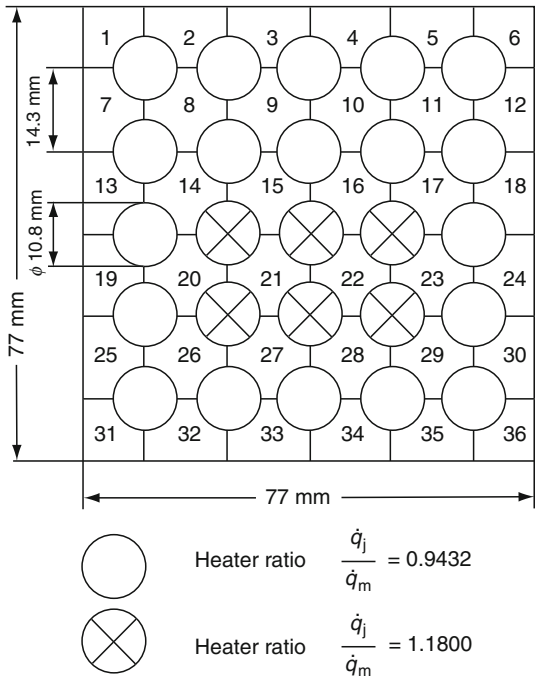
Example 9

The 5 × 5 rod cluster illustrated in Fig. 28 is subjected to uniform axial heating. The diameter of the rods is $10.8 \cdot 10^{-3}$, the spacing is $14.3 \cdot 10^{-3}$, and the heated length is 2.985 m; the rods are accommodated in a square housing of $77 \cdot 10^{-3}$ m side. Water flows through the assembly at a pressure of 160 bar, an inlet temperature of 296.0°C, and an average mass flux of 3,660 kg/m^2 s. The power ratios $\dot{q}_{\mathrm{j}}/\dot{q}_{\mathrm{m}}$ for the rods are

6 rods – mean value · 1.1800
19 rods – mean value · 0.9432.

If the power rating for the cluster is $\dot{Q}_{\mathrm{act}} = 3{,}750$, can the likelihood of a boiling crisis be excluded?

The types of channel and the geometries are listed in Table 2.



H3.5. Fig. 28. Cross section through a 5 × 5 rod bundle.

H3.5. Table 2. Types of channel and their geometry

Channel number in Fig. 28		No.	Wetted hydraulic diameter (10^{-3} m)	Heated periphery (10^{-3} m)	Area (10^{-6}) m²
I	1, 6, 31, 36	4	10.62	8.48	75.11
II	2, 3, 4, 5, 7, 12, 13, 18, 19, 24, 25, 30, 32, 33, 34, 35	16	12.25	16.96	95.77
III	8, 9, 10, 11	4	13.3	33.93	112.88
IV	14, 17, 26, 29	4	13.3	33.93	112.88
V	15, 16, 20, 23, 27, 28	6	13.3	33.93	112.88
VI	21, 22	2	13.3	33.93	112.88
		36		848.16	3638.84

The diameter d_{ins} of the inscribed circle depicted in Fig. 27 is

$$d_{\mathrm{ins}} = \left(\sqrt{2} \cdot 14.3 \cdot 10^{-3} - 10.8 \cdot 10^{-3}\right) \mathrm{m} = 9.42 \cdot 10^{-3} \mathrm{m}.$$

The mean heat flux is

$$\dot{q}_{\mathrm{m}} = \frac{3{,}750}{25 \cdot \pi \cdot 10.8 \cdot 10^{-3} \cdot 2.985} \mathrm{kW/m^2} = 1{,}481 \mathrm{kW/m^2}.$$

The mean enthalpy difference, as determined from Eq. (19), is

$$\Delta h_{\mathrm{m}} = \frac{3{,}750}{3{,}660 \cdot 3638.84 \cdot 10^{-6}} \mathrm{kJ/kg} = 281.6 \mathrm{kJ/kg}.$$

If $\Phi_j^2 = 1$ in Eq. (17),

$$\sum_{j=1}^{n} \frac{f_j}{f} \sqrt{d_{h,j}} = 0.112(\mathrm{m})^{1/2}.$$

The results of the following steps in the calculation are entered in Table 3.

The following figures can be read off against 160 bar in steam tables:

$$h' = 1650.5 \text{ kJ/kg}$$
$$\Delta h_v = 934.3 \text{ kJ/kg}$$
$$h_{inl} = 1316.0 \text{ kJ/kg}.$$

Table 4 lists the parameters that have been calculated from these variables and inserted in Eq. (18) and that are required for the determination of critical boiling by means of Eqs. (1) and (4).

The correlation for $\dot{x}_j$ is

$$\dot{x}_j = \frac{\Delta h_m}{\Delta h_v} \left(\frac{\Delta h_j}{\Delta h_m} \right) + \dot{x}_{inl}.$$

Since the vapor fractions $\dot{x}_j$ are small, there is no need to correct the two-phase multiplier Φ^2, which was initially assumed to be $\Phi^2 = 1$. If higher values of $\dot{x}_j$ occur, the ratio $\dot{m}_j/\dot{m}_m$ must be corrected by iteration.

Values obtained from Eqs. (22) and (24) are listed in Table 5. The figures listed in the $\dot{q}_{max,j}$ column represent the maximum heat flux in each type of channel. The minimum value is obtained from Eq. (23). Thus

$$\left(\frac{\dot{q}_{cr}}{\dot{q}} \right)_{v1} = \frac{1{,}883}{1{,}748} = 1.077.$$

The lowest value $\dot{q}_{cr}/\dot{q} = 1.077$ in the cluster lies within the standard deviation of 16% for measurements performed on tubes [2]. Hence the possibility of film boiling cannot be entirely excluded. Although the critical heat flux of 1,883 kW/m^2 is higher than the heat flux actually applied, that is, 1,748 kW/m^2, the safety margin of 135 kW/m^2 does not suffice to cover the range of scatter of the measurements [2]. In this case, the remedy would be to reduce the heat input or the inlet temperature or to increase the mass flux.

The minimum value determined from Eq. (25) is

$$\Delta \dot{x}_{v1} = 0.196 - 0.0453 = 0.151.$$

In this case, therefore, the likelihood of dryout can be excluded.

3 Flow of Other Liquids

3.1 Pure Liquids

3.1.1 Upward or Downward Flow in Vertical Tubes

Subcooled or Saturated Liquids at the Tube Inlet

According to Katto and Ohno [43], the critical heat flux during upward flow in uniformly heated, vertical tubes can be determined from the following equation:

$$\dot{q}_{cr} = \dot{q}_{cr,n}(1 - K\dot{x}_{inl}) \quad (26)$$

where $\dot{q}_{cr,o}$ is the critical heat flux for liquid that is saturated when it enters the flow channel; $\dot{x}_{inl} = (h_{inl} - h_s)/\Delta h_v$ is the vapor mass fraction at the inlet cross section of the tube; in this case, h_s is the saturation enthalpy corresponding to the pressure at the tube inlet, h_{inl} is the enthalpy of the liquid, and Δh_v is the enthalpy of vaporization; K is the subcooling parameter.

Equation (26) is not valid unless the liquid in the tube inlet is subcooled ($\dot{x}_{inl} < 0$) or – in the limiting case – barely saturated. A different mathematical approach is required if the liquid does contain vapor when it enters the tube, but this will be dealt with at a later stage.

Data obtained in measurements on R 12 [43] are presented graphically in Fig. 29 as an example. They verify the linear relationship expressed by Eq. (26) between $\dot{q}_{cr}$ and the extent of subcooling for a constant mass velocity $\dot{m}$ and a given pressure p. The only cases in which pronounced departures from the linear relationship normally occur [44] arise if the liquid velocity is low ($u_1 < 0.2$–0.3 m/s) at the inlet to short tubes or if the vapor mass fraction at the tube outlet does not differ significantly from zero, that is, $\dot{x}_{cr} \approx 0$. Other cases of departure from a

H3.5. Table 5. Values obtained from Eqs. (22) and (24)

Type of channel	$\dot{q}_{cr,j}$ (kW/m^2)	$\dot{q}_{max,j}$(kW/m^2)	$\dot{x}_{cr,j}$
I	3,428	1,397	0.210
II	3,046	1,397	0.205
III	2,293	1,397	0.202
IV	2,182	1,748	0.196
V	2,080	1,748	0.196
VI	1,883	1,748	0.196

linear relationship were observed in experiments that were performed at high pressures and very high mass velocities, for example, $\dot{m} > 3{,}800$ kg/m^2 s, on R 12 in tubes of 1,000 mm length, and 3 and 5 mm diameter [45].

Equations (27–41) allow $\dot{q}_{cr,o}$ and K to be determined. The ranges of parameters within which they are valid are discussed in the following section.

$$q_1^* = C(\sigma^*)^{0.043}\frac{1}{\ell^*} \tag{27}$$

$$q_2^* = 0.1(0^*)^{0.133}(\sigma^*)^{1/3}\frac{1}{1+0.0031\ell^*} \tag{28}$$

$$q_3^* = 0,098(\varrho^*)^{0.133}(\sigma^*)^{0.433}\frac{(\ell^*)^{0.27}}{1+0.0031\ell^*} \tag{29}$$

$$q_4^* = 0.234(\varrho^*)^{0.513}(\sigma^*)^{0.433}\frac{(\ell^*)^{0.27}}{1+0.0031\ell^*} \tag{30}$$

$$q_5^* = 0.0384(\varrho^*)^{0.6}(\sigma^*)^{0.173}\frac{1}{1+0.28(\sigma^*)^{0.233}\ell^*} \tag{31}$$

The dimensionless quantities in Eqs. (27–31) are defined as follows:

$$q_1^* = \frac{\dot{q}_{cr,o}}{\dot{m}\Delta h_v} \tag{32}$$

$$\sigma^* = \frac{\sigma\varrho_\ell}{\dot{m}^2\ell} \tag{33}$$

$$\ell^* = \frac{\ell}{d} \tag{34}$$

$$\varrho^* - \frac{\varrho_z}{\varrho_\ell}. \tag{35}$$

The subscript i in Eq. (32) represents the subscripts 1–5 in Eqs. (27–31). The significance of the symbols in Eqs. (27–35) is as follows: $\dot{m}$ mass velocity; σ surface tension; ϱ_g and ϱ_l density of the gas/vapor and the liquid; l heated length of tube; and d inner diameter of tube.

All the values for the properties of the fluid must be referred to the saturation temperature corresponding to the inlet pressure.

The following applies for the dimensionless parameter C in Eq. (27):

$$C = 0.25 \text{ for } \ell^* < 50; \tag{36}$$

$$C = 0.25 + 9\cdot 10^{-4}(\ell^* - 50) \text{ for } \ell^* \text{ for } \ell^* = 50{-}150; \tag{37}$$

$$C = 0.34 \text{ for } \ell^* > 150. \tag{38}$$

Measured values of $\dot{q}_{cr,o}$ for Refrigerant R 12 [43] are compared in dimensionless form with figures calculated from Eqs. (27–38) in Fig. 30. A corresponding diagram in which values measured at a lower pressure by Groeneveld [46] are compared with the calculations is presented in Fig. 31.

Equations (39–41) allow the subcooling parameter K to be expressed in terms of the quantities defined by Eqs. (33–35) and in terms of the parameter C {Eqs. (36–38)}. The choice of equation depends on the range of parameters involved.

$$K_1 = \frac{1.043}{4C(c^*)^{0.043}} \tag{39}$$

$$K_2 = \frac{5}{6}\cdot\frac{0.0124 + 1/\ell^*}{(\varrho^*)^{0.130}(\sigma^*)^{1/3}} \tag{40}$$

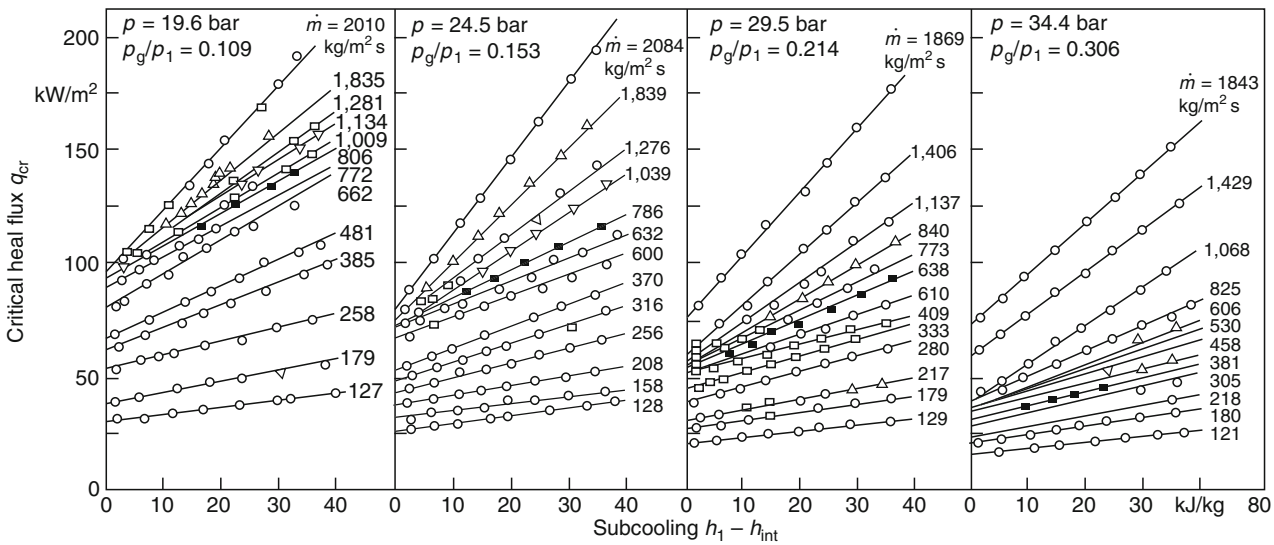
$$K_3 = 1.12\cdot\frac{1.52(\sigma^*)^{0.223} + 1/\ell^*}{(\varrho^*)^{0.6}(\sigma^*)^{0.173}} \tag{41}$$

A comparison of figures calculated from Eqs. (39–41) with values obtained by measurement on R 12 [43] is presented in Fig. 32. The measured values plotted were determined from the slopes of the curves that are reproduced in Fig. 29 and that fit Eq. (26).

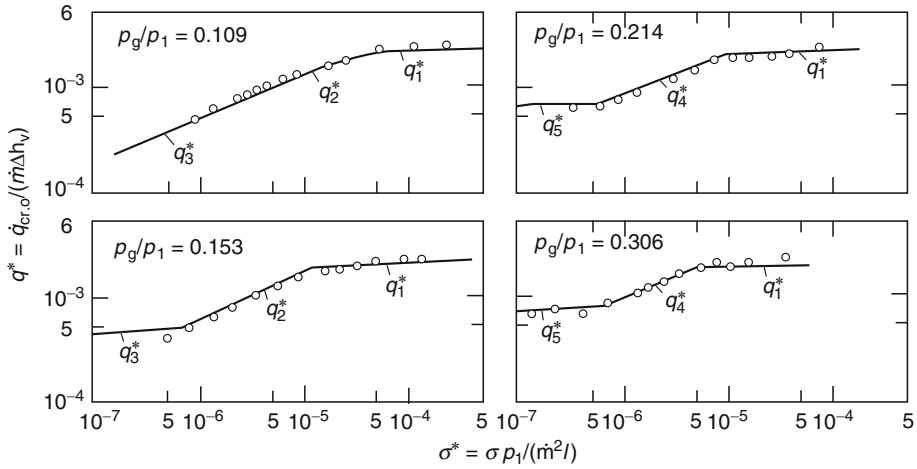
An idea of the accuracy of Eqs. (39–41) can be obtained from Figs. 33 and 34, in which the calculated values are compared with measurements performed by various authors on some refrigerants.

Ranges of Validity for the Equations

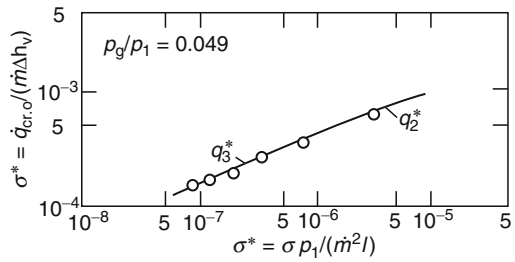
The ranges of the parameters within which Eqs. (27–41) are valid are reviewed in Figs. 30–33, and rules for their delimitation are



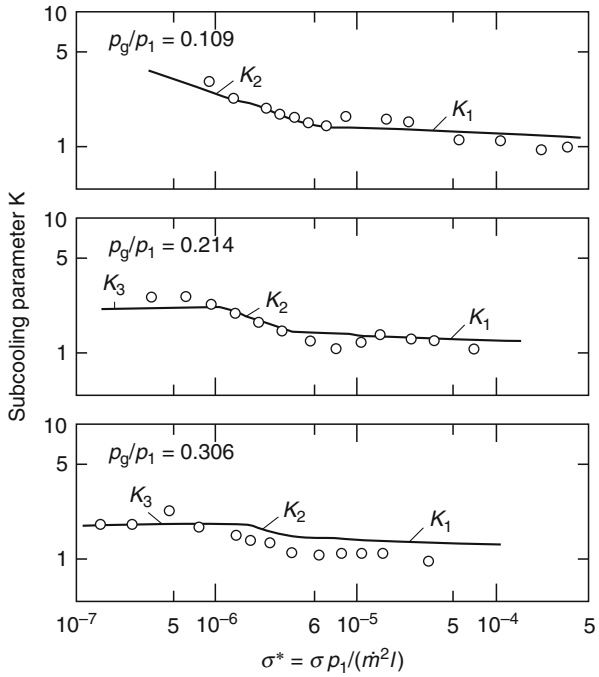
H3.5. Fig. 29. Measured values of the critical heat flux $\dot{q}_{cr}$ for R 12 (d = 0.01 m; ℓ/d = 100) [43].



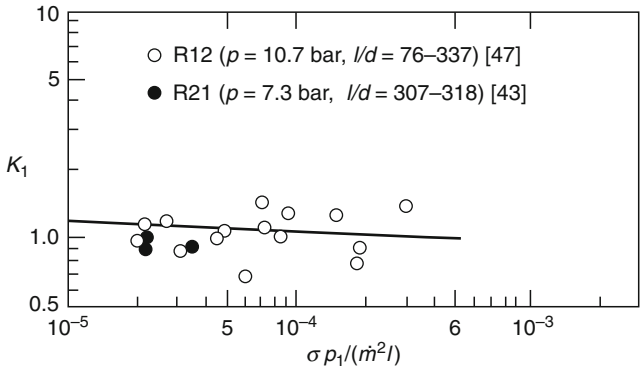
H3.5. Fig. 30. Comparison between values measured on R 12 and figures calculated from Eqs. (27) and (35) for q_i^* (i = 1–5; d = 0.01 m; ℓ/d = 100) [43].



H3.5. Fig. 31. Comparison between values measured on R 12 and figures calculated from Eqs. (28), (29), and (32–35) for q_2^* and q_3^* (d = 7.8 mm; ℓ/d = 176.9) [46].



H3.5. Fig. 32. Comparison between values measured on R 12 and figures calculated from Eqs. (39) and (41) for the subcooling parameter K_i (i = 1–3; d = 0.01 m; ℓ/d = 100) [43].



H3.5. Fig. 33. Comparison between measured values and figures calculated from Eq. (39) for the subcooling parameter K_1.

submitted below. A distinction is drawn between two pressure ranges, each represented by a pressure ratio.

(a) Determination of the critical heat flux for

$$\varrho^* = \left(\frac{\varrho_\ell}{\varrho_\ell}\right) \leq 0.15$$

In this range, the following rule applies to the calculation of $\dot{q}_{cr}$ by means of Eqs. (27–29):

$$\begin{aligned} q_1^* \leq q_2^* : &\quad q^* = q_1^* \\ q_1^* > q_2^* : &\quad q_2^* \leq q_3^* \rightarrow q^* = q_1^*, \\ &\quad q_2^* > q_3^* \rightarrow q* = q_3^*. \end{aligned}$$

The associated values for the subcooling parameter K are determined as follows from Eqs. (39) and (40):

$$\begin{aligned} K_1 \geq K_2 : &\quad K = K_1, \\ K_1 < K_2 : &\quad K = K_2. \end{aligned}$$

(b) Determination of the critical heat flux for

$$\varrho^* = (\varrho_\ell/\varrho_\ell) > 0.15.$$

For this range, Eqs. (27), (30), and (31) are applied as follows:

$$\begin{aligned} q_1^* \le q_4^* : &\quad q^* = q_1^*, \\ q_4^* > q_4^* : &\quad q_4^* \ge q_5^* \rightarrow q^* = q_4^*, \\ &\quad q_4^* < q_5^* \rightarrow q^* = q_5^*. \end{aligned}$$

The following rule applies to the determination of the subcooling parameter K from Eqs. (39–41):

$$\begin{aligned} K_1 \ge K_2 : &\quad K = K_1, \\ K_1 < K_2 : &\quad K_2 \le K_3 \rightarrow K = K_2, \\ &\quad K_2 > K_3 \rightarrow K = K_3. \end{aligned}$$

Critical Vapor Mass Fraction

The critical vapor mass fraction is derived from an energy balance. Thus

$$\dot{x}_{cr} = \frac{4\dot{q}_{cr}}{\dot{m}\Delta h_V}\frac{\ell}{d} + \dot{x}_{inl}. \qquad (42)$$

If critical boiling occurs at the end of the heated section, the value to be inserted for ℓ in Eq. (42) is the total length. Otherwise, it is the length of the section up to the occurrence of the boiling crisis.

Comparison with Measured Data

Equations (26–41) were developed from a dimensional analysis [47] and were reconciled with numerous values obtained from measurements by various authors [43–55]. The substances on which the measurements were performed were R 12, R 21, R 22, R 113, R 114, hydrogen, nitrogen, and helium (I). As a rule, only the measured values for the critical heat flux $\dot{q}_{cr,\,o}$ referred to $\dot{x}_{inl}$ were adopted for reconciliation and comparison. In most cases, the agreement between the measured values and the values of q^* calculated from Eqs. (27–31) was satisfactory.

Calculated and measured values of $\dot{q}_{cr}$ for various fluids are compared in Figs. 35 and 36, in order to impart an idea on the reliability of Eq. (27), which is more generally valid and in which an allowance has been made for any subcooling that might occur in the inlet cross section.

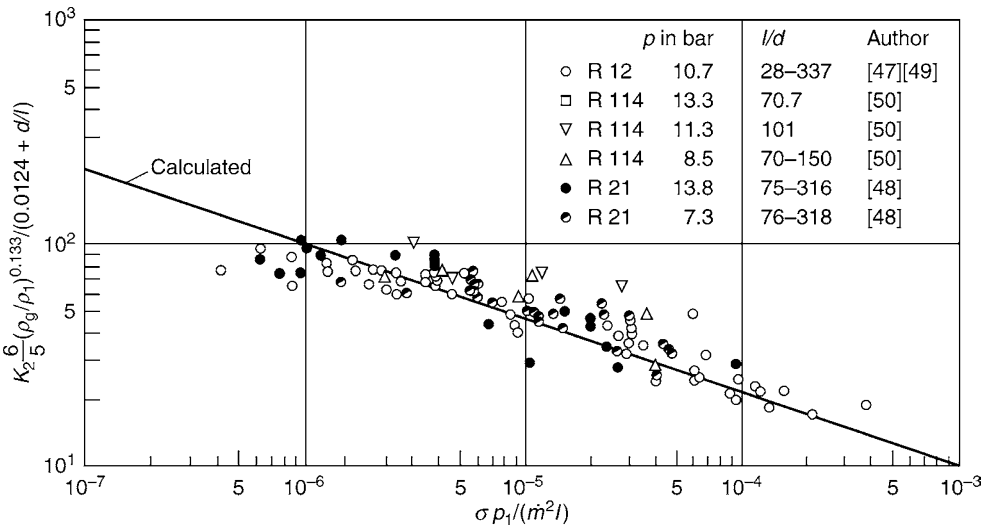
Figure 35 presents the values measured on halocarbon refrigerants. A total of 2,046 measurements was taken from six different data banks to check the *Katto* and *Ohno* correlation. It must be noted that the data were not selected from the standpoint of their reliability. Space considerations precluded the inclusion of some of the measured values with a tolerance of ±20% in this diagram. In view of the wide range of parameters embraced by the data investigated, the agreement between the measurements and the calculations must be regarded as very good.

The corresponding comparison for helium (I), hydrogen, nitrogen, potassium, and ammonia is presented in Fig. 36. Five data banks with a total of 438 measured values were available. The data were not selected any further. The overwhelming majority of the measured values lay within a tolerance of ±30%. In this case, too, not enough space was available to allow all of the data to be entered in the diagram. The values of $\dot{q}_{cr}$ represented range from about 10^{-1}–10^4 kW/m^2, and the main system parameters in some cases were varied within wide limits.

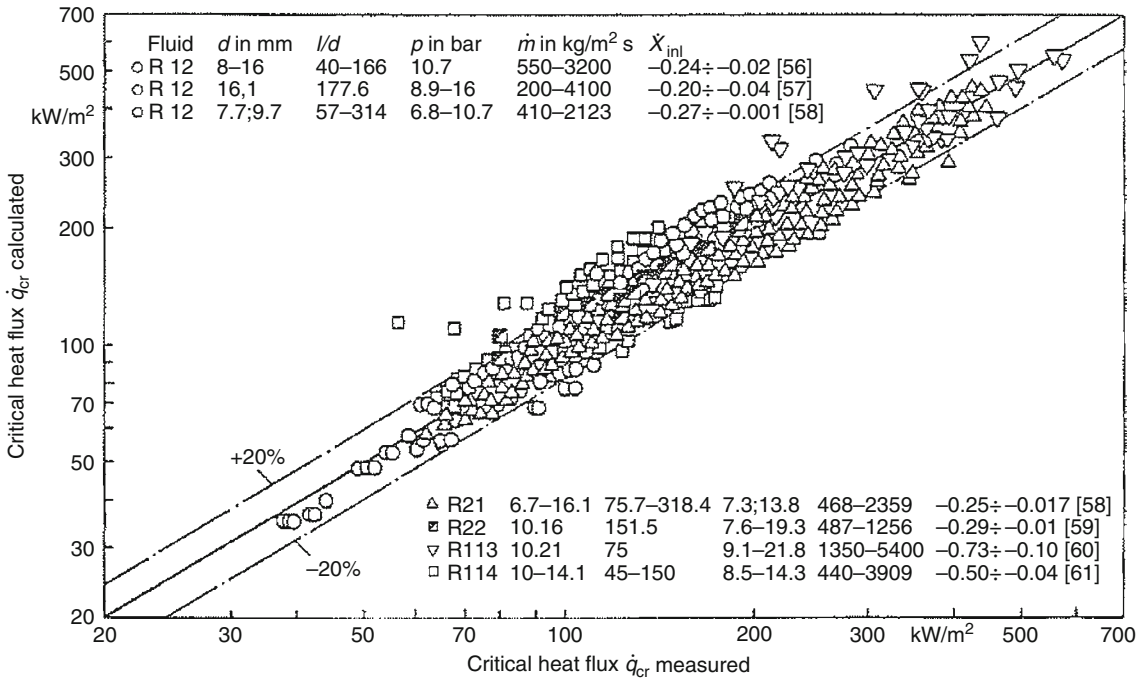
The refrigerants (CFCs, HCFCs) used in Fig. 35 to test the reliability of Katto/Ohno's method are now (CFCs) or soon (HCFCs) only allowed for research purposes. They are forbidden for practical application because of their ozone depletion potential. Test with refrigerants allowed for practical application (HFCs) show a similar reliability as those used in Fig. 35. This holds also for nonfluorocarbon refrigerants which are not used for the reliability test in Fig. 36 namely, e.g., propane, butane, and CO_2. The conclusion that can thus be drawn is that the Katto/Ohno method is very reliable for nonaqueous fluids.

Restrictions on the Validity

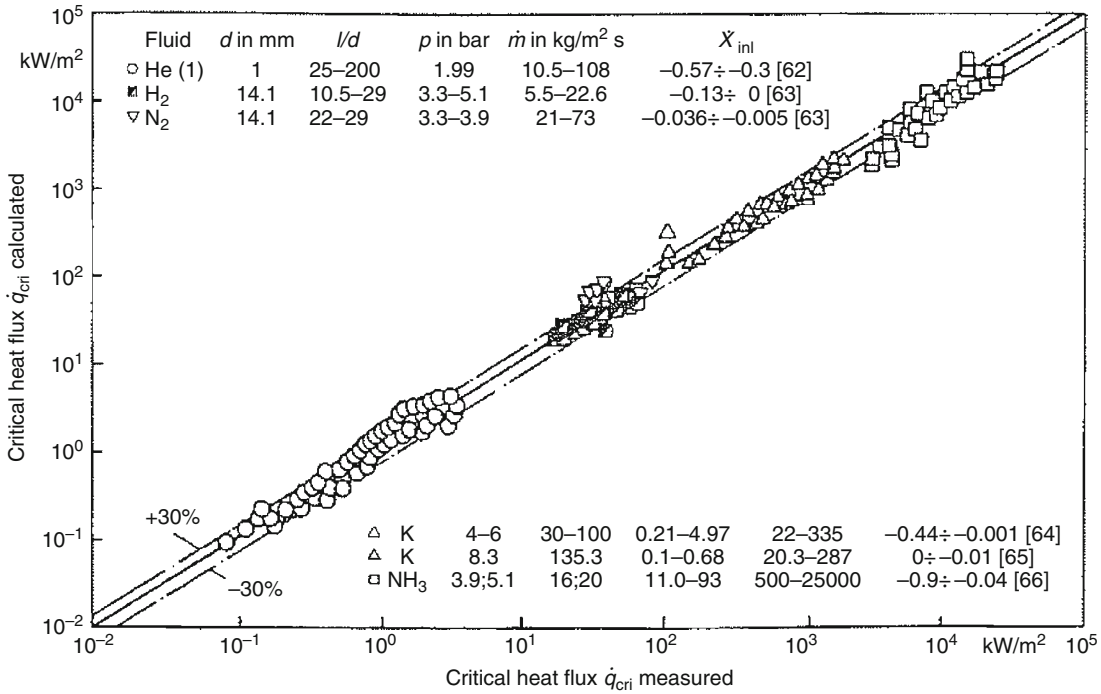
Under the following conditions, the mathematical method described in Sect. 3.1.1 does not yield reliable values; or, at least, it is not adequately supported by data derived from measurements.



H3.5. Fig. 34. Comparison between measured values and figures calculated from Eq. (40) for the subcooling parameter K_2.



H3.5. Fig. 35. Comparison between measured values and figures calculated by the *Katto/Ohno* method for the critical heat flux of fluorocarbon refrigerants.



H3.5. Fig. 36. Comparison between measured values and figures calculated by the *Katto/Ohno* method for the critical heat flux for helium (I), hydrogen, nitrogen, potassium, and ammonia.

- The system is instable. If there are fluctuations in the pressure or the mass flux, the boiling crisis may occur at considerably smaller heat fluxes.
- The vapor mass fraction at the tube inlet is greater than zero ($\dot{x}_{inl} > 0$). In this case, the method presented in Sect. 2.1.1 should be chosen; it can be applied to other fluids by the *Ahmad* procedure, which is described in the last part of Sect. 3.1. Although some of the data plotted in Fig. 36 apply to $\dot{x}_{inl} > 0$, they fit the correlation just as accurately as the other measured values. Further measurements are required to determine whether this finding applies in general.

- The vapor mass fraction at the end of the heated section is less than zero ($\dot{x}_{cr} < 0$). This situation may arise in short lengths of tube if the mass flux is high and subcooling occurs. In this case, too, the method described in Sect. 2.1.1 should be adopted and modified by the *Ahmad* procedure when appropriate. Attention is drawn to the fact that the values plotted for R 113 in Fig. 35 and those plotted for ammonia in Fig. 36 mostly correspond to a negative $\dot{x}_{cr}$. Here, too, it would appear that the *Katto/Ohno* yields reliable results. However, the general validity of this statement must continue to be questioned until more measured values become available for comparison.
- If the length-to-diameter ratio of the tube is very large ($\ell/d > 600$), Eqs. (28) and (29) no longer yield reliable results. Again, preference should be given to the method given in Sect. 2.1.1 and by *Ahmad*.

Downward Flow through Tubes

The effect exerted by the direction of flow on the critical heat flux has been studied by Cumo et al. [67], and the results that they obtained on Refrigerant R 12 are presented in Fig. 37. On an average, the values determined for upward flow are 11% higher than those for downward flow. Equation (27) yields results that correspond comparatively accurately with the measured values in the $\dot{m}$ = 120–325 kg/m^2 s range; and the values of $\dot{q}_{cr,o}$ calculated from Eq. (28) are somewhat too high in the $\dot{m}$ = 503–1,043 kg/m^2 s range. An explanation for this phenomenon has been offered by Katto [44]. On the whole, the results obtained by Eqs. (26–41) correspond well to all the measured values (Figs. 35 and 36). Consequently, there is no point in modifying Eq. (28) to accommodate the data presented in Fig. 37.

In the light of the accuracy with which the correlations given can conform to the measured values, the studies by *Cumo* et al. demonstrate that the critical heat flux is not significantly altered by the direction of flow. For practical purposes, it is recommended that the values for the critical heat flux determined by Eqs. (26–41) be reduced by 10% if flow is downward.

Example 10

Nitrogen at a pressure of 5 bar flows with a mass velocity of 30 kg/m^2 s through a vertical evaporator tube of 1.0 m length and 12 mm inner diameter. The inlet temperature is 85 K, and the tube is heated axially at a rate of 40 kW/m^2. Determine the location of the boiling crisis and the associated vapor mass fraction.

The following applies for nitrogen: $h_{inl} = -105.5$ kJ/kg, h' (5 bar) = −87.3 kJ/kg, and Δh_v (5 bar) = 173.8 kJ/kg. Hence,

$$\dot{x}_{inl} = \frac{-105.5 - (-87.3)}{173.8} = -0.1$$

Other properties of nitrogen at 5 bar are $\varrho_\ell = 724.4$ kg/m^3, $\varrho_g = 20.23$ kg/m^3 and $\sigma = 5.3 \cdot 10^{-3}$ N/m.

The location of the boiling crisis is determined by iteration commencing with, say, $\ell = 0.5$, which results in $\dot{q}_{cr} < 40$ kW/m^2. ℓ is then reduced stepwise until the set value $\dot{q}_{cr} = 40$ kW/m^2 is attained. The value obtained after a few stages in the iteration is $\ell = 0.364$ m. The calculation proceeds as follows.

$$\text{Eq. (33)}: \sigma^* = \frac{5.3 \cdot 10^{-3}\ \text{N/m} \cdot 724.4\ \text{kg/m}^3}{30^2\ \text{kg}^2/\text{m}^4\ \text{s}^2 \cdot 0.364\ \text{m}} = 0.0117;$$

$$\text{Eq. (34)}: \ell^* = \frac{0.364}{0.012} = 30.3; \quad \text{Eq. (35)}: \varrho^* = \frac{20.23}{724.4} = 0.0279;$$

$$\text{Eq. (36)}: C = 0.25, \ \text{da}\ \ell^* < 50.$$

Since $\varrho^* < 0.15$, the range of validity given under the heading (a) applies. Thus

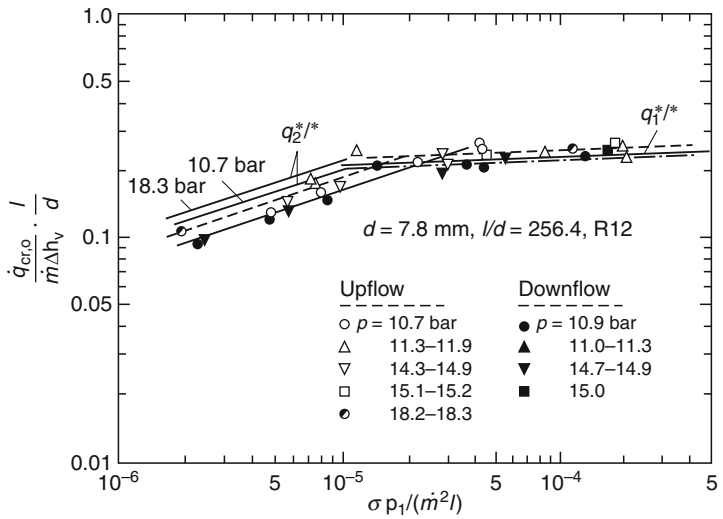
$$\text{Eq. (27)}: \quad q_1^* = 6.81 \cdot 10^{-3}; \ \text{Eq. (28)}: \ q_2^* = 12.87 \cdot 10^{-3}.$$

$$q_1^* < q_2^* \rightarrow q^* = q_1^*.$$

$$\text{Eq. (39)}: K_1 = 1.26; \ \text{Eq. (40)}: K_2 = 0.269. \ K_1 > K_2 \rightarrow K = K_1.$$

$$\text{Eq. (32)}: \dot{q}_{cr,o} = q_1^* \dot{m} \Delta h_v = 6.81 \cdot 10^{-3} \cdot 30\ \text{kg/m}^2\ \text{s}$$

$$173.8\ \text{kJ/kg} = 35.5\ \text{kW/m}^2.$$



H3.5. Fig. 37. Comparison between upward and downward flow in vertical tubes [67].

Eq. (26) : $\dot{q}_{cr} = 35.5\ \mathrm{kW/m^2} \cdot [1 - 1.26(-0.1)] = 40\ \mathrm{kW/m^2}$.

The critical vapor mass fraction can then be obtained from Eq. (42), that is,

$$\dot{x}_{cr} = \left(\frac{4 \cdot 40\ \mathrm{kW/m^2}}{30\ \mathrm{kg/m^2\ s} \cdot 173.8\ \mathrm{kJ/kg}} \right) \cdot 30.3 - 0.1 = 0.83.$$

Example 11

Refrigerant R 12 flows upward in a vertical evaporator tube subjected to uniform axial heating. Determine the critical heat flux and the critical vapor mass fraction.

Inner diameter of tube	$d = 14 \cdot 10^{-3}$ m	
Length of tube	$\ell = 2$ m	
Pressure	$p = 10$ bar	
Mass flow rate	$\dot{M} = 0.17$ kg/s	
Inlet temperature	$\vartheta_{inl} = 28.94°C$	
Properties of R 12	$\vartheta_s = 41.5°C$;	$\varrho_\ell = 1245.6$ kg/m^3;
(at 10 bar)	$\varrho_g = 56.90$ kg/m^3;	$h' = 240.2$ kJ/kg;
	$\Delta h_v = 128.3$ kJ/kg.	

Specific heat capacity of the liquid between ϑ_{inl} and ϑ_s:

$$c = 1.02\ \mathrm{kJ/kg\ K}; \quad \sigma = 6.5 \cdot 10^{-3}\ \mathrm{N/m}.$$

Vapor mass fraction at the inlet cross section:

$$h_{inl} = h' - c(\vartheta_s - \vartheta_{inl}).$$

$$\begin{aligned} \text{Hence } \dot{x}_{inl} &= -c(\vartheta_s - \vartheta_{inl})/\Delta h_v \\ &= [1.02\ \mathrm{kJ/kg\ K}\ (41.5 - 28.94)\ \mathrm{K}]/128.3\ \mathrm{kJ/kg} \\ &= -0.1. \end{aligned}$$

$$\text{Mass velocity } \dot{m} = \frac{4\dot{M}}{\pi d^2} = \frac{4 \cdot 0.17\ \mathrm{kg/s}}{\pi\, 0.014^2\ \mathrm{m^2}} = 1{,}104\ \mathrm{kg/m^2\ s}.$$

The calculation proceeds as follows (cf. Example 10).

$$\sigma^* = 3.33 \cdot 10^{-6}; \ell = 142.9; \varrho^* = 0.0457.$$

Since ℓ^* lies between 50 and 150, Eq. (37) yields $C = 0.33$.

Since $\varrho^* < 0.15$, the range of validity given under the heading (a) applies.

$$q_1^* = 1.36 \cdot 10^{-3};\ q_2^* = 0.686 \cdot 10^{-3};\ q_1^* > q_1^*;$$
$$q_3^* = 0.731 \cdot 10^{-3};\ q_2^* < q_3^* \rightarrow q^* = q_2^*.$$
$$K_1 = 1.34;\ K_2 = 1.63;\ K_1 < K_2 \rightarrow K = K_2.$$

$$\dot{q}_{cr,\ell} = 0.686 \cdot 10^{-3} \cdot 1104\ \mathrm{kg/m^2\ s} \cdot 128.3\ \mathrm{kJ/kg} = 97.2\ \mathrm{kW/m^2}.$$

$$\dot{q}_\ell = 97.2\ \mathrm{kW/m^2}\ [1 - 1.63(-0.1)] = 113\ \mathrm{kW/m^2}.$$

$$\dot{x}_{cr} = \left(\frac{4 \cdot 113\ \mathrm{kW/m^2}}{1{,}104\ \mathrm{kg/m^2\ s} \cdot 128.3\ \mathrm{kJ/kg}} \right) \cdot 142.9 - 0.1 = 0.36.$$

3.1.2 Horizontal and Inclined Tubes

The peculiarities of the boiling crisis in nonvertical tubes have already been dealt with in Sect. 2.1.2. There is no qualitative difference between the behavior of water and that of other fluids. For this reason and also because systematic studies have, as yet, been confined to water, the mathematical method described in Sect. 2.1.2 should also be adopted for other fluids. The figures thus obtained apply to water and can be converted into the corresponding figures for the fluid by the method proposed by *Ahmad* (Sect. 3.1.7). The procedure is as follows:

- Conversion of the properties of the fluid into the corresponding figures for water as laid down in Sect. 3.1.7.
- Determination of the Froude number from Eq. (6) with the figures thus obtained for water. The critical vapor mass fraction $\dot{x}_{cr}$ is calculated as described in Sect. 2.1.1.
- If $Fr > 10$, the angle of inclination of the tube does not have any effect on the boiling crisis. As a first approximation, this will also apply to the fluid concerned. Consequently, the boiling crisis should be determined by the method given in Sect. 3.1.1.
- If $Fr < 10$, the angle of inclination of the tube is likely to exert an effect. In this case, the values for water obtained as described above should be taken for the determination of the boiling crisis.

Details of this procedure are given in Example 14.

Note. In a study on the critical heat flux of water and Refrigerant R 12 in horizontal and vertical tubes, Merilo [10] observed that very good results were obtained by adopting the Ahmad method for converting the conditions for critical boiling in vertical tubes. In horizontal tubes, however, the equivalent critical heat flux for R 12, that is, the value of $\dot{q}_{cr}$ obtained by converting the conditions for water, was always less than that for water. At the most, the figures differed by a factor of 1.7. It cannot be said at present whether this finding is of general validity, and further studies on the subject would be required to clarify the matter. For this reason, a corresponding safety factor should be included in the values of the critical heat flux calculated for other fluids if $Fr < 10$.

3.1.3 Microchannels

Flow boiling in microchannels are often used as a cooling method for high heat flux systems such as electronic chips or laser diodes. Studies with microchannel tubes [68] and rectangular microchannels [69] revealed strong dependence of the critical heat flux on mass velocity, heated length and equivalent microchannel diameter but – in contrast to macrochannels – no significant influence of liquid subcooling.

Wojtan et al. [68] carried out experiments with refrigerants R 134a and R 245fa flowing in tubes of 0.5 and 0.8 mm internal diameter. Other experimental system conditions were : heated length 1 : 20–70 mm, mass velocity $\dot{m}$: 400–1,600 kg/m^2 s, heat flux $\dot{q}$: 3.2–600 kW/m^2, saturation temperature : 30°C, 35°C, inlet subcooling : 2–15 K, *We*-number: 293–21,044, ϱ_g/ϱ_ℓ: 0.009–0.041, l/d : 25-141. The authors proposed the following modified Katto/Ohno correlation

$$\dot{q}_{cr} = 0.437\ \dot{m}\ \Delta h_v\, We^{-0.24} \left(\frac{\varrho_g}{\varrho_\ell} \right)^{0.073} \left(\frac{l}{d} \right)^{-0.72} \qquad (43)$$

with the liquid Weber number

$$We = \frac{\dot{m}^2 l}{\varrho_\ell \sigma} \tag{44}$$

Wojtan et al.'s experimental data are predicted with the mean absolute error of 7.6 % with 82.4 % of data falling within a ±15 % error band.

Park and Thome [69] carried out experiments with refrigerants R 134a, R 236fa, and R 245fa flowing in arrays of vertically arranged rectangular micro channels. One test section had 20 parallel rectangular channels, 467 µm wide and 4,052 µm deep, a second one had 29 channels, 199 µm wide 756 µm deep. They found that using the heated equivalent diameter $d_{eq} = d$ defined as : (4x flow area)/heated perimeter and the actual mass velocity $\dot{m} = \dot{M}/(\text{width} \times \text{depth})$ their data matched well with the correlation of Wojtan et al., Eqs. (43) and (44).

3.1.4 Helical Coils

No qualitative difference exists between the effect of water and that of other fluids on the boiling crisis in helical coils (cf. Sect. 2.1.3). Since design data derived from systematic studies on other fluids are not yet available, the method of calculation recommended is that devised by Jensen and Bergles [70]. This method has been based on measurements with Refrigerant R 113. It differs from, say, the *Katto/Ohno* method (Sect. 3.1.1) in that the authors assume the validity of the local conditions hypothesis, which states that the critical heat flux is uniquely defined by the local values of the main system parameters.

The critical heat flux in subcooled boiling ($\dot{x}_{cr} \leq -0.1$) can be determined from the following equation:

$$\dot{q}_{cr} = KG\dot{m}\Delta h_v Re^{-0.6}[1.234 - 3.873 \cdot 10^{-6} Re_\ell + (-1.367 - 3.15 \cdot 10^{-6} Re_\ell)\dot{x}]. \tag{45}$$

The dimensionless K in Eq. (45) allows for the effect of the centrifugal forces in the coil and is given by

$$K = 0.769\left(\frac{\dot{m}^2}{\varrho_\ell^2 g D_W}\right)^{-0.26} \quad \text{for} \quad \frac{\dot{m}^2}{\varrho_\ell^2 g d} > 10 \tag{46}$$

and

$$K = 1 \quad \text{for} \quad \frac{\dot{m}^2}{\varrho_\ell^2 g d}. \tag{47}$$

At low fluid velocities, allowance must be made for the effect of the buoyancy of the vapor in the two-phase mixture. Thus, Eq. (45) contains a factor C that is a function of the Reynolds and Grashof numbers and is defined by

$$C = 0.4(Gr/Re_\ell^2)^{-0.21} \quad \text{for } Gr/Re_\ell^2 \geq 0.0127 \tag{48}$$

and

$$C = 1 \quad \text{for } Gr/Re_\ell^2 < 0.0127 \tag{49}$$

The Reynolds and Grashof numbers in Eqs. (45), (48), and (49) are given by

$$Re_\ell = \frac{\dot{m} d}{\eta_\ell} \tag{50}$$

and

$$Gr = \frac{g d^3 (\varrho_\ell - \varrho_g)\varrho_\ell}{\eta_\ell^2}. \tag{51}$$

On an average, figures calculated from Eq. (45) deviated by 7.4% from values obtained in measurements. The maximum deviation was 45.3%.

The equation that applies for the boiling crisis in saturated boiling ($\dot{x}_{cr} \geq 0.1$) for $\dot{m} > 950$ kg/m^2 s is

$$\dot{q}_{cr} = 1.713 \cdot 10^4 Re_g^{-1.143} \dot{x}^{-0.436} \cdot (d/D_W)^{0.31} \dot{m}\Delta h_v \tag{52}$$

The corresponding equation for $\dot{m} \leq 950$ kg/m^2 s is

$$\dot{q}_{cr} = 4.09 \cdot 10^{-6} Re_g^{0.5} \dot{x}^{-0.460} (d/D_W)^{0.17} \dot{m}\Delta h_v \tag{53}$$

In this case, too, the Reynolds number is defined by Eq. (50) except that the dynamic viscosity of the vapor η_g is substituted for that of the liquid.

On an average, figures calculated from Eqs. (52) and (53) deviated by 3% from measured values. The maximum deviation was 14.1%. All the values for the fluid properties expressed in Eqs. (45–53) apply to the conditions at saturation.

No data could be obtained by measurement in the $-0.1 < \dot{x}_{cr} < 0.1$ range, in which the transition from bubble to annular flow occurs. In this case, the boiling crisis cannot be uniquely located, because it may occur several times along the path formed by the coil [70]. Jensen and Bergles [70] demonstrated that the only means of avoiding operating conditions of this nature in evaporator coils is to take resort to one of the following alternatives:

- Ensuring that the critical vapor mass fraction at the end of the helical tube is less than −0.1 ($\dot{x}_{cr} < -0.1$).

  or

- Ensuring that the critical heat flux in saturated boiling {Eqs. (52) and (53)} is lower than that in subcooled boiling {Eqs. (45–51)} when $\dot{x} = -0.1$.

The *Jensen* and *Bergles* method has been derived solely from measurements on the one fluid (R 113), at the one pressure (9.4 bar), and in tubes of the same diameter (d = 7.62 mm). The other system parameters were varied as follows: $\dot{m}$ = 570–5,470 kg/m^{2}s; $\dot{q}_{cr}$ = 54–800 kW/m^2; $\dot{x}_{cr}$ = −0.55–0.94; D_w = 117.5–409.6 mm; ℓ = 635–1,295 m; $\Delta T = T_s - T_{inl}$ = 0–110 K. (ΔT is the subcooling at the inlet.)

The term $\dot{q}_{cr}/\dot{m}\Delta h_v$, which was also introduced by *Katto* and *Ohno*, allows Eqs. (45), (52), and (53) to be expressed in a dimensionless form. Nevertheless, the restricted range of parameters within which the measurements were performed detracts from the concept of general validity for this method of calculation. The reliability must still be verified by future measurements. Therefore, larger factors of safety must be allowed in the design of evaporator coils that have to cope with parameters that differ significantly from those in the experiments mentioned above [70].

Example 12

R 12 is to be evaporated at a system pressure of $p = 1$ bar in a helical-tube evaporator. The mass velocity is 2,000 kg/m^{2}s, and the refrigerant is subcooled when it enters the evaporator ($\dot{x}_{\text{inl}} = -0.15$). The diameter of the windings in the helical coil is $D_w = 0.5$ m, the length of the tube is $\ell = 6$ m, and the tube inner diameter is $d = 10 \cdot 10^{-3}$. The heat flux remains constant over the length of the coil. What would its value be if the boiling crisis were to occur just at the end of the coil?

Properties of R 12 at 1 bar

$$\vartheta_\ell = -30^\circ\text{C}; \varrho_\ell = 1489.3 \text{ kg/m}^3; \varrho_g = 6.22 \text{ kg/m}^3;$$
$$\Delta h_v = 166.1 \text{ kJ/kg}; \quad \eta_\ell = 370.5 \cdot 10^{-6} \text{ Pa s};$$
$$\eta_g = 10.14 \cdot 10^{-6} \text{ Pa s}.$$

The Reynolds number is determined from Eq. (50), but the value to be inserted for the dynamic viscosity is that of the vapor because saturated boiling occurs ($\dot{x}_{\text{cr}} > 0.1$). Thus

$$Re_g = \frac{2{,}000 \text{ kg/m}^2 \text{ s} \cdot 10 \cdot 10^{-3} \text{ m}}{10.14 \cdot 10^6 \text{ Pa s}} = 1.97 \cdot 10^6.$$

Since the boiling crisis in this case occurs during saturated boiling, Eq. (52) applies. The critical value must be taken for the vapor mass fraction, and it is related to $\dot{q}_{\text{cr}}$ through the energy balance. Inserting Eq. (42) in Eq. (52) gives rise to an implicit equation for $\dot{x}_{\text{cr}}$, which can be solved by iteration. The following figures are obtained after a few stages: $\dot{x}_{\text{cr}} = 0.76$ and $\dot{q}_{\text{cr}} = 126.4$ kW/m^2.

Check for instability:

The critical heat flux $\dot{q}_{\text{cr}}$ in saturated boiling must be less than that in subcooled boiling (indicated below by the symbol $\dot{q}_{\text{cr,sub}}$) if $\dot{x} = -0.1$ is inserted in Eq. (45).

Determination of the dimensionless numbers in Eq. (45) Eqs. (46) and (47):

$$\frac{\dot{m}^2}{\varrho_\ell^2 g d} = 18.38 > 10 \rightarrow$$

$$K = 0.769 \left(\frac{2{,}000^2 \text{ kg}^2/\text{m}^4 \text{ s}^2}{1489.3^2 \text{ kg}^2/\text{m}^6 \cdot 9.81 \text{ m/s}^2 \cdot 0.5 \text{ m}} \right)^{-0.26} = 0.997;$$

Eqn (51):

$$Gr = \frac{9.81 \text{ m/s}^2 \cdot 10^{-6} \text{ m}^3 (1489.3 - 6.22) \cdot 1489.3 \text{ kg}^2/\text{m}^6}{370.5^2 \cdot 10^{-12} \text{ Pa}^2 \text{ s}^2}$$
$$= 1.58 \cdot 10^8;$$

$$\text{Eq. (50)}: \quad Re_\ell = \frac{2{,}000 \text{ kg/m}^2 \text{ s} \cdot 10 \cdot 10^{-3} \text{ m}}{370.5 \cdot 10^{-6} \text{ Pa s}} = 5.4 \cdot 10^4;$$

Eqn (48) and (49):

$$Gr/Re_\ell^2 \simeq 0.054 > 0.0127 \rightarrow C = 0.4 \cdot 0.054^{-0.21} = 0.74.$$

Eq. (45):

$$\dot{q}_{\text{cr,sub}} = 0.997 \cdot 0.74 \cdot 2{,}000 \text{ kg/m}^2 \text{ s} \cdot 166.1 \text{ kJ/kg}$$
$$\cdot (5.4 \cdot 10^4)^{-0.6} [1.234 - 3.873 \cdot 10^{-6} \cdot 5.4 \cdot 10^4$$
$$+ (-1.367 - 3.15 \cdot 10^{-6} \cdot 5.4 \cdot 10^4)(-0.1)]$$
$$= 417 \text{ kW/m}^2.$$

Since $\dot{q}_{\text{cr}} < \dot{q}_{\text{cr,sub}}$, instability does not occur.

3.1.5 Effect of Nonuniform Heating

Nonuniform Peripheral Heating

The method presented in Sect. 2.1.4 for the determination of the critical heat flux in nonuniformly heated tubes can also be applied to liquids other than water.

Nonuniform Axial Heating

The procedure to adopt in this case is the same as that described in Sect. 2.1.4. Both the "local conditions" and the "integral power" hypotheses can be adopted, and the smaller of the two values thus obtained should be taken as the critical heat flux. The ranges of parameters within which the equations are valid are given in Sect. 3. Thus, the first step is to vary the value of ℓ for a uniformly heated tube in order to determine the critical heat flux as a function of the length. The next step is to apply the two hypotheses (Figs. 23 and 24) to check the margin of safety between the figures calculated and the conditions for critical boiling. In this case it is advisable to locate the reference point A at the commencement of the heated length.

3.1.6 Flow through Vertical Annuli

The procedure to adopt in this case is that given in Sect. 2.2.1.

Heat Applied through the Wall of the Outer Tube

The critical heat flux is determined from Eqs. (26–41). The value to insert for the tube diameter is that of the outer tube (d_o in Fig. 25). The critical vapor mass fraction at the end of the heated section is obtained from the energy balance, that is,

$$\dot{x}_{\text{cr,o}} = \frac{4\dot{q}_{\text{cr}}}{\dot{m}\Delta h_v} \frac{\ell}{d_o} \frac{1}{1 - \left(\frac{d}{d_o}\right)^2} + \dot{x}_{\text{inl}}. \tag{54}$$

Heat Applied through the Wall of the Inner Tube

As a first approximation, the critical heat flux in the inner tube is identical to that in the wall of the outer tube. Hence Eqs. (26–41) are again adopted for the determination of $\dot{q}_{\text{cr}}$, and the value to be inserted for the diameter is again $d = d_o$. The critical vapor mass fraction at the end of the heated section is then given by

$$\dot{x}_{\text{cr,i}} = \frac{4\dot{q}_{\text{cr}}}{\dot{m}\Delta h_v} \frac{\ell}{d} \frac{1}{1 - \left(\frac{d_o}{d}\right)^2 - 1} + \dot{x}_{\text{inl}}. \tag{55}$$

Heat Applied through Both Tube Walls

Here, too, the method to be adopted is that given in Sect. 2.2.1. The procedure is as follows:

- The critical heat flux is determined from Eqs. (26–41) on the assumption that $d = d_o$.
- The critical vapor mass fractions $\dot{x}_{\text{cr,o}}$ and $\dot{x}_{\text{cr,i}}$ are calculated from Eqs. (54) and (55).
- The true critical vapor mass fraction $\dot{x}_{\text{cr}}$ is determined by interpolation as recommended in Sect. 2.2.1.
- The maximum heat flow rate that can be transferred $\dot{Q}_{\text{act}}$ and the heat fluxes $\dot{q}_o$ and $\dot{q}_i$ in the inner and outer tube walls are calculated from Eqs. (13–15).

Example 13

Refrigerant R 114 flows upward in a vertical annulus of $d_o = 25 \cdot 10^{-3}$ m, $d = 15 \cdot 10^{-3}$ m, and a heated length of 4 m. The pressure is $p = 5$ bar; and the mass velocity $\dot{m} = 2{,}500$ kg/m^2 s. The fluid at the inlet cross section is subcooled, that is, $\dot{x}_{inl} = -0.05$, and the annulus is heated through both tube walls {power ratio $y = \dot{Q}_o/(\dot{Q}_o + \dot{Q}_i) = 0.5$}. The total heat applied must be 80% of the maximum feasible. What are the values for the heat flux in the outer and inner tubes?

Properties of R 114 at 5 bar

$$\vartheta_s = 54^\circ C; \varrho_\ell = 1361.4\,\text{kg/m}^3; \varrho_g = 36.07\,\text{kg/m}^3$$

$$\Delta h_v = 115.49\,\text{kJ/kg}; \sigma = 9.2 \cdot 10^{-3}\,\text{N/cm}.$$

Procedure (cf. Example 10)

$$\sigma^* = 5.0 \cdot 10^{-7}; \ell^* = \ell/d_0 = 160; \varrho^* = 0.0265.$$

Since $\ell^* > 150$, Eq. (38) applies and yields $C = 0.34$.

Since $\varrho^* > 0.15$, the range of validity given under the heading (a) applies

$$q_1^* = 1.14 \cdot 10^{-3}; q_2^* = 0.327 \cdot 10^{-3}; q_3^* = 0.297 \cdot 10^{-3}.$$

Therefore, $q_1{}^* > q_2{}^*$ and $q_2{}^* > q_3{}^* \rightarrow q^* = q_3{}^*$.

$$K_1 = 1.43 \text{ and } K_2 = 3.17; K_1 < K_2 \longrightarrow K = K_2.$$

$\dot{q}_{cr,o} = 0.297 \cdot 10^{-3} \cdot 2{,}500\,\text{kg/m}^2\text{s} \cdot 115.49\,\text{kJ/kg} = 85.9\,\text{kW/m}^2$;
$\dot{q}_{cr} = 85.9\,\text{kW/m}^2[1 - 3.17(-0.05)] = 99.5\,\text{kW/m}^2$.

Applying Eq. (54) for the critical vapor mass fraction $\dot{x}_{cr,o}$:

$$\dot{x}_{cr,o} = \frac{4 \cdot 99.5\,\text{kW/m}^2 \cdot 4\,\text{m}}{2{,}500\,\text{kg/m}^2\,\text{s} \cdot 115.49\,\text{kJ/kg} \cdot 25 \cdot 10^{-3}\,\text{m}\,[(15/25)^2]} - 0.05 = 0.295.$$

Applying Eq. (55) for $\dot{x}_{cr,i}$:

$$\dot{x}_{cr,i} = \frac{4 \cdot 99.5\,\text{kW/m}^2 \cdot 4\,\text{m}}{2{,}500\,\text{kg/m}^2\,\text{s} \cdot 115.49\,\text{kJ/kg} \cdot 15 \cdot 10^{-3}\,\text{m}\,[(15/25)^2 - 1]} - 0.05 = 0.157.$$

Since $0 < y < 0.8$, the following linear interpolation yields $\dot{x}_{cr}$:

$$\dot{x}_{cr} = \left(\frac{\dot{x}_{cr.o} - \dot{x}_{cr.i}}{0.8}\right) \cdot 0.5 + \dot{x}_{cr.i} = 0.243.$$

Maximum rate at which heat can be transferred {Eq. (13)}:

$$\dot{Q}_{act,max} = (\dot{x}_{cr} - \dot{x}_{in1})\Delta h_v \dot{m} f = (0.243 + 0.05) \cdot 115.49\,\text{kJ/kg} \cdot 2{,}500\,\text{kg/m}^2\,\text{s}\,(\pi/4) \cdot (25^2 - 15^2) \cdot 10^{-6}\,\text{m}^2 = 26.58\,\text{kW}.$$

Heater setting: $\dot{Q}_{act} = 0.8 \cdot \dot{Q}_{actmax} = 21.26$ kW.

Heat fluxes in the outer and inner tube walls:

$$\text{Eq. (14)}: \quad \dot{q}_o = \frac{y\dot{Q}_{act}}{\pi d_o \ell} = 33.84\,\text{kW/m}^2;$$

$$\text{Eq. (15)}: \quad \dot{q}_i = \frac{(1-y)\dot{Q}_{act}}{\pi d \ell} = 56.39\,\text{kW/m}^2.$$

3.1.7 Application to Other Liquids by Converting the Results Obtained on Water (Ahmad Method)

The theory of mathematical similarity has been applied for converting the parameters that describe the boiling crisis in water, which is by far the liquid that has been most frequently investigated, into the corresponding parameters for other fluids. The *Ahmad* method [71] is currently the best of these, and it was specially developed for the conversion of the critical boiling parameters involved in upward flow through vertical channels [72–74]. The requirements that must be met to establish similarity in this method are listed in Table 6. The stipulation is that the system parameters for the fluids concerned must be selected so that the dimensionless numbers required for the calculation agree. The dimensionless number for converting the mass velocity is ψ, which is defined by

$$\psi = \frac{\dot{m} d_h}{\eta'} \left(\sqrt{\frac{\gamma}{\varrho'}} \frac{\eta'}{d_h}\right)^{2/3} (\eta'/\eta'')^{1/8} \tag{56}$$

where

$$\gamma = \left|\frac{d(\varrho'/\varrho'')}{dp}\right|. \tag{57}$$

The critical heat flux $\dot{q}_{cr}$ and vapor mass fraction $\dot{x}_{cr}$ at the point where the boiling crisis is located are related as follows through the energy balance for the channel:

H3.5. Table 6. Conditions for similarity in the *Ahmad* method for upward flow in vertical tubes

Parameter	Dimensionless number	Range of validity [72–74]	
		Tube and annulus[a]	Rod bundle 4, 9, 19, 25 rods
System pressure	ϱ_ℓ/ϱ_g	7 to 980	3 to 20
Mass velocity	ψ {Eq. (56)}	5 to 100	5 to 40
Vapor mass fraction at boiling crisis	$\dot{x}_{cr}$	−0.4 to 0.9	−0.35 to 0.9
Critical heat flux	$\dot{q}_{cr}/(\dot{m}\Delta h_v)$	No limit	No limit
Geometry (remains unchanged)			
Vapor mass fraction at channel inlet	$\dot{x}_{inl}$	−0.02 to 0.8	−0.04 to −0.8
Ratio of heated length to hydraulic diameter	ℓ/d_h	60 to 310	60 to 250
Fluids (used for the test; the validity for other fluids is not excluded)		Water, Refrigerant R 12, R 21, R 22, R 113, R 114, CO_2	Water, Refrigerant R 12

[a]The only liquids for which the annular channel was checked were water and R 12

$$\dot{x}_{cr} - \dot{x}_{inl} = \frac{A_{hld}}{A} \frac{\dot{q}_{cr}}{\dot{m} \Delta h_v}. \quad (58)$$

where A_{htd} is the area of the heated surface and A is the cross-sectional area of the flow channel.

An example for the conversion of the critical boiling parameters in a 5 × 5 rod bundle (cf. Sect. 2.2.2) is illustrated in Fig. 38. The curves shown have been drawn through points that represent the critical vapor mass fraction for water corresponding to three inlet conditions $\dot{x}_{inl}$ for the liquid at a constant density ratio. The diagram allows the critical vapor mass fractions for the fluid concerned, for example, R 12, to be read off against the value of ψ calculated from Eq. (56). The critical heat flux for a geometrically similar channel, e.g. one through which R 12 flows, can then be determined from Eq. (58).

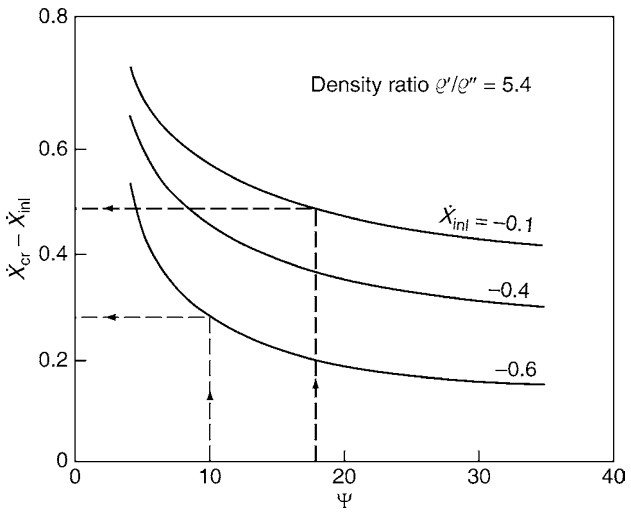
If the necessary experimental values for water are not available, the system parameters for the fluid concerned must first of all be converted into the equivalent values for water under similar conditions, as listed in Table 6. These values allow the critical boiling parameters $(\dot{q}_{cr}; \dot{x}_{cr})$ for water to be determined as described in Sect. 2. The conversion of these parameters, in turn, into the corresponding values for the fluid concerned proceeds in accordance with the instructions implied in Table 6.

The *Ahmad* method can be successfully applied if the correlations for heat transfer in single-phase flow of water are also the same as those for the fluid concerned. If this is not the case, for example, for molten metals, the method involves greater errors.

Example 14

R 12 flows under the following conditions in a horizontal, uniformly heated tube:

Tube inner diameter $d = 20 \cdot 10^{-3}$m	
Pressure	p = 25 bar
Mass velocity	$\dot{m} = 500\,kg/m^2s$
Heat flux	$\dot{q} = 34\,kW/m^2$



H3.5. Fig. 38. Determination of the conditions for critical boiling by the *Ahmad* method.

What is the length of the path through which the fluid must flow before the boiling crisis occurs on the crest and underside of the tube?

The first step is to convert the system parameters for the flow of R 12 into the corresponding values for water by means of Table 6.

Inner diameter of tube

Since the geometry remains the same, $d = d_h = 20 \cdot 10^{-3}$m.

Properties of R 12 at 25 bar

$$\vartheta_\ell = 83.4°C; \varrho_\ell = \varrho' = 1032.9\,kg/m^3; \Delta h_v = 90.52\,kJ/kg;$$
$$\eta_\ell = \eta' = 157.9 \cdot 10^{-6}\,Pa\,s; \eta_g = \eta'' = 17.42 \cdot 10^{-6}\,Pa\,s.$$

Pressure. The density ratio ϱ_ℓ/ϱ_g for R 12 at 25 bar is the same as that for water at 147.5 bar.

Properties of water at 147.5 bar; $\vartheta_s = 340.8°C; \varrho_\ell = \varrho' = 607.66\,kg/m^3; \varrho_g = \varrho'' = 94.24\,kg/m^3; \Delta h_v = 1{,}016\,kJ/kg;$ $\eta_\ell = \eta' = 75.22 \cdot 10^{-6}$ Pa s; $\eta_g = \eta'' = 25.31 \cdot 10^{-6}$ Pa s.

Mass velocity. The dimensionless number ψ {Eq. (56)} must be the same for both fluids. Inserting values taken from steam tables in Eq. (57) gives

$$|\gamma|_{R12} = 0.424\,l/bar; \quad |\gamma|_{H_2O} = 0.0869\,l/bar.$$

Therefore,

$$\psi_{R12} = \left(\frac{500\,kg/m^2\,s \cdot 0.02\,m}{157.9 \cdot 10^{-6}\,Pa\,s}\right)\left[\sqrt{\frac{0.424\,l/bar}{1032.9\,kg/m^3}} \cdot \left(\frac{157.9 \cdot 10^{-6}\,Pa\,s}{0.02\,m}\right)\right]^{2/3} \cdot \left(\frac{157.9}{17.42}\right)^{1/8} = 5.3.$$

Inserting $\psi = \psi_{R\ 12}$ and the appropriate values for water in Eq. (56) and solving for $\dot{m}$ gives $\dot{m}_{H2O} = 638\,kg/m^2\,s$.

Critical heat flux. The *Ahmad* method requires that the dimensionless number $\dot{q}_{cr}/\dot{m}\ \Delta h_v$ must be the same for both fluids. It therefore follows that

$$\dot{q}_{cr.H_2O} = \frac{34\,kW/m^2 \cdot 638\,kg/m^2\,s \cdot 1016.1\,kJ/kg}{500\,kg/m^2\,s \cdot 90.52\,kJ/kg} = 487.1\,kW/m^2.$$

The critical vapor mass fraction is calculated from Eq. (1) or Eq. (4). In this case, it is Eq. (4) that applies. Thus

$$\dot{x}_{cr} = 32.302 \cdot 487.1^{-0.125} \cdot 638^{-0.333} \cdot 20^{-0.07} \cdot e^{-0.00795 \cdot 147.5} = 0.44.$$

Equation (6) yields

$$Fr = \frac{0.44 \cdot 638\,kg/m^2\,s}{\sqrt{94.24\,kg/m^3 \cdot 9.81\,m/s^2 \cdot 0.02\,m\,(607.66 - 94.24)\,kg/m^3}} = 2.85.$$

Since $Fr < 10$, it can be expected that the inclination of the tube exerts an effect. Thus inserting the numerical value for Fr in Eq. (7) gives $\Delta\dot{x}_{cr} = 16/(2 + 2.85)^2 = 0.68$.

Equation (8) yields

$$\dot{x}_{cr,up} = 0.44 - \frac{0.68}{2} = 0.095 \quad \text{and} \quad \dot{x}_{cr,low} = 0.44 + \frac{0.68}{2} = 0.78.$$

It follows from the energy balance {Eq. (42)} that

$$\ell = \frac{\dot{m}\Delta h_v}{\dot{q}_{cr}} \frac{d}{4}(\dot{x}_{cr} - \dot{x}_{inl}).$$

According to definition, the numerical values for the terms in the equation for ℓ are the same in both cases. Hence, the following applies for the flow of R 12 and water:

$$\ell_{cr,up} = \left(\frac{500\,\text{kg/m}^2\,\text{s} \cdot 90.52\,\text{kJ/kg}}{34\,\text{kW/m}^2}\right)\left(\frac{0.02\,\text{m}}{4}\right)(0.095 + 0.1)$$
$$= 1.3\,\text{m};$$
$$\ell_{cr,low} = 5.8\,\text{m}.$$

3.2 Binary Mixtures

The critical heat flux in a binary mixture can be determined by the critical heat fluxes of the individual components – calculated for the same pressure p, mass flux $\dot{m}$ and quality $\dot{x}$ – and by the molar fraction of the more volatile component within the liquid phase (cf. the Stephan–Körner equation for the determination of heat transfer during boiling of binary mixtures [75]):

$$\dot{q}_{cr}^{Mix} = \dot{q}_{cr,\,id}^{Mix}(1 + X) \tag{59}$$

with

$$\dot{q}_{cr,\,id}^{Mix} = [\dot{q}_{cr}^{MV}\tilde{x} + \dot{q}_{cr}^{LV}(1 - \tilde{x})]. \tag{60}$$

$\dot{q}_{cr}^{MV}$ and $\dot{q}_{cr}^{LV}$ are the critical heat fluxes of the pure more volatile and less volatile components with the lower and higher boiling point, respectively (Fig. 39), determined by the method described in Sect. 2 or Sect. 3.1. X is a factor for which the following is true: $X \geqq 0$.

3.2.1 Refrigerant Mixtures

Based on measurements of *Marroquin Nisch* with mixtures of the refrigerants R 114/R 13B1 and R 142b/R 22 [76] the following relationship has been derived for X in Eq. (59):

$$X = \left\{3.2 \cdot 10^5 \frac{(|\tilde{y} - \tilde{x}|)^{2.7}}{Re_l^{LV}} + 9.6 \frac{(|\tilde{y} - \tilde{x})^{1.9}}{(Re_l^{LV})^{0.1}} \cdot \left[\frac{T_s^{MV}}{T_s^{Mix} - T_s^{MV}}\right] P*^{2.2}\right\} \cdot e^{-3(0.2+\dot{x}_A)} \tag{61}$$

with

$$Re_l^{LV} = \frac{\dot{m}\,d_h}{\eta_l^{LV}} \tag{62}$$

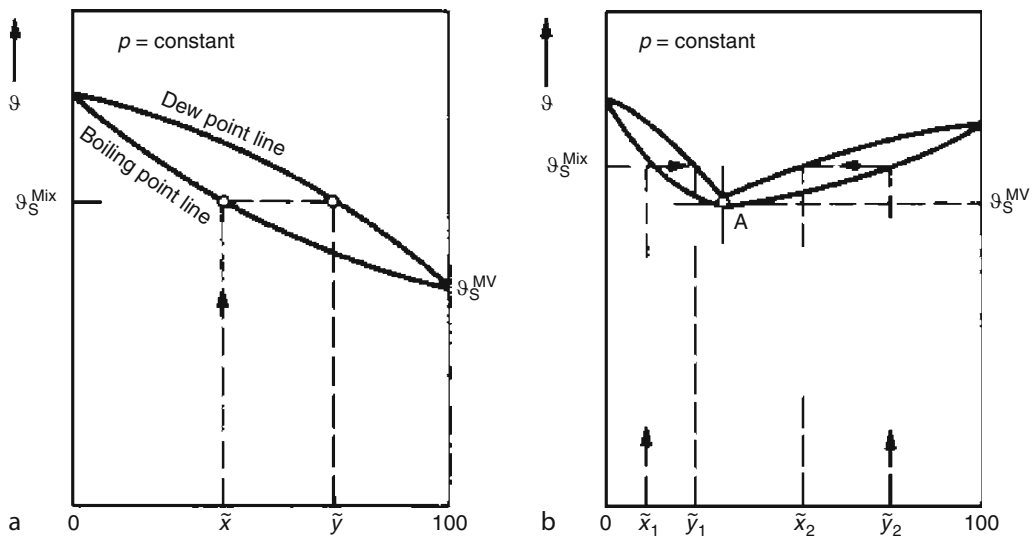
and

$$P^* = \frac{1}{2}\left(\frac{P}{P_c^{LV}} + \frac{P}{P_c^{MV}}\right) \tag{63}$$

$\tilde{y}$ and $\tilde{x}$ are the molare fractions of the liquid and vapor phase, respectively, in the more volatile component, T_s^{Mix} is the temperature of the mixture on the boiling point curve calculated by the method given in Subchap. D5.1 "Calculation of Vapour liquid equilibria" and T_s^{MV} is the boiling point of the more volatile component, calculated by the method given in Subchap. D5.1 "Calculation of Vapour liquid equilibria", both temperatures in K (Fig. 39, $\vartheta_s = T_S - 273.15$ K). $\dot{x}_A$ is the quality at the outlet of the evaporator section. d_h in eqn. (62) is the hydraulic diameter of the flow channel and η_l^{LV} the dynamic viscosity of the liquid phase of the less volatile component at T_s^{Mix}. P_c^{LV} and P_c^{MV} in Eq. (63) are the critical pressures of the individual components.

Equation (61) is based on measurements with mixtures of the refrigerants R 114/R 13B1 and R 142b/R 22 [75] in the parameter ranges $0.26 \leq p/p_c \leq 0.61$; $-0.2 \leq \dot{x}_A \leq +0.2$; $1{,}000 \leq \dot{m} \leq 2{,}000$ kg/m^2 s; $3.4 \leq l/d \leq 38.8$, with l as the heated channel length and d as the tube diameter.

The outlet quality $\dot{x}_A$ can be determined in accordance with Eq. (1), Subchap. H3.4, under the assumption of



H3.5. Fig. 39. Equilibrium curves for binary mixtures: (**a**) without and (**b**) with an azeotropic point A and a boiling point minimum.

thermodynamic equilibrium. Equations (61–63) represent an extension of a method proposed by Sterman et al. [77], which has been developed solely based on measurements with a subcooled mixture (Mono isopropyl diphenyl-benzene-mixture; vertical annular channel: length 110 mm, outer/inner diameter 16 mm/10 mm; p = 0.2 MPa; $25 \leq \Delta\vartheta_u \leq 70$ K; $4 \leq u_E \leq 12$ m/s).

Figure 40 shows a typical measurement result for $\dot{x}_A = -0.2$ in comparison with calculated values according to Eqs. (59–63). The relative increase of the critical heat flux compared to the linearly interpolated value (Eq. 60) in accordance with $(\dot{q}_{cr}^{Mix} - \dot{q}_{cr,id}^{Mix})/\dot{q}_{cr}^{Mix} = X/(1+X)$ is plotted in the lower part of the ordinate. The upper part shows the trend of $(\tilde{y} - \tilde{x})$ of both mixtures. The higher $(\tilde{y} - \tilde{x})$, the higher is the relative increase of the critical heat flux. This is also true for increasing subcooling at the outlet. By contrast, Fig. 41 shows that a relative increase is no longer detectable at $\dot{x}_A = 0.1$, that is $X \approx 0$.

3.2.2 Accuracy and Scope of Eqs. (59–63)

A comparison of calculated values with all data measured by *Marroquin Nisch* is shown in Fig. 42. The majority of data lies within a tolerance range of ±25%. Measurements of Celata et al. [79] for a mixture of the refrigerants R 114/ R12 are included in the same range. These data have been investigated in the following parameter ranges: $0.24 \leq p/p_c \leq 0.86$; $0 \leq \dot{x}_A \leq 1$; $400 \leq \dot{m} \leq 1{,}600$ kg/m^2 s; l/d = 277.4. Hence, Eqn. (59–63) have been verified by measurements with three different mixtures of refrigerants for a wide parameter range. These equations enable the calculation of critical heat fluxes within a tolerance range of ±25%. This is true for outlet qualities between $-0.2 \leq \dot{x}_A \leq 1$. For higher subcooling at the outlet, Eq. (64) has to be used instead of Eqs. (61–63).

3.2.3 Other Mixtures

For mixtures of nonrefrigerants, measurements of Marroquin Nisch [76] and Tolubinskiy and Matorin [78] are available. In [76], the data of a *n*-propanol–acetone mixture are presented for the parameter ranges p = 0.11 MPa; $\dot{x}_A = 0$ and 0.1; $\dot{m} = 100$ and 500 kg/m^2 s and $3.4 \leq l/d \leq 38.8$. *Tolubinskiy and Matorin* have performed measurements with water–ethyl alcohol, water–acetone, water–ethylene glycol and benzene–ethyl alcohol in short vertical tubes ($l/d \approx 15$) for the parameter ranges $0.3 \leq p \leq 1.3$ MPa; inlet velocity $2.5 \leq u_E \leq 10$ m/s; inlet subcooling 10 K $\leq \Delta\vartheta_U \leq$ 110 K. Figure 43 shows typical results of their

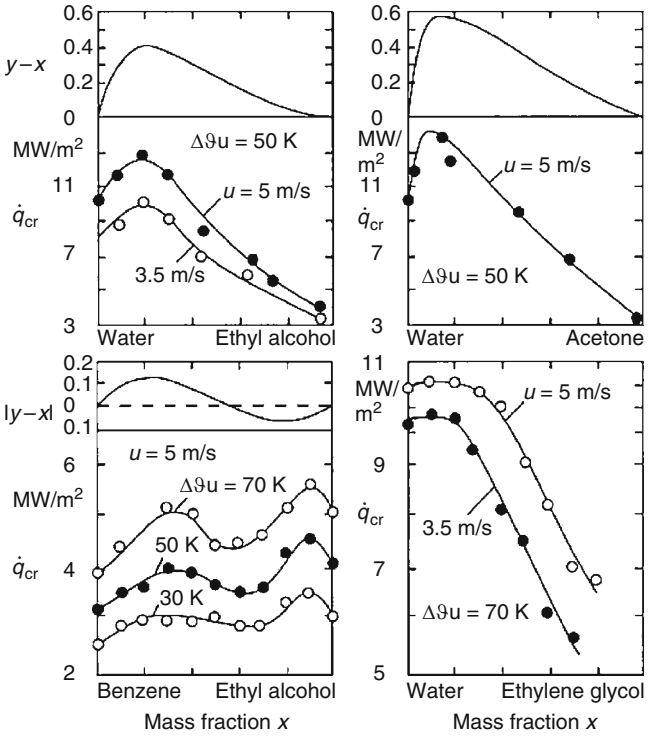
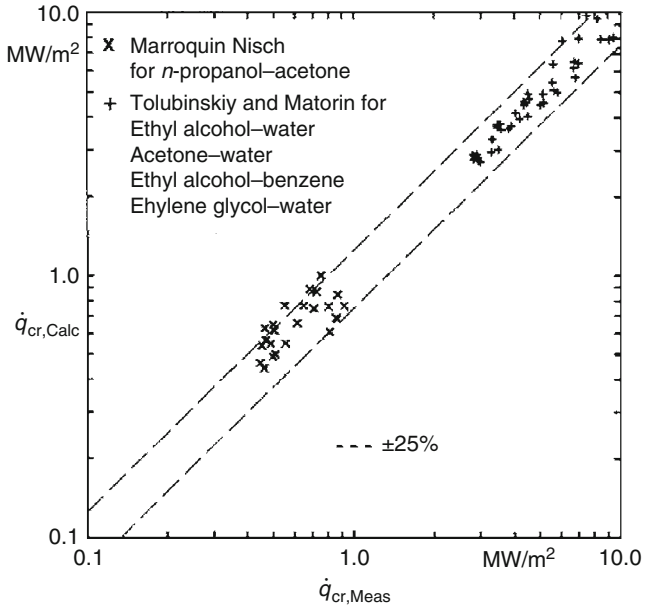
H3.5. Fig. 42. Comparison of measured and calculated values in accordance with Eqs. (59–63). Mixtures of refrigerants: Marroquin Nisch [76] and Celata et al. [79].



H3.5. Fig. 43. Critical heat flux of subcooled binary mixtures at 0.66 MPa acc. to Tolubinskiy and Matorin [78].



H3.5. Fig. 44. Comparison of measured and calculated values in accordance with Eqs. (59), (60), and (64).

investigations, which prove the fact, that an increase of the critical heat flux compared to the linearly interpolated value ($X > 0$ in Eq. (59)) emerges – especially at high inlet subcooling in the short tubes. However, *Marroquin Nisch* found also values $X > 0$ in comparatively long tubes and at saturation condition of the mixture which he has investigated.

An equation of type (59) and (60) is proposed in [78]:

$$X = 1.5\,(|\tilde{y} - \tilde{x}|)^{1.8} + 6.8(|\tilde{y} - \tilde{x}|)\left[\frac{T_S^{Mix} - T_S^{MV}}{T_S^{MV}}\right] \qquad (64)$$

The symbols used correspond to those of Eq. (61). If the binary mixture forms an azeotrope at a minimum boiling point A, as shown in Fig. 39, the temperature at this point is taken to be T_S^{MV} ($\vartheta_S = T_S - 273.15$ K). Figure 44 demonstrates, that both the data of *Tolubinskiy and Matorin* and the data of *Marroquin Nisch* can be reproduced by this method within a tolerance range of approx. ±25%. Hence, Eqs. (59), (60), and (64) can be recommended for the determination of the critical heat fluxes of mixtures of nonrefrigerants.

It has to be pointed out, that Eqs. (59–64) have been developed empirically due to a comparatively low number of measured data. However, all measurements, available up to now, have shown that the critical heat flux of a binary mixture is not less than the value resulting from the linear interpolation performed in Eq. (60). Hence, the critical heat flux estimated by this method is, at least, not too low.

Equations (59), (60), and (64) have to be used, if $\dot{x}_A < -0.2$ is valid for the subcooling of the mixture at the outlet of the evaporator channel.

Example 15

An acetone/1-propanol – mixture with the molar fraction of $\tilde{x} = 0.5$ is flowing through an evaporator channel with $d = 20 \cdot 10^{-3}$ m vertically upward. The pressure is $p = 0.15$ MPa, the mass flux $\dot{m} = 1{,}000$ kg/m² s. One has to calculate the relative increase of the critical heat flux $(\dot{q}_{cr}^{Mix} - \dot{q}_{cr,id}^{Mix})/\dot{q}_{cr}^{Mix} = X/(1+X)$ compared to the linearly interpolated value in accordance with Eq. (60) for the following conditions:

a. Subcooling of the mixture at tube outlet: $\Delta\vartheta = 34.9$ K. Therefore $\dot{x}_A$ at the tube outlet has to be determined additionally.
b. Quality at tube outlet: $\dot{x}_A = +0.22$.

Fluid properties at $p = 0.15$ MPa for the more volatile component (acetone): $T_S^{MV} = 342.1$ K. At $\tilde{x} = 0.5$: $T_S^{Mix} = 353.15$ K.

a. In accordance with Subchap. H3.4, Eqn. (1), $\dot{x}_A = (h(z) - h'(p))/\Delta h_v(p)$; data of the mixture acc. to Lee, Kesler, and Plöcker (LKP), D5.1 and Dfa 4 [86]. $h(z) = 180.85$ kJ/kg, $h'(p) = 275.3$ kJ/kg, $\Delta h_v(p) = 590.3$ kJ/kg.

One gets $\dot{x}_A = -0.16$. For $p = 0.15$ MPa and $\tilde{x} = 0.5$, LKP leads to $\tilde{y} - \tilde{x} = 0.28$.

Equation (64) is valid: $X = 0.21$. Relative increase: $X/(1+X) = 0.17$.

b. No change, since $\dot{x}_A$ is not affecting Eq. (64).

4 Symbols

A	cross sectional area (m²)
A_{htd}	area of heated surface (m²)
C	dimensionless parameter (–)
d	inner diameter of tube; rod diameter (m)

d_h	hydraulic diameter (m)
d_{ins}	diameter of inscribed circle (cf. Fig. 27) (m)
D_w	diameter of winding in a coil; spacing of tube centers (m)
f_{rel}	relative error (–)
Fr	Froude number (–)
g	acceleration due to gravity (m/s^2)
Gr	Grashof number (–)
h	enthalpy (kJ/kg)
Δh	enthalpy difference (kJ/kg)
Δh_v	specific enthalpy of vaporization (kJ/kg)
K	subcooling parameter (–)
K_l	correction factor for heated length (–)
ℓ	length (m)

H3.6 Postdryout Heat Transfer in Flow Boiling

Anastassios Katsaounis[1] · *Matthias Kind*[2]
[1]Beuth Hochschule für Technik Berlin, Berlin, Germany
[2]Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

1 Introduction

The equations submitted in this subchapter are valid if the boiling crisis or critical heat flux, as defined in Subchap. H3.5, has been exceeded. (For literature and special symbols, see Subchap. H3.8.) They are also checked here for their validity under the given boundary conditions, e.g., independently controlled wall temperature or heat flux.

1. Transition boiling

Transition boiling occurs if the wall temperature is lower than the maximum or the Leidenfrost-temperature (cf. Sect. 4). It is characterized by periodic wetting of the heated wall, i.e., the wall is contacted alternately by the boiling liquid and the vapor. If the heated wall is not wetted, a distinction is made between the two regimes "film boiling" and "postdryout heat transfer."

2. Film boiling

If the bulk of the liquid phase is subcooled, i.e., if the thermodynamic vapor mass fraction is negative, or if the vapor mass fraction is small (bubble flow), a film of vapor is formed at the wall while the bulk liquid continues to flow. This condition can be regarded as the inverse annular flow. If the heat flux is independently controlled, the poor heat transfer within the film of vapor, which has a lower thermal conductivity than that of the liquid, gives rise to a high wall temperature; or, if the wall temperature is given, a low heat flux is transferred. This condition is referred to as "film boiling."

3. Postdryout heat transfer

Postdryout heat transfer, also known as the dispersed-droplet regime, occurs if an excessively high wall temperature causes large quantities of vapor to be formed and thus forces the liquid film away from the surface. It also arises as a sequel to film boiling if an increase in the evaporation rate causes the flow pattern to change into one in which liquid droplets are dispersed in a fast-flowing vapor core. Owing to the presence of the liquid droplets, heat transfer in this case is generally better than that in film boiling.

There are many evaporation processes in which heat is transferred after the critical boiling state has been transgressed. Examples can be found in conventional and nuclear evaporators, cooling systems for liquid-propelled rockets, metalworking techniques, and refrigeration equipment. Others arise in the chemical industry, in which case the wall temperature is often independently controlled and it must always be checked whether or not the maximum or the Leidenfrost temperature is exceeded.

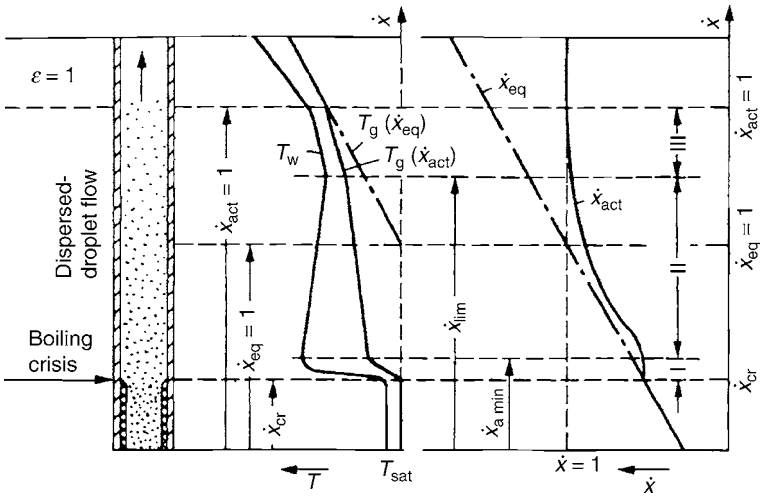
Postdryout heat transfer occurs most frequently in evaporation processes and has been the subject of numerous studies [1–6].

For steam–water flow inside vertical tubes, a temperature-based look-up table for heat-transfer coefficients has been compiled by Groeneveld et al. [7], providing an alternative to the calculation procedures outlined in parts 2 and 3. This look-up table is based on more than 20.000 fully developed film-boiling data points selected from a databank on film boiling at the University of Ottawa. It covers the following range of parameters:

$$\begin{aligned} 0.1 \le p &\le 200\ \text{MPa}, \\ 0 \le \dot{m} &\le 7,000\ \text{kg/m}^2\text{s}, \\ -0.2 \le \dot{x}_{\text{eq}} &\le 2, \\ 50 \le (T_{\text{w}} - T_{\text{sat}}) &\le 1,200\ \text{K}. \end{aligned}$$

2 Determination of Postdryout Heat Transfer During Droplet Flow

In Fig. 1, the wall and vapor temperature profiles are schematically shown for the case of constant heat flux at postdryout conditions. Furthermore, the vapor mass fractions at equilibrium



H3.6. Fig. 1. Schematic diagram showing the postdryout wall and vapor temperature profiles and vapor mass fractions under actual condition and at equilibrium.

and at actual boiling conditions are given. It is assumed that in Stage I ($\dot{x}_{cr} < \dot{x} \leq \dot{x}_{\alpha\,min}$), directly after the occurrence of the boiling crisis, the active vapor mass fraction $\dot{x}_{act}$ does not increase significantly, because here heat is transferred from the wall to the vapor phase. But, further downstream, the wall temperature increases rapidly because of the poor heat transfer between the wall and the vapor. Thereafter, the adjacent vapor is superheated, with the result that the droplets evaporate and the vapor mass fraction, the vapor velocity, and the heat transfer coefficient between the wall and the vapor increase (Stage II, $\dot{x}_{\alpha\,min} < \dot{x} < \dot{x}_{lim}$). In this stage, the wall temperature rises more slowly or, under certain conditions (in a vertical tube), even reduces. By experiments it has been demonstrated [8] that this regime of reduced increase of wall temperature rise comes to an end once a certain equilibrium vapor mass fraction $\dot{x}_{lim}$ is reached. Thereafter, the third stage (Stage III) follows, in which the surface area of the droplets decreases with an attendant reduction in the rate of evaporation.

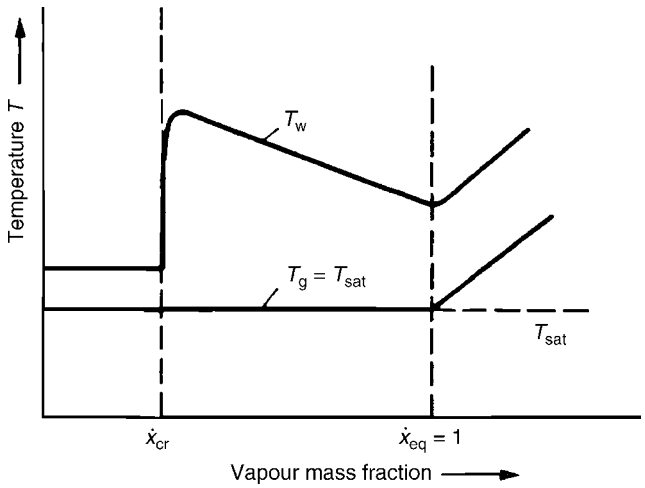
For the calculation of rates of heat transfer, two limiting cases are assumed: thermodynamic equilibrium and thermodynamic nonequilibrium.

Thermodynamic equilibrium

In this case, both the vapor and the liquid droplets are at the saturation temperature, i.e., $T_g = T_d = T_{sat}$. The heat applied is completely consumed in evaporating the liquid droplets, and the vapor mass fraction steadily increases. The resultant increase in the vapor velocity and the improvement in heat transfer give rise to a reduction of the wall temperature, as can be seen in Fig. 2. This limiting condition can be expected at high mass velocities if the operating pressure is high, i.e., in the vicinity of the critical pressure [3–6].

Thermodynamic nonequilibrium

In thermodynamic nonequilibrium, only part of the heat is consumed in evaporating the liquid droplets at the saturation temperature $T_d = T_{sat}$. The remainder serves to superheat the vapor, the temperature of which thus steadily rises ($T_g > T_{sat}$). If it is assumed that all the heat applied is consumed solely in



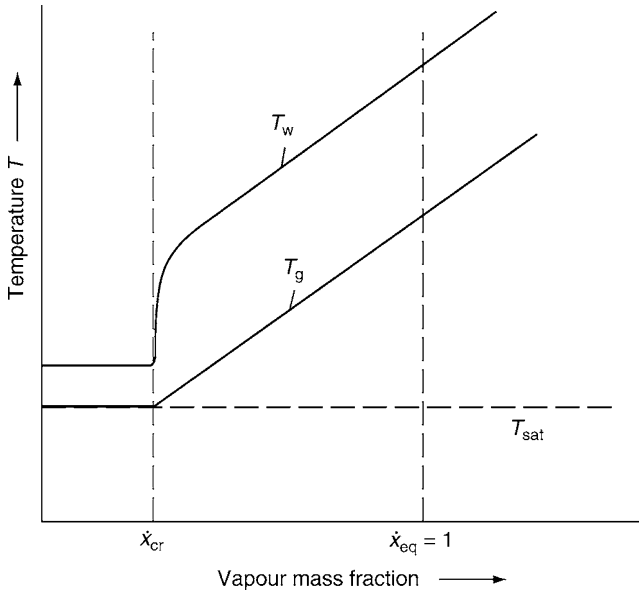
H3.6. Fig. 2. Temperature profile for evaporation in tubes at thermodynamic equilibrium.

superheating the vapor, the wall and the vapor temperature profiles will be as shown in Fig. 3. This condition arises in Stage I, $\dot{x}_{cr} < \dot{x} \leq \dot{x}_{\alpha\,min}$, illustrated in Fig. 1. In most cases, the values determined for the heat transfer coefficient under the assumption of thermodynamic nonequilibrium agree with measured values better and over a wider range of parameters than the corresponding figures calculated under the assumption of thermodynamic equilibrium.

2.1 Upward Flow Through Straight Vertical Tubes Under Thermodynamic Nonequilibrium

As a consequence of thermodynamic nonequilibrium, the enthalpy of the vapor is higher than the value at saturation, i.e., $h_g > h''(p)$. Thus, the active vapor mass fraction $\dot{x}_{act}$ is

$$\dot{x}_{act} = \frac{h - h'(p)}{h_g - h'(p)} = \frac{h - h'(p)}{\Delta h_v(p) + h_g - h''(p)}, \qquad (1)$$



H3.6. Fig. 3. Temperature profile for evaporation in tubes at thermodynamic nonequilibrium.

whereas, using

$$h = \frac{\dot{q} A_{htd}}{\dot{m} A} + h_{inl} \tag{2}$$

for the enthalpy, the vapor mass fraction at equilibrium is obtained from

$$\dot{x}_{eq} = \frac{h - h'(p)}{\Delta h_v(p)}. \tag{3}$$

The active vapor mass fraction $\dot{x}_{act}$ is less than the value at equilibrium $\dot{x}_{eq}$, and the ratio $\dot{x}_{act}/\dot{x}_{eq}$ is referred to as the nonequilibrium factor $\dot{\omega}$, i.e.,

$$\dot{\omega} = \frac{\dot{x}_{act}}{\dot{x}_{eq}} \quad (0 \le \dot{\omega} \le 1) \tag{4}$$

Hein and Köhler [8–10] proposed the following equation for the determination of $\dot{\omega}$:

$$\dot{\omega} = \frac{2}{1 + \sqrt{1 + 4 \dfrac{c_{pg}}{\Delta h_v} \dfrac{\dot{q}}{(\alpha_{gd} A_d / A_{htd})}}}. \tag{5}$$

The term "$\alpha_{gd} A_d$" in Eq. (5), i.e., the product of the coefficient of heat transfer α_{gd} between the vapor and the liquid droplets and the area A_d of the evaporating droplets, is unknown.

The following relationships were derived by Hein and Köhler from the experimental values:

(a) For $\dot{m}/b < 1,767 \cdot 10^3$:

$$\alpha_{gd} \frac{A_d}{A_{htd}} = 1.473 \cdot 10^{-7} (\dot{m}/b)^{1.33}. \tag{6}$$

(b) For $\dot{m}/b \ge 1,767 \cdot 10^3$:

$$\alpha_{gd} \frac{A_d}{A_{htd}} = 3.078 \cdot 10^{-24} (\dot{m}/b)^4, \tag{7}$$

where b is the Laplace coefficient, as defined by

$$b = \left(\frac{\sigma}{g(\rho' - \rho'')} \right)^{0.5}. \tag{8}$$

The units for $\dot{m}$ and α_{gd} in Eqs. (6) and (7) are kg/m^2 s and kW/m^2 K, respectively.

The active vapor mass fraction $\dot{x}_{act}$ is calculated from Eq. (4); and the enthalpy of the superheated vapor h_d from Eq. (1). The temperature of the vapor in dispersed-droplet flow can then be obtained from Eq. (9):

$$T_g = T_{sat} + \frac{\Delta h_v}{c_{pg}} \left(\frac{1}{\dot{\omega}} - 1 \right). \tag{9}$$

Here, the specific heat capacity is defined by Eq. (10) and has to be calculated by an iteration procedure:

$$c_{pg} = \frac{h_g - h''}{T_g - T_{sat}}. \tag{10}$$

The wall temperature is given by

$$T_w = T_g + \frac{\dot{q}}{\alpha_{wg}}, \tag{11}$$

where α_{wg} is the heat transfer coefficient between the tube wall and the stream of vapor (gas). The method recommended by Hein and Köhler for the determination of α_{wg} is described in Chap. G2 [11]. The Reynolds number that pertains to this method is for two-phase flow, i.e.,

$$\mathrm{Re} = \mathrm{Re}_g \left\{ \dot{x}_{act} + (1 - \dot{x}_{act}) \frac{\rho_g}{\rho_l} \right\}, \tag{12}$$

where $\mathrm{Re} = \dot{m} d_h / \eta_g$ is the Reynolds number for the vapor stream.

The temperature to which the properties of the fluid are referred, for the determination of the heat transfer coefficient α_{wg}, is the average in the boundary layer, which corresponds to the arithmetic mean of the vapor and the wall temperatures. However, the density ρ_g in Eq. (12) must be referred to the vapor temperature T_g.

The vapor mass fraction $\dot{x}_{\alpha\,min}$ at the point where the heat transfer coefficient is a minimum (see Fig. 1) is given by

$$\dot{x}_{\alpha\,min} = \frac{\dot{x}_{cr}}{\dot{\omega}}. \tag{13}$$

$\dot{x}_{cr}$ in Eq. (13), e.g., for water, is obtained from Eq. (3) in Subchap. H3.5; and $\dot{\omega}$, from Eq. (5).

The point at which Stage III in Fig. 1 commences is fixed by the following correlation:

$$\begin{aligned} \dot{x}_{lim} &= 1.16 - 0.125 \log_{10}(\rho'/\rho'') \quad \text{for } \rho'/\rho'' \le 3, \\ \dot{x}_{lim} &= 1.25 - 0.320 \log_{10}(\rho'/\rho'') \quad \text{for } 3 < \rho'/\rho'' \le 26, \\ \dot{x}_{lim} &= 0.97 - 0.120 \log_{10}(\rho'/\rho'') \quad \text{for } 26 < \rho'/\rho''. \end{aligned} \tag{14}$$

Using this information about $\dot{x}_{lim}$ the range of validity for Stage II, $\dot{x}_{\alpha\,min} < \dot{x}_{eq} \le \dot{x}_{lim}$, is known.

The model recommended above was verified [3] together with four others taken from the literature [12–15] by comparing the calculated results with the measured values for water [9,16,17], refrigerant R12 [18], and hydrogen [19].The range of parameters within which the experiments were performed is listed in Table 1. It was thus demonstrated [3] that the best agreement with the experimental values over the entire range of verification was achieved by the *Hein and Köhler* method.

H3.6. Table 1. Experiments to verify the model calculations

Fluid	Pressure (bar)	ρ'/ρ'' (–)	$\dot{m}$ (kg/m²s)	$\dot{q}$ (kW/m²)	d (mm)	l (m)	Data points (–)

Figures 4a, b and 5 are intended to facilitate calculations in the case of water (see Example 1).

Example 1

Water enters a vertical evaporator tube of 12 mm inner diameter at a pressure of 15 MPa (150 bar), at a heat flux of $\dot{q} = 1,000\ \mathrm{kW/m^2}$, and at an inlet velocity of $u = 3$ m/s. Determine the postdryout heat transfer coefficient α_{conv} and tube inner wall temperature T_w for $\dot{x}_{eq} = 0.8$ under the assumption of thermodynamic nonequilibrium.

According to Subchap. H3.5, $\dot{q} > \dot{q}_{cr}$. A value of $\dot{\omega} = 0.82$ can be read off against $\dot{m} = 603.1\ \mathrm{kg/m^3} \cdot 3\ \mathrm{m/s} = 1,810\ \mathrm{kg/m^2 s}$ in Fig. 4b. The value of the steam superheat that can be read off at $\dot{\omega} = 0.82$ in Fig. 5 is 28°C. Hence, $T_g = (342.1 + 28)^\circ\mathrm{C} \approx 370^\circ\mathrm{C}$. The same results can be obtained by applying Eqs. (4), (5), and (9), in which case the specific heat capacity c_{pg} must be determined by iteration. Inserting the values for η_g and for $\dot{x}_{act} = \dot{\omega} \cdot \dot{x}_{eq} = 0.82 \cdot 0.8 = 0.66$ in Eq. (12) then yields the Reynolds number for the two-phase mixture:

$$\mathrm{Re} = \frac{603.1 \cdot 3 \cdot 0.012}{2.36 \cdot 10^{-5}} \left[0.66 + (1 - 0.66)\frac{74.2}{603.1}\right] = 6.46 \cdot 10^5.$$

Iteration is commenced at $T_m = T_g$, and a value of Nu_g is read at $d/l \approx 0$ from the diagram in Chap. G2. From this, it follows that $\alpha_{wg} = 10.0\ \mathrm{kW/m^2\,K}$ and $T_w = T_g + \dot{q}/\alpha_{wg} = (370 + 100)^\circ\mathrm{C} = 470^\circ\mathrm{C}$. If the temperature-dependent properties, i.e., Pr and λ, are taken into account, then a wall temperature of 506°C is obtained after three steps in the iteration.

In this example, the values for the properties of water were taken from the literature [20].

2.2 Upward Flow Through Straight Vertical Tubes and Annular Gaps Under Thermodynamic Equilibrium

The empirical correlation proposed by Groeneveld [21] applies for high system pressures ($\rho'/\rho'' \leq 6$) and high mass flow rates ($\dot{m} > 2{,}000\ \mathrm{kg/m^2\,s}$) and assumes thermodynamic equilibrium. It has been demonstrated [3,22] that this correlation yields values for the postdryout heat transfer coefficient that still agrees with the measured values listed in Table 1. Hence, by virtue of its simplicity, it can be adapted for a rough determination of heat transfer coefficients within the given range of parameters. Note that it does not encompass the $\dot{x}_{cr} < \dot{x} \leq \dot{x}_{\alpha\,min}$ range, i.e., Zone I in Fig. 1.

Groeneveld [21] expanded the empirical relationship proposed by Miropol'skiy [23]:

$$\mathrm{Nu}'' = A\left(\mathrm{Re}''\frac{\dot{x}_{eq}}{\varepsilon_{hom}}\right)^B \mathrm{Pr}_w^C\, Y^D, \tag{15}$$

where $A = 0.00327$, $B = 0.9$, $C = 1.32$, and $D = -1.5$ for tubes and annular channels.

The Nusselt number is defined by

$$\mathrm{Nu}'' = \frac{\alpha_{conv} d_h}{\lambda''}. \tag{16}$$

The hydraulic diameter d_h is given by

$$d_h = \frac{4A}{U}. \tag{17}$$

The Reynolds number for the saturated vapor is calculated from the total mass velocity, i.e.,

$$\mathrm{Re}'' = \frac{\dot{m} d_h}{\eta''}. \tag{18}$$

Pr_w is the Prandtl number for the vapor at the wall temperature.

The heat flux is given by

$$\dot{q} = \alpha_{conv}(T_w - T_{sat}). \tag{19}$$

The term

$$\varepsilon_{hom} = \frac{\dot{x}_{eq}}{\dot{x}_{eq} + (\rho''/\rho')(1 - \dot{x}_{eq})} \tag{20}$$

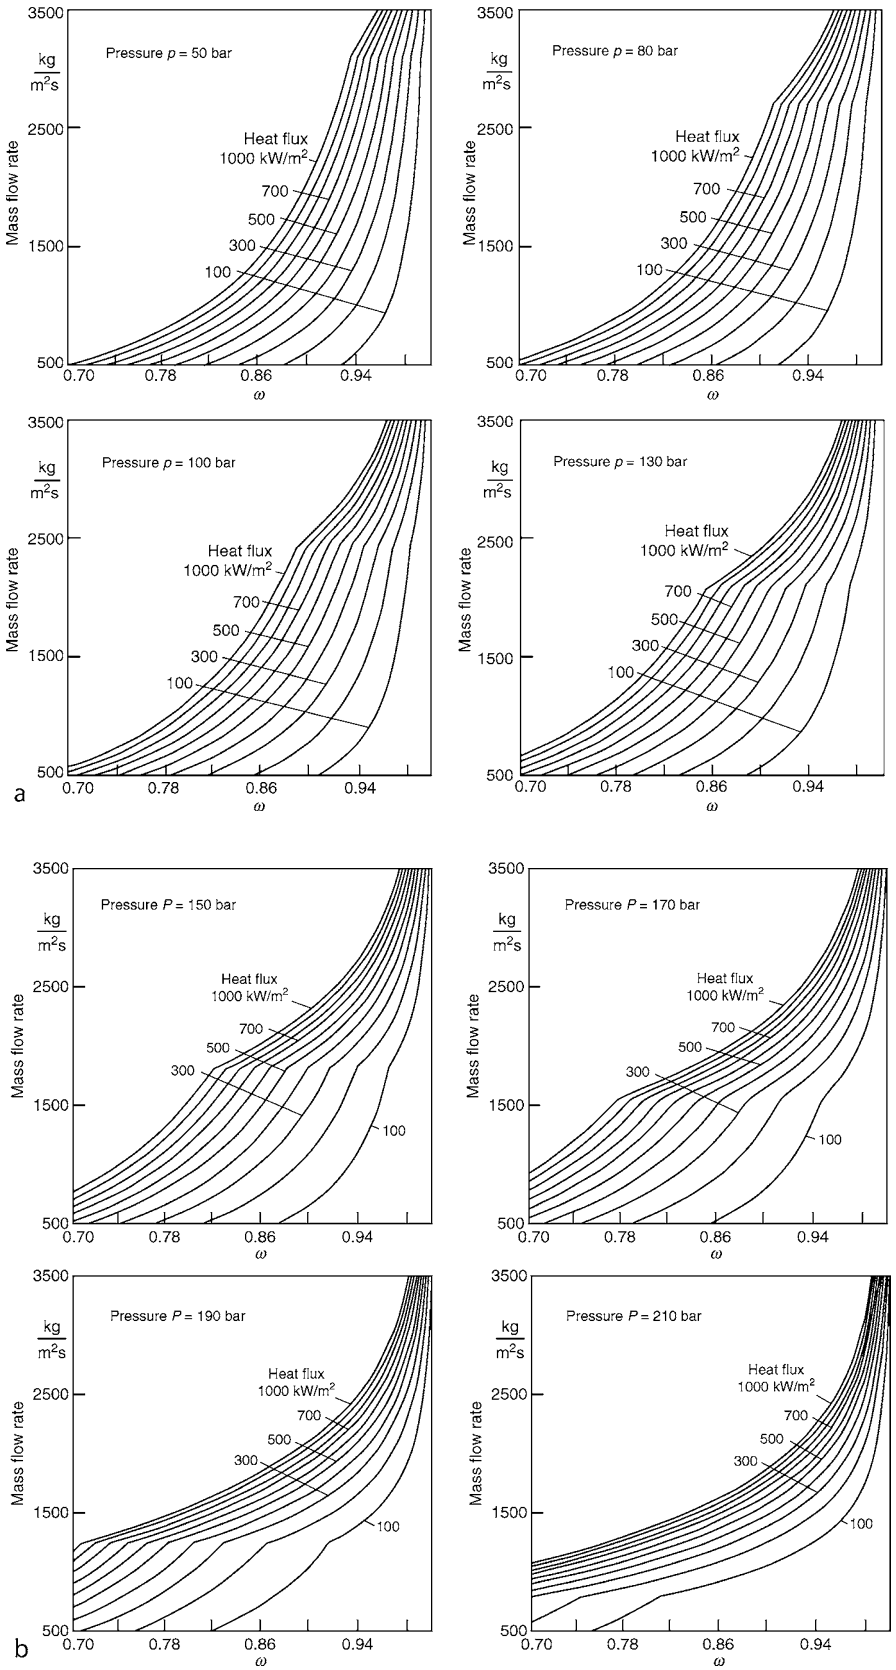
is the void fraction in the homogeneous flow, i.e., the vapor velocity corresponds to that of the dispersed phase.

If thermodynamic equilibrium is assumed, the vapor mass fraction $\dot{x}_{eq}$ is obtained from the enthalpy balance expressed by Eq. (3).

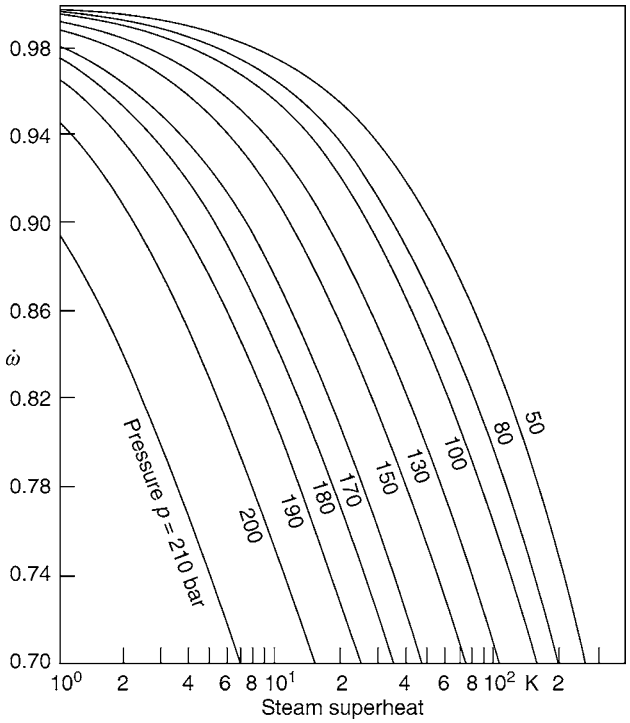
The term "Y" is given by

$$Y = 1 - 0.1\left[\left(\frac{\rho'}{\rho''} - 1\right)(1 - \dot{x}_{eq})\right]^{0.4}. \tag{21}$$

Values of the Nusselt number Nu'' measured on vertical rod bundles (3 and 19 heated rods) were found to be much higher in some cases than the corresponding values calculated from Eq. (15) [21]. Another comparison between the figures calculated from Eq. (15) and measurements on horizontal and vertical three-rod assemblies immersed in refrigerant R 12 confirmed that the equation could be applied for vertical sections, if $\dot{x}_{eq} > 0.15$. The values for the Nusselt number Nu'' obtained in measurements over a horizontal section were, without exception, higher than the figures calculated from Eq. (15) [24].



H3.6. Fig. 4. Thermal nonequilibrium factor $\dot{\omega}$ at various pressures, calculated for water [9], as a function of heat flux and mass velocity.



H3.6. Fig. 5. Steam superheat as a function of the thermal nonequilibrium factor $\dot{\omega}$ and the operating pressure.

Correlations derived for the determination of postdryout heat transfer coefficients and based on values obtained in measurements on methane, propane, and R 12 are cited in the literature [25,26]. They have also been checked by the author for their applicability to water and nitrogen within a restricted range of parameters. The results of other studies on heat transfer in the liquid-deficient regime on water and R 12 in horizontal tubes have been published [18,22,27].

The example presented in Fig. 6 illustrates how the Nusselt number Nu″ can be determined by graphical iteration.

Example 2

If the data are the same as those given in Example 1 but if thermodynamic equilibrium is assumed, determine the heat transfer coefficient and wall temperature for (a) $\dot{x}_{eq} = 0.4$ and (b) $\dot{x}_{eq} = 0.8$. The required properties of water can be obtained from the literature [20].

(a) Equation (21) gives

$$Y = 1 - 0.1\left[\left(\frac{603.1}{96.7} - 1\right)(1 - 0.4)\right]^{0.4} = 0.842.$$

It follows from Eq. (20) that

$$\varepsilon_{hom} = \frac{0.4}{0.4 + \frac{96.7}{603.1}(1 - 0.4)} = 0.806.$$

The Prandtl number at the saturation temperature, i.e., Pr″, is taken as a first approximation for Pr_w in solving Eq. (15) by iteration. Equation (15) thus becomes

$$Nu'' = 0.00327\left(\frac{603.1 \cdot 3 \cdot 0.012 \cdot 0.4}{2.28 \cdot 10^{-5} \cdot 0.806}\right)^{0.9} 2.48^{1.32} \cdot 0.842^{-1.5} = 1,796.$$

The heat transfer coefficient is then obtained from

$$\alpha_{conv} = \frac{Nu''\lambda''}{d_h} = \frac{1,796 \cdot 0.1164}{0.012} = 17.4 \cdot 10^3 \ W/m^2\,K.$$

Hence, the wall temperature is

$$T_w = T_{sat} + \frac{\dot{q}}{\alpha_{conv}} = 342.1 + \frac{1,000}{17.4} = 399.6°C.$$

A wall temperature of $T_w = 399.6°C$ corresponds to $Pr_w = 1.30$, and the calculation is repeated with this value. After four steps in the iteration, each of which is performed solely to determine the Prandtl number Pr_w, values of $\alpha_{conv} = 3.78$ kW/m² K and $T_w = 607°C$ are obtained.

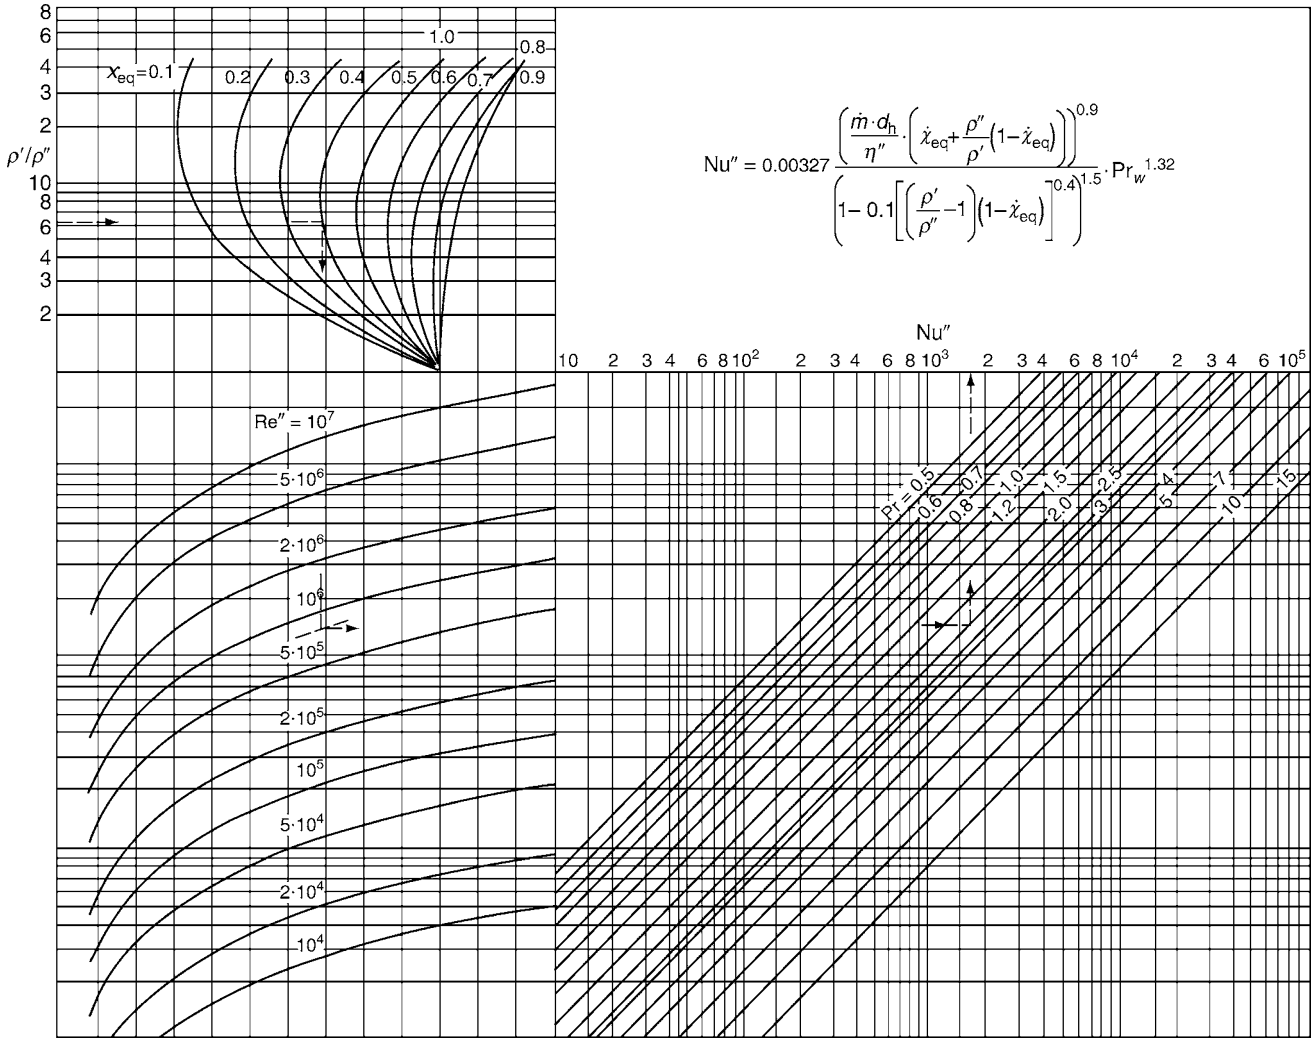
(b) The same procedure as in (a) is adapted. In this case, a heat transfer coefficient of $\alpha_{conv} = 5.4$ kW/m²K and a wall temperature of $T_w = 527.3°C$ are obtained after three steps in the iteration.

2.3 Flow Through Straight Horizontal and Upward Inclined Tubes

Gravity and inertia forces cause the flow patterns in two-phase flow through horizontal tubes to differ from those formed in upward flow through vertical tubes (cf. Subchaps. H3.4 and H3.5). The flow patterns in horizontal tubes depend on whether the gravity or inertia predominates and on the vapor mass fraction in the stream. Thus various forms may be assumed, e.g., bubble, stratified, plug, slug, or annular flow. It can be derived from the literature [28,29] that the transition from stratified and wavy to annular flow is characterized by a modified Froude number, i.e., the ratio of the inertia forces to gravity.

Hein et al. [27,30], Köhler [8], and Kefer et al. [31] performed extensive measurements relating to the boiling crisis and to heat transfer in vertical, horizontal, and inclined evaporator tubes—predominantly in the annular and dispersed-droplet flow regimes. If the Froude number calculated from the measured values by the method described in Subchap. H3.5, Sect. 2.1.2, is higher than 10, the angle of inclination of the tube does not exert a significant effect on the location of the critical boiling state.

If flow is stratified or if the liquid film formed on the crest of a horizontal tube during annular flow is very thin, the boiling crisis first occurs at the upper surface of the tube, where the vapor mass fraction $\dot{x}_{cr,up}$ is lowest [27,30]. It has also been determined by measurements [8,30] that the maximum temperature on the inner wall at the crest of a horizontal tube is less than that in a vertical tube under otherwise identical conditions. This can be ascribed to the fact that the temperature at the unwetted upper surface, which is cooled by suspended droplets, is higher than that at the wetted lower surface, which is cooled



H3.6. Fig. 6. Groeneveld [21] diagram for the postdryout heat transfer at thermodynamic equilibrium in vertical cylindrical tubes and annular gaps. The Nusselt number Nu″ was determined from Eq. (15).

more efficiently by nucleate boiling. Thus, heat is conducted over the circumference from the crest to the lower side of the tube. The boiling crisis occurs sooner at the crest of a horizontal tube, i.e., at a lower vapor mass fraction, than it does under otherwise identical conditions in upward flow through a vertical tube. The effect is more pronounced in measurements of the critical boiling state and on heat transfer in horizontal tubes that are heated only on the upper side [32].

Another fact that can be derived from the literature [9] is that, if the conditions are the same, heat transfer in a horizontal tube is equal to that in a vertical tube whenever the boiling crisis occurs at the same position on the upper ($\dot{x}_{cr,up}$) and lower ($\dot{x}_{cr,low}$) horizontal surfaces, i.e., if $\dot{x}_{cr,up} \approx \dot{x}_{cr,low} \approx \dot{x}_{cr}$ and if $\dot{x}_{cr}$ is the critical vapor mass fraction under the same conditions in a vertical tube.

In the dispersed-droplet flow regime ($\dot{x} > \dot{x}_{cr,low}$), the vapor forms a continuous phase and water droplets accumulate in the lower section of the horizontal tube. It can therefore be assumed that the thermal disequilibrium is less in the lower section of the tube than in the upper [18]. Dispersed-droplet flow differs from the flow of liquids in that the natural convection has practically no effect on the temperature distribution in the wall of the tube [8].

The first step in analyzing heat transfer during flow through straight, horizontal, or inclined tubes is to determine the Froude number Fr by the method described in Subchap. H3.5, Sect. 2.1.2, and the dryout point on the upper ($\dot{x}_{cr,up}$) and lower ($\dot{x}_{cr,low}$) surfaces of the tube. The following three cases must then be taken into consideration.

1. If Fr $\geq$ 10 or if $\dot{x}_{cr,low} - \dot{x}_{cr,up} \leq 0.1$, heat transfer can be determined as described in Sect. 2.1 [22].
2. If the vapor mass fraction $\dot{x}$ in the stream lies within the $\dot{x}_{cr,up} \leq \dot{x} \leq \dot{x}_{cr,low}$ range and if Fr < 10, heat transfer cannot be easily determined. The material and wall thickness of the tube and the ratio of the wetted to the unwetted area of the inner walls exert a significant effect on heat transport [8,30]. Comprehensive calculations that involve the

two-dimensional Fourier differential equation for thermal conductivity and its solution (cf. Chap. E2) are required for this range of parameters [31].

3. Heat transfer in the $\dot{x} > \dot{x}_{cr,low}$ range of pure dispersed-droplet flow can be determined by the method given in Sect. 2.1.

3 Determination of Heat Transfer During Transition and Film Boiling

At negative or very low vapor fractions of the flow ($\dot{x} \leq 0.2$ [33] respectively $\varepsilon \leq 0.3$ [1]) and after the boiling crisis happened, transition or film boiling appears. Also, film boiling is observed before rewetting of superheated surfaces by flooding. Partial film boiling, named transition boiling, can be observed in the region between boiling crisis and minimal heat flux if the wall temperature is imposed. In this case, the minimal heat flux $\dot{q}_{min}$ corresponds to the maximum temperature T_{max} of the heated surface. The maximum temperature at flow boiling corresponds to the lowest temperature, which allows stable film boiling. A slight reduction of this maximum wall temperature leads to transition boiling or partial film boiling.

3.1 Transition Boiling

Transition boiling is observed at low or negative vapor mass fractions and is characterized by random alternating contact with the heating surface by the vapor and then the liquid.

In the near-transition boiling range, the boiling curve (heat flux versus temperature difference) plotted on a log-log scale is approximately linear. Consequently, a rough prediction of the behavior in transition boiling can be achieved by interpolation if the conditions at the critical boiling state ($\dot{q}_{cr}$; ΔT_{cr}) and the minimum heat flux ($\dot{q}_{min}$; ΔT_{max}) are known. The following equation is adapted in this case [1,31]:

$$\ln\left(\frac{\dot{q}_{TB}}{\dot{q}_{min}}\right) = \ln\left(\frac{\dot{q}_{cr}}{\dot{q}_{min}}\right) \cdot \frac{\ln(\Delta T_{max}/\Delta T_{TB})}{\ln(\Delta T_{max}/\Delta T_{cr})}. \qquad (22)$$

No information is given in the literature on how the temperature difference $\Delta T_{cr} = T_{cr} - T_{sat}$ and the heat transfer coefficient α_{cr} can be calculated. If neither of these values is available from measurements, ΔT_{cr} can be obtained as a first approximation from

$$\Delta T_{cr} = f_{corr} \frac{\dot{q}_{cr}}{\alpha_B}, \qquad (23)$$

where f_{corr} is a correction factor.

However, the condition $\Delta T_{cr} < \Delta T_{max}$ must apply, in which case $\alpha_{cr} = \alpha_B / f_{corr}$.

The method of determination for the critical heat flux $\dot{q}_{cr}$ is given in Subchap. H3.5; and for the heat transfer coefficient in developed nucleate boiling α_B, in Subchap. H3.4.

Nucleate boiling correlations do not allow for the decrease in the slope of the boiling curve before the critical boiling state is reached (cf. Fig. 1 in Subchap. H3.5). The temperature difference on the occurrence of the critical boiling state is actually greater, and allowance is made for this fact by the correction factor f_{corr} ($f_{corr} > 1$).

Auracher [33] performed measurements in the $0 \leq \dot{x} \leq 0.2$ range of vapor mass fractions on R 114 (dichlorotetrafluoroethane [$C_2F_4Cl_2$]) in vertical tubes. The results were reevaluated in order to determine the heat transfer coefficient in developed nucleate boiling α_B in Subchap. H3.2, and the correction factor $f_{corr} = \alpha_B/\alpha_{cr}$ was thus obtained. It can be seen from Fig. 7 that f_{corr} is independent of pressure within the observed range. The value shown for the correction factor in the diagram still has to be verified by measurements on other fluids. Nevertheless, it is recommended that a figure of $f_{corr} \approx 1.2$ be used in calculations until reliable results obtained on several fluids become available.

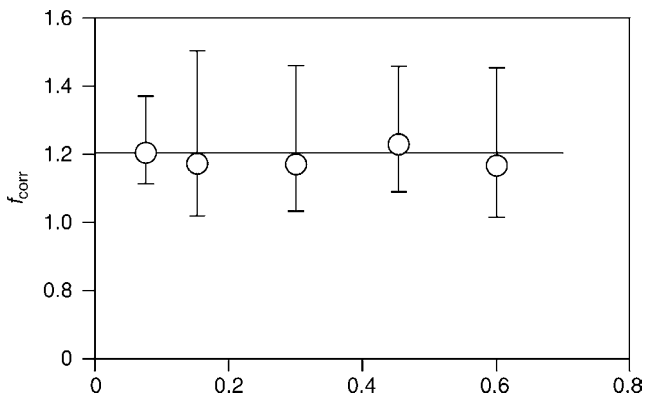
From atmospheric pool boiling experiments with water in a vertical plate [34], it is known that the properties of the surface of the plate (roughness, stain, oxidation) influence ΔT_{cr} considerably. Furthermore, it is known from steady-state [35] and transient [36] water measurements in a short vertical pipe at low pressure and low mass flow rates, that ΔT_{cr} is a function of pressure, mass flow rate, and subcooling of the fluid (see procedures to estimate $\dot{q}_{cr}$ and α_{cr} given in Subchaps. H3.4 and H3.5). Katsaounis [37] evaluated flow boiling measurements of Auracher [33] (R 114 in vertical pipes) and Weber [35,38] (water in short vertical pipes) according to the relations given by France et al. [39] for the heat flux

$$\frac{\dot{q}_{TB}}{\dot{q}_{cr}} = \exp[-K \cdot (\Delta T_{TB} - \Delta T_{cr})], \qquad (24)$$

and the heat transfer coefficient

$$\frac{\alpha_{TB}}{\alpha_{cr}} = \frac{\Delta T_{cr}}{\Delta T_{TB}} \cdot \exp[-K \cdot (\Delta T_{TB} - \Delta T_{cr})] \qquad (25)$$

(see Table 2). For these calculations ΔT_{cr} was evaluated by Eq. (23), and due to the specifics of these two measurements, Katsaounis [37] took the critical heatflux used for estimating ΔT_{cr} either from Auracher's measured data or from an empirical relation based on Weber's data. For estimating the respective maximum temperatures at transitional boiling (Leidenfrost-temperatures), Eq. (43) from Schroeder-Richter [40] was used.



H3.6. Fig. 7. f_{corr} for R 114 as a function of the reduced pressure.

H3.6. Table 2. Experimental data versus calculation procedure of Katsaounis [37]

Fluid	Pressure (bar)	$\dot{m}$ (kg/m²s)	ψ	ΔT_{sub}, $\dot{x}$ (K, –)	d (mm)	l (m)	Data points (Eq. (26))
Water [38]	2.5–12	10–500	0.38–19.2	$5 \leq \Delta T \leq 50$	9.7	50.0	750
R 114 [33]	2.5–20	500–3,000	5.1–103.0	$0 \leq \dot{x} \leq 0.2$	14.0	87.0	970

Factor K in Eqs. (24) and (25) is obtained as a function of the dimensionless flow rate ψ

$$K = 0.033 + 8.4 \cdot 10^{-4} \cdot \psi - 9.1 \cdot 10^{-6} \cdot \psi^2 \qquad (26)$$

with ψ to be calculated from Eq. (54) in Subchap. H3.5 as follows:

$$\psi = \dot{m} \cdot \frac{d}{\eta'} \cdot \left(\sqrt{\frac{\gamma}{\rho'}} \cdot \frac{\eta'}{d} \right)^{2/3} \cdot \left(\frac{\eta'}{\eta''} \right)^{1/8} \qquad (27)$$

with

$$\gamma = \left| \frac{\mathrm{d}(\rho'/\rho'')}{\mathrm{d}p} \right| \qquad (28)$$

given as Eq. (55) in the same subchapter.

As was shown by Katsaounis [37], neither there is (for R 144) a significant dependence of Eq. (26) on vapor mass fraction $\dot{x}$ at the locus of measurement, nor there is (for water) a dependence on the subcooling of the fluid ΔT_{sub} at the entrance of measurement section.

Equations (24–28) show acceptable agreement with the correlations of France et al. [39] for $\dot{q}_{TB}$. Furthermore, measured data of Ragheb et al. [41] and Cheng et al. [42] can be reproduced well by the above equations if $\dot{q}_{cr}$ and ΔT_{cr} are given.

In the case of the transient measurements of Huang [36] in the regime of transitional boiling, Katsaounis [37] shows that the K-factor is lower than predicted by Eq. (26) for steady-state experiments. Thus, heat transfer coefficients from transient measurements of transitional film boiling (quenching experiments) are higher than the ones taken from steady-state experiments. This result is in accordance with the differences of critical heat fluxes from steady-state and from transient experiments [43]. The transient experiments of Huang [36] were carried out in the same measurement device and under the same variation of the experimental parameters as the experiments carried out by Weber [35].

Advice for the use of the equations

The following advices are given as how to apply Eqs. (22) and (24) respectively Eq. (25) for the estimation of the heat flux and the heat transfer coefficient in the transitional boiling regime. An approximation of the heat flux in the transitional boiling regime can be obtained from Eq. (22), if $\dot{q}_{cr}$ - and ΔT_{cr} -data (boiling crisis) and $\dot{q}_{min}$ - and ΔT_{max} -data at the state of minimal heat flux are known.

A more precise estimation of the heat flux is obtained from Eqs. (24–28) within the parameter range of Table 2. To do so, $\dot{q}_{cr}$ must be calculated by the procedures given in Subchap. H3.5, and ΔT_{cr} must be calculated from Eq. (23). For water, the maximum temperature for transition boiling is to be calculated from Eq. (44) respecting the range of validity of this equation.

In case, the maximum temperature is not known from measurements, the Leidenfrost-temperature must be estimated using Eq. (43). The influences of the different parameters on the Leidenfrost-temperature (see Sect. 4.2) bring about, that the maximum temperature is higher than the Leidenfrost-temperature according to Eq. (43) (see Example 3).

3.2 Film Boiling During Flow Through Vertical Cylindrical Tubes

Results of heat transfer measurements on film boiling are fewer and less accurate than those published on dispersed-droplet flow (cf. Sect. 2). For instance, correlations quoted in the literature are of restricted validity [1,2,44–49]. A recommendation often encountered in the literature is that the heat transfer coefficient in developed convective film boiling can be calculated from the same equations as those for pool boiling. This can be accepted provided that laminar flow can be assumed in the vapor film and if the mass flow rate is low ($\dot{m} < 500\,\mathrm{kg/m^2s}$). The overall heat transfer coefficient α_0 for saturated boiling can thus be obtained from the equations given in Sect. 5 of Subchap. H2.2. Alternatively, Eqs. (33–37) in this subchapter can be applied, in which case a factor of 0.8 must be substituted for the factor 0.62 that precedes the square bracket on the right-hand side of Eq. (34) in order to allow for the vertical position of the tube.

The characteristic length to insert in the expression for the Nusselt number is

$$d \equiv L = 2\pi \left[\frac{\sigma}{g(\rho' - \rho'')} \right]^{0.5}. \qquad (29)$$

It can be derived from the literature [1,2,34,42,47–54] that film boiling incurs much higher heat fluxes in subcooled (α_{sub}) than in saturated (α_0) liquids under otherwise identical conditions. In common with other authors [55,56], Groeneveld [45] recommended the following equation for determining the effect of liquid subcooling on the heat transfer coefficient:

$$\alpha_{sub} = \alpha_0 (1 + 0.025 \Delta T_{sub}). \qquad (30)$$

Although this empirical equation was derived from measurements on water, it can be adapted as a first approximation for other fluids if the flow velocity is less than 1 m/s [22,52,57].

As the liquid phase progressively evaporates downstream in the cylindrical tube, the liquid bulk in inverse annular flow disintegrates into droplets, with the result that dispersed-droplet flow gradually sets in and the heat transfer mechanism alters accordingly. The heat transfer coefficient and the wall temperature in dispersed-droplet flow are calculated as described in Sect. 2.

The boundary between the two heat transfer mechanisms, fully developed film flow and dispersed-droplet flow, is thus the intersect of the values for the heat fluxes determined by the two methods. This implies that the heat flux should be calculated by both methods and that the highest value should be taken [45], i.e.,

$$\dot{q} = \max\left[\alpha(T_w - T_{sat}); \alpha_{wg}(T_w - T_g)\right] \tag{31}$$

where α is the heat transfer coefficient in film boiling and α_{wg} is the heat transfer coefficient in dispersed droplet flow as in Sect. 2.1.

Example 3

Water flows through a boiler tube of 12 mm inner diameter with a mass flow rate of 500 kg/m^2 s, a pressure of 15 MPa (= 150 bar), and a saturation temperature of $T_{sat} = 342.1°C$. It is assumed that the critical boiling state occurs at $\dot{x}_{eq} = 0.01$ and that the inner wall temperature rises from the value at the boiling crisis T_{cr} to $T_w = 540°C$. Determine the heat transfer coefficients and the corresponding heat fluxes in the entire temperature range (T_{cr} to 540°C).

The first step is to determine the critical heat flux at $p_r = 150/221.1 = 0.678$ and $\dot{x} = 0.01$ by the method described in Subchap. H3.5. Thus,

$$\dot{q}_{cr} = 10^3\left[10.3 - 17.5 \cdot 0.678 + 8(0.678)^2\right] \cdot \left(\frac{0.008}{0.012}\right)^{0.5} \cdot \left(\frac{500}{1,000}\right)^{0.68p_r - 1.2 \cdot 0.01 - 0.3} \cdot e^{-1.5 \cdot 0.01} = 1,532\,\text{kW/m}^2.$$

The heat transfer coefficient in nucleate boiling in tubes with a slightly oxidized surface and a roughness height of $R_a = 0.8$ µm is determined by the method given in Subchap. H3.4. Thus,

$$\alpha_B = 0.72 \cdot 25.58\left(\frac{1,532}{150}\right)^{(0.8 - 0.1 \cdot 10^{0.76p_r})} \cdot \left[2.816 \cdot 0.678^{0.45} + \left(3.4 + \frac{1.7}{1 - 0.678^7}\right)0.678^{3.7}\right] \cdot \left(\frac{10}{12}\right)^{0.4}\left(\frac{0.8}{1}\right)^{0.133} = 179.5\,\text{kW/m}^2\,\text{K}.$$

The temperature difference at the dryout point can now be determined from Eq. (23), i.e.,

$$\Delta T_{cr} = 1.2 \cdot \frac{1,532}{179.5} = 10.2\ \text{K}.$$

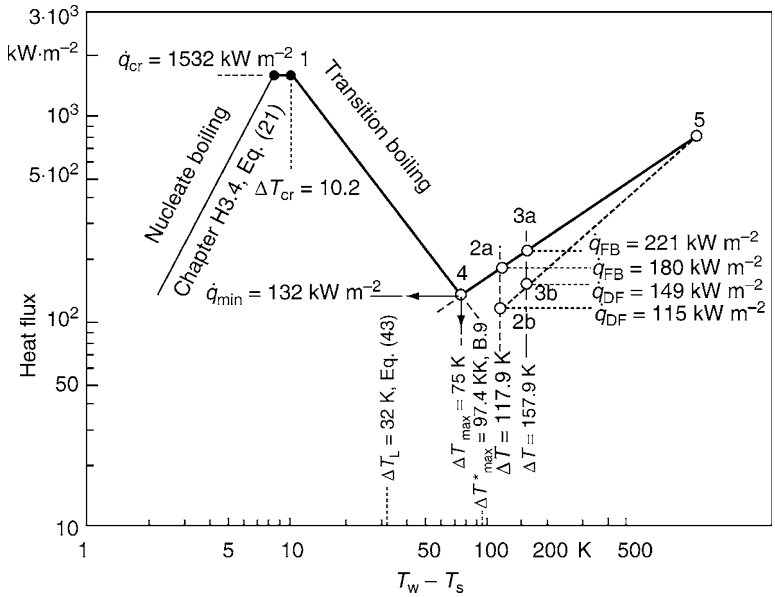
It follows that $T_{cr} = 342.1 + 10.2 = 352.3°C$ (Point 1 in Fig. 8).

From Fig. 9, it can be seen that in this example the maximum temperature T_{max} at transitional boiling attains a value between the Leidenfrost-temperature $T_L = 374.15°C$ (Eq. (43)) and the regression line through the measured data ($T^*_{max} = 440°C$).

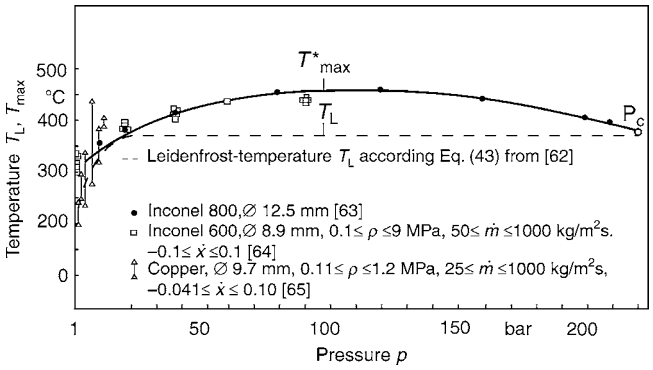
Thus, in the temperature range between $T_{cr} = 352.3°C$ and T_{max} heat transfer occurs in the partial film boiling regime. In order to calculate heat fluxes by Eqs. (24–28), system properties have to be taken from Chap. D2 for $p = 150$ bar and $T_s = 342.1°C$: $\eta' = 69.49 \cdot 10^{-6}$ kg/(m s), $\eta'' = 23.03 \cdot 10^{-6}$ kg/(m s), $\rho'(150\,\text{bar}) = 603.17$ kg/m^3, $\rho''(150\,\text{bar}) = 97.07$ kg/m^3, and $\rho'(151\,\text{bar}) = 601.3$ kg/m^3, $\rho''(151\,\text{bar}) = 98.15$ kg/m^3.

The calculation is as follows:

$$\gamma \approx \frac{\Delta(\rho'/\rho'')}{\Delta p} = \frac{603.17/97.07 - 601.3/98.15}{(151 - 150)\text{bar}} = 0.0874\ \text{bar}^{-1} = 0.0874 \cdot 10^{-5}\left(\text{m s}^2/\text{kg}\right),$$



H3.6. Fig. 8. Boiling curve plotted from calculated values. Heat flux as a function of $T_w - T_{sat}$.



H3.6. Fig. 9. Maximum temperature for water as a function of pressure. Curve plotted from measured values [73–75].

$$\psi = \frac{500 \cdot 0.012}{69.49 \cdot 10^{-6}} \cdot \left[\sqrt{\frac{0.0874 \cdot 10^{-5}}{603.17}} \cdot \left(\frac{69.49 \cdot 10^{-6}}{0.012} \right) \right]^{2/3} \cdot \left(\frac{69.49 \cdot 10^{-6}}{23.03 \cdot 10^{-6}} \right)^{1/8} = 3.617,$$

$$K = 0.033 + 8.4 \cdot 10^{-4} \cdot 3.617 - 9.1 \cdot 10^{-6} \cdot 3.617^2 = 0.03592.$$

The following table is computed using

$$\frac{\dot{q}_{TB}}{\dot{q}_{cr}} = \exp[-0.03592 \cdot (\Delta T_{TB} - \Delta T_{cr})].$$

ΔT_{TB} (K)	$\dot{q}_{TB}/\dot{q}_{cr}$ (–)	$\dot{q}_{TB}$ (kW/m²)
20	0.7033	1,077.4
40	0.3429	525.3
60	0.1672	256.1
80	0.0815	124.8

These data are plotted in Fig. 8.

If the wall temperature exceeds T_{max}, the wall can no longer be wetted. Then, the heat transfer solely occurs by film boiling or droplet flow. The following calculations have to be carried out for determining the intersection No. 4 (ΔT_{max}; $\dot{q}_{min}$) between the calculated line for transition film boiling and that of fully developed film boiling rep. droplet flow (Fig. 8).

(a) Determination of the heat transfer coefficient on the assumption of fully developed film boiling

The reference length for the heat transfer coefficient is obtained from Eq. (29). Thus,

$$L = 2\pi \left[\frac{5.23 \cdot 10^{-3}}{9.81(603.1 - 96.7)} \right]^{0.5} = 6.45 \cdot 10^{-3} \text{m}.$$

The heat transfer coefficient α_{conv} corresponding to a wall temperature of $T_w = 460°C$, which lies between the Leidenfrost-point and the given temperature of 540°C, is determined from Eq. (34) in Sect. 3.3. But the average temperature of the vapor film, to which the properties of the stream are referred [20], must first be calculated, i.e., $T_m = 0.5(342.1 + 460) \approx 401°C$. Hence,

$$\rho_g = 63.6 \text{ kg/m}^3, \quad \eta_g = 25.0 \cdot 10^{-6} \text{ Pa s},$$
$$c_{pg} = 4.14 \text{ kJ/kg K}, \quad \lambda_g = 79.8 \cdot 10^{-3} \text{ W/mK},$$
$$\text{Pr}_g = 1.296, \quad \text{Pr}_w = 1.118.$$

The difference between the temperature of the wall and that of the liquid is $\Delta T_{wl} = 460 - 342.1 = 117.9$ K. Inserting in Eq. (37) gives

$$\Delta h_v^* = 1,004 \left[1 + \frac{0.4 \cdot 4.14 \cdot 117.9}{1,004} \right] = 1,432.4 \text{ kJ/kg}$$

The convective heat transfer coefficient for laminar flow in the vapor film is calculated from Eq. (34), i.e.,

$$\alpha_{conv} = 0.8 \left[\frac{79.8^3 \cdot 10^{-9} \cdot 9.81 \cdot 63.6 \cdot (603.1 - 63.6) \cdot 1,432.4 \cdot 10^3}{25.0 \cdot 10^{-6} \cdot 4.45 \cdot 10^{-3} \cdot 117.9} \right]^{0.25} = 1,515.8 \text{ W/m}^2\text{K}.$$

The radiation component of the heat transfer coefficient is obtained from Eq. (35), i.e.,

$$\alpha_{rad} = 0.79 \cdot 5.67 \cdot 10^{-8} \frac{460^4 - 342.1^4}{117.9} = 11.8 \text{ W/m}^2\text{K}.$$

The coefficient of total heat transfer in film boiling is then obtained from Eq. (33). Thus,

$$\alpha = 1,515.8 + \frac{3}{4} \cdot 11.8 \approx 1,524.7 \text{ W/m}^2\text{K}.$$

The corresponding heat flux is $\dot{q}_{FB} = \alpha \Delta T_{wl} = 1.525 \cdot 117.9 \approx 180$ kW/m² (Point 2a in Fig. 8).

(b) Determination of the heat transfer coefficient on the assumption of dispersed-droplet flow

From an energy balance and with an assumed mean heat flux of $\dot{q} = 856$ kW/m² the vapor mass fraction is estimated at a distance of 200 mm after the locus of critical heat flux in the evaporator pipe to be

$$\dot{x}_{eq} = \dot{x}_{inl} + 4 \cdot \frac{\dot{q}}{\dot{m} \cdot \Delta h_v} \frac{l}{d} = 0.123.$$

The heat transfer coefficient at droplet flow is determined following Sect. 2.1 with $T_w - T_{eq} = 117.9$ K and $\dot{q} = 180$ kW/m²:

With

$$b = \sqrt{\frac{5.224 \cdot 10^{-3} \text{ N/m}}{9.81 \text{ m/s}^2 \cdot (603.1 - 97.07) \text{ kg/m}^3}} = 1.0257 \cdot 10^{-3} \text{m}$$

and

$$\frac{\dot{m}}{b} = \frac{500}{1.0257 \cdot 10^{-3}} = 487.4 \cdot 10^3 \text{ kg/(m}^3\text{ s)} < 1,767 \cdot 10^3 \text{ kg/(m}^3\text{ s)}$$

is

$$\alpha_{gd} \frac{A_d}{A} = \left(1.473 \cdot 10^{-7} \left(\text{kW m}^{1.33} \text{ s}^{1.33}\right)/\left(\text{kg}^{1.33} \text{ K}\right)\right) \cdot \left(487.4 \cdot 10^3 \text{ kg/(m}^3\text{ s)}\right)^{1.33} = 5.41 \text{ kW/m}^2\text{K}.$$

Inserting $\dot{\omega} = 0.6$ and $c_{pg} = 4.13$ kJ/(kg K) the gas temperature is determined to be

$$T_g = 342.1 + \frac{1,004}{4.14}\left(\frac{1}{0.6} - 1\right) = 503.8°C.$$

From that follows $h_g(150\ \text{bar},\ 503.8°C) = 3,312\ \text{kJ/kg}$ and $h''(150\ \text{bar}) = 2,615\ \text{kJ/kg}$,

$$c_{pg} = \frac{(3,312 - 2,615)\text{kJ/kg}}{(503.8 - 342.1)\text{K}} = 4.31\ \text{kJ/(kg K)}.$$

Further, the following data are to be determined:

$$\dot{\omega} = \frac{2}{\left[1 + \sqrt{1 + \left(\frac{4{\cdot}4.31\ \text{kJ/kg K}}{1,004\ \text{kJ/kg}}\right) \cdot \frac{180\ \text{kW/m}^2}{(5.41\ \text{kW/m}^2\,\text{K})}}\right]} = 0.887,$$

$$\dot{x}_{act} = \dot{\omega}\dot{x}_{eq} = 0.887 \cdot 0.123 = 0.109,$$

and

$$\text{Re}_g = \frac{500 \cdot 0.012}{25.0 \cdot 10^{-6}}\left[0.109 + (1 - 0.109)\frac{63.6}{603.17}\right] = 4.87 \cdot 10^4.$$

With $\xi = \left[1.82 \cdot \log_{10}(4.87 \cdot 10^4) - 1.64\right]^{-2} = 0.021$, $\left(\text{Pr}_g/\text{Pr}_w\right)^{0.11} = 1.0164$, and $d/l \approx 1$, the value for Nu_g is either determined from the nomogram given in Chap. G1, or it is calculated from

$$\text{Nu}_g = \frac{(0.021/8) \cdot (4.87 \cdot 10^4 - 10^3) \cdot 1.296}{\left[1 + 12.7 \cdot \sqrt{0.021/8} \cdot (1.296^{2/3} - 1)\right]} \cdot 1.0164 = 147.$$

The heat transfer coefficient at fully developed droplet flow is

$$\alpha_{wg} = 147 \cdot \frac{79.8 \cdot 10^{-3}\ \text{W/(m K)}}{0.012\ \text{m}} = 977.5\ \text{W/(m}^2\,\text{K)}.$$

Hence, the heat flux is $\dot{q}_{FB} = 977.5\ \text{W/m}^2\text{K} \cdot 117.9\ \text{K} = 115.2\ \text{kW/m}^2$.

After a second iteration using the new $\dot{q}_{FB}$-value, one obtains $T_g = 371.7°C$, $\dot{\omega} = 0.907$, $\dot{q}_{act} = 0.112$, $\text{Re}_g = 49,300$, $\text{Nu}_g = 147.8$, and thus $\alpha_{wg} = 982.4\ \text{W/m}^2\,\text{K}$ and $\dot{q}_{FB} = 115.8\ \text{kW/m}^2$ (see point 2b in Fig. 8). Thereafter, the calculations from procedure shown in (a) and (b) has to be repeated for some other wall temperature, e.g., $T_w = 500°C$, which ought to be in between T_{max} and $T_w = 540°C$.

(a) The heat transfer coefficient at film boiling is now $\alpha = 1,400\ \text{W/m}^2\,\text{K}$ and the heat flux is $\dot{q}_{FB} = 1.4 \cdot 157.9 = 221.0\ \text{kW/m}^2$ (see point 3a in Fig. 8)

(b) After three iterations the heat transfer coefficient for droplet flow is calculated to be $\alpha_{wg} = 943.6\ \text{W/m}^2\,\text{K}$ which leads to a heat flux of $\dot{q}_{DF} = 0.9436 \cdot 157.9 = 149.0\ \text{kW/m}^2$ (see point 3b in Fig. 8).

The intersection between the line $\overline{2a\ 3a}$ and the heat flux at partial film boiling gives the maximum temperature $T_{max} = T_{sat} + \Delta T_{max} = 342.1 + 75 = 417.1°C$ and the corresponding heat flux $\dot{q}_{min} = 132.0\ \text{kW/m}^2$. This maximum temperature lies between the Leidenfrost-temperature according to Eq. (43), $T_L = 374.15°C$ ($\Delta T_L = T_w - T_{sat} = 32.0\ \text{K}$), see Fig. 8.

Furthermore, from Fig. 8 it can be read that the two straight lines $\overline{2b\ 3b}$ and $\overline{2a\ 3a}$ intersect in point 5. To the right of this point heat transfer occurs in the droplet flow regime, and to the left it occurs in the film boiling regime.

3.3 Film Boiling During Flow over Horizontal Cylinders

The heat transfer coefficient α_{conv} for forced convection in a direction perpendicular to the axis of a cylinder depends on the Froude number [57], which is defined by

$$\text{Fr} = \frac{u_l}{\sqrt{gd}}. \tag{32}$$

If $\text{Fr} \leq 1$, the total heat transfer coefficient is given by

$$\alpha = \alpha_{conv} + \frac{3}{4}\alpha_{rad}. \tag{33}$$

The term "α_{conv}" is the convection component and is given by

$$\alpha_{conv} = 0.62\left[\frac{\lambda_g^3 g \rho_g \left(\rho' - \rho_g\right)\Delta h_v^*}{\eta_g d \Delta T_{wl}}\right]^{1/4}. \tag{34}$$

The term "α_{rad}" is the radiation component and is defined by

$$\alpha_{rad} = C_{wl}\left(T_w^4 - T_l^4\right)/\Delta T_{wl}. \tag{35}$$

C_{wl} and h_v^* are defined by Eqs. (36) and (37):

$$C_{wl} = \frac{\sigma}{1/\varepsilon_w + 1/\varepsilon_l - 1}, \tag{36}$$

$$\Delta h_v^* = \Delta h_v\left(1 + \frac{0.4 c_{pg}\Delta T_{wl}}{\Delta h_v}\right). \tag{37}$$

σ is Stefan's constant for black body radiation, and ε_w and ε_l are the emissivities of the heated surface and the liquid. If ε_l cannot be obtained from tables [58], a value of $\varepsilon \approx 1$ is taken. Δh_v is the enthalpy of vaporization, and the mean temperature of the vapor film is $T_g = 0.5(T_w + T_l)$.

If $\text{Fr} \geq 2.0$, the Nusselt number is calculated from the following relationship:

$$\overline{\text{Nu}} = 2.7\left(\text{RePr}^* \frac{\nu_l}{\nu_g}\right)^{0.5}. \tag{38}$$

Nu and Pr^* are defined by Eqs. (39) and (40)

$$\overline{\text{Nu}} = \frac{\alpha_{conv} d}{\lambda_g}, \tag{39}$$

$$\text{Pr}^* = \frac{\eta_g \Delta h_v^*}{\lambda_g \Delta T_{wl}}. \tag{40}$$

The Reynolds number is given by

$$\text{Re} = \frac{u_l \rho_l d}{\eta_l}. \tag{41}$$

The numerical values to be inserted for the properties in Eq. (41) are those relating to the temperature of the liquid.

The correlation for the total heat transfer coefficient for the case of $\text{Fr} \geq 2$ allows for the radiation component, i.e.,

$$\alpha = \alpha_{conv} + \frac{7}{8}\alpha_{rad}. \tag{42}$$

Equation (38) has been checked in the $2 \leq \text{Fr} \leq 15$ range with various liquids, viz. benzene, carbon tetrachloride, ethanol, and *n*-hexane [57]. The diameter of the heaters in the experiments ranged between 9.8 and 16.2 mm.

All the properties of the vapor film (subscript "g") must be referred to the mean film temperature $T_g = 0.5(T_w + T_l)$.

The heat transfer coefficient in the $1 < Fr < 2$ range is obtained by linear interpolation of the boundary values for Fr = 1 and Fr = 2.

Studies by Motte and Bromley [59] on ethanol, benzene, *n*-hexane, and carbon tetrachloride demonstrated that heat transfer can be significantly improved through subcooling and the flow velocity. The effect of flow velocities of up to 4 m/s in these liquids has been presented in diagrams [22,59], and the effect of subcooling at low velocities ($u_l \leq 1$ m/s) can be derived from Eq. (30).

Example 4

What is the heat transfer coefficient between a slightly oxidized, horizontal heated rod of 12 mm diameter and liquid nitrogen flowing at a velocity of 3 m/s? The wall temperature is 900 K; the liquid is saturated, and the pressure in the system is 1 MPa (= 10 bar).

The properties of nitrogen can be obtained from the literature [60]. At $p = 10$ bar, $T_{sat} = T_l = 103.7$ K. Hence the difference in temperature between the wall and the liquid is $\Delta T = 796.3$ K and is thus greater than the temperature difference at the Leidenfrost-point (Sect. 4). Consequently, the film boiling occurs and the Froude number is

$$Fr = \frac{3}{\sqrt{9.81 \cdot 0.012}} = 8.7.$$

The equation to apply is therefore Eq. (38).

The properties of nitrogen at $T_l = 103.7$ K are

$$\rho_l = 668.9 \text{ kg/m}^3, \quad \eta_l = 6.57 \cdot 10^{-5} \text{ Pa s},$$
$$\Delta h_v = 153.9 \text{ kJ/kg}, \quad \nu_l = 0.98 \cdot 10^{-7} \text{ m}^2/\text{s},$$
$$Re = \frac{3 \cdot 668.9 \cdot 0.012}{6.57 \cdot 10^{-5}} = 3.67 \cdot 10^5.$$

The average temperature is

$$T_g = 0.5(900 + 103.7) \text{ K} = 501.9 \text{ K} \approx 502 \text{ K}.$$

Properties at T_g and $p = 10$ bar

$$\rho_g = 6.68 \text{ kg/m}^3, \quad \eta_g = 2.59 \cdot 10^{-5} \text{ Pa s},$$
$$\lambda_g = 0.039 \text{ W/mK}, \quad \nu_g = 3.88 \cdot 10^{-6} \text{ m}^2/\text{s},$$
$$c_{pg} = 1.06 \text{ kJ/kg K}, \quad \Delta h_v^* = 153.9(1 + 0.4 \cdot 1.06 \cdot 796.3/153.9)^2 = 1,569.9 \text{ kJ/kg},$$
$$Pr^* = \frac{2.59 \cdot 10^{-5} \cdot 1,569.9 \cdot 10^3}{0.039 \cdot 796.3} = 1.31,$$
$$\overline{Nu} = 2.7\left(3.67 \cdot 10^5 \cdot 1.31 \frac{0.98 \cdot 10^{-7}}{3.88 \cdot 10^{-6}}\right)^{0.5} = 297.0,$$
$$\alpha_{conv} = \frac{297.0 \cdot 0.039}{0.012} = 965.4 \text{ W/m}^2 \text{ K}.$$

The radiation component is obtained by inserting $\varepsilon_l \approx 1$ and $\varepsilon_w = 0.79$ in Eqs. (35) and (36). Thus,

$$\alpha_{rad} = 0.79 \cdot 5.67 \cdot 10^{-8} \frac{900^4 - 103.1^4}{796.3} = 36.8 \text{ W/m}^2 \text{ K}.$$

Inserting in Eq. (42) gives

$$\alpha = \left(965.4 + \frac{7}{8} \cdot 36.8\right) \text{ W/m}^2 \text{ K} = 997.7 \text{ W/m}^2 \text{ K}.$$

4 Determination of the Maximum Temperature at Which a Surface Is Wetted (Leidenfrost-Point)

Leidenfrost [61] was the first to observe the wetting of a surface heated to a temperature substantially higher than the saturation temperature of the wetting liquid. In describing the evaporation of water droplets on a red-hot metallic body, he noted that the droplets did not wet the surface of the metal until the temperature fell below a certain point, which is known as the Leidenfrost-temperature and is denoted by T_L. This point marks the boundary between transition and fully developed film boiling and is thus referred to as the "departure from film boiling (DFB)." The associated heat flux is known as the "minimum film boiling heat flux ($\dot{q}_{min}$)"; and the associated Leidenfrost-temperature as the "maximum film boiling temperature (T_{max})."

Wetting occurs frequently in engineering practice, e.g., in metallurgical processes, in hardening steel during quenching, in cryogenic engineering during filling, and in the operation of conventional and nuclear steam generators or heat exchangers.

4.1 Calculation of the Leidenfrost-Temperature of a Heated Surface

Schroeder-Richter and Bartsch [40,62] propose a thermomechanical model for the calculation of the Leidenfrost-temperature, assuming stable transition boiling in a situation of forced upward flow and using nonequilibrium thermodynamic principles. The fundamental assumption of this model is that the liquid surrounding the vapor film and the vapor at the heated wall are at equilibrium at their respective pressures. This presumes a situation of mechanical nonequilibrium and thus a relevant overpressure at the heated wall. Considering the conservation laws for mass, momentum and energy at the phase boundary between vapor and liquid at the locus of the Leidenfrost-phenomenon, they derive

$$h''(T_{sat}) - h'(T_L) = 0.5 \cdot [\nu''(T_{sat}) - \nu''(T_L)] \cdot [p(T_L) - p(T_{sat})], \quad (43)$$

which can be interpreted as a new way of defining the Leidenfrost-temperature.

Assuming stagnant vapor at the heated surface, this temperature replaces the temperature derived from the spinodal (see Subchap. H3.5, Fig. 1). The Leidenfrost-temperature T_L can be determined by iteration, using T_{sat} (p) as the equilibrium temperature of the fluid at pressure p in the body of the flow. For example, such an iterative calculation gives for water at $p = 1$ a Leidenfrost-temperature of $T_L = T_{sat} + 150$ K. The advantage of this equation is that it is valid for any fluid [40].

4.2 Calculation of the Maximum Temperature for Wetting of Isothermal Heated Surfaces

Figure 9 shows the Leidenfrost-temperature for water after Schroeder-Richter in comparison to measured data of Hein et al. [63], Groeneveld and Stewart [64], and Feng [65]. It can be seen, that the measured maximum temperature at transitional boiling is higher than the one defined by Eq. (43). This deviation can be justified by influences of the properties of the heating surface, and by differences in the thermodynamic properties of the flowing fluid at the core temperature and the stagnant fluid at the wall which is at maximum temperature.

The influence of the wall material on the wall temperature at wetting may only then be neglected, if isothermal or quasi-isothermal conditions exist at the wall, i.e., $(\lambda\rho c_p)_w \gg (\lambda\rho c_p)_l$. If this is not the case and the thermophysical properties of the liquid are comparable to those of the wall material, i.e., if $(\lambda\rho c_p)_w \approx (\lambda\rho c_p)_l$, then transient wetting phenomena exert larger local fluctuations of the wall temperature. In this case, thermophysical properties of the wall have to be considered for the calculation of the wall temperature.

Hitherto existing investigations about the maximum temperature have shown the influence of the following experimental parameters on the wetting temperature:

- Surface properties, i.e., roughness, stain, and oxidation [66–69].
- System pressure. Figure 9 shows the measured data of the maximum temperature. They are in good agreement with the data published elsewhere by Emmerson and Snoek [70]. Up to the critical pressure, these data show the maximum temperature of brass surfaces during partial wetting by droplets of R 12, R 113, chloroform, and carbon tetrachloride.
- Mass flow rate. Auracher [33] with R 114 and Feng and Johannsen [65,71] with water investigated the influence of the mass flow rate on the maximum temperature during transition flow boiling in tubes. Measurements by Feng [65] show that in the pressure range between 0.1 to 1.2 MPa the maximum temperature increases with increasing mass flow rate, see Fig. 10 [37].

The empirical equation proposed by Groeneveld [1,22,64] has been transformed into a dimensionless form and validated with measured data given by Feng [65] in short vertical tubes with water in the parameter range of $0.11 \le p \le 1.2$ MPa, $-0.041 \le \dot{x} \le 0.10$, and $25 \le \dot{m} \le 1,000$ kg/m^2 s. From this, the relationship

$$\frac{T_{max}(\text{in °C})}{T_{crit}(\text{in °C})} = \left[0.760 + 2.607 \cdot p_r - 4.865 \cdot p_r^2 - \frac{26.727 \cdot \dot{x}}{2.82 + 26.986 \cdot p_r}\right] \cdot f(\dot{m}) \quad (44)$$

was developed. It is the equation given by Groeneveld and Stewart [64] and expanded in [37] by the term

$$f(\dot{m}) = 0.943 + 5.87 \cdot 10^{-4} \cdot \dot{m} \quad (45)$$

is developed for the given parameter range, see Fig. 11. In this equation $\dot{x} = (h - h'(p))/\Delta h_v$ is to be set, with h being the specific enthalpy of the liquid in the bulk of the flow. Considering the range of its validity, Eq. (44) of Groeneveld and Stewart can be used to calculate the maximum temperature during flow boiling of water in tubes within the parameter range of $0.1 \le p \le 6.0$ MPa, $25 \le \dot{m} \le 1{,}000$ kg/m^2 s, and $-0.1 \le \dot{x} \le 0.1$, see Fig. 9 [37].

Subcooling the liquid ($T_l < T_{sat}$) has a significant effect on the Leidenfrost-point. This is evident from Eq. (43) and from the results plotted in Fig. 12 of measurements on various materials in water at low pressures ($p \le 0.5$ MPa). The following empirical equation, derived from the results of measurements in water [53,66,72], can be recommended for use in industry:

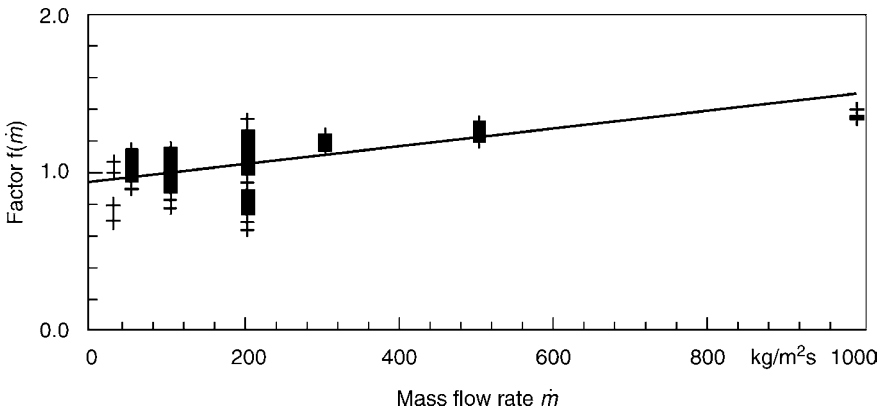
$$T_{max} - T_{sat} = 200\text{K} + 6.15(T_{sat} - T_l). \quad (46)$$

It is valid for surfaces in the range of $5 \cdot 10^3 \le (\lambda\rho c)_w^{1/2} \le 10^4$ W s$^{1/2}$/m^2 K, e.g., stainless steel and Zircaloy.

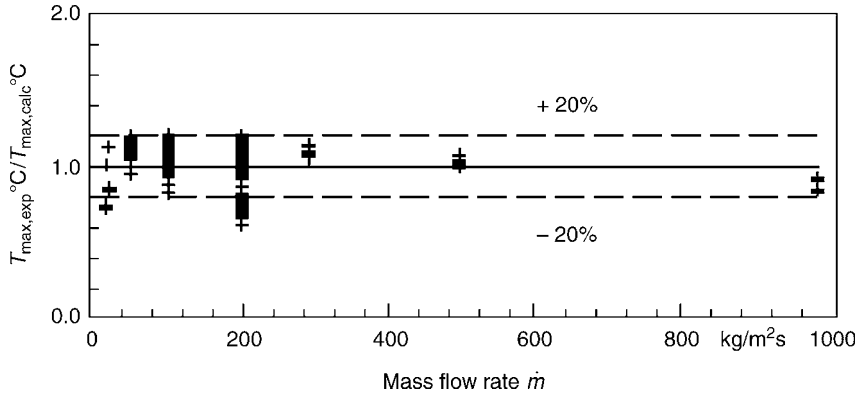
The best straight line drawn through points representing measurements on silver surfaces wetted with water has also been included in Fig. 12.

4.3 Calculation of the Maximum Temperature for Wetting of Nonisothermal Heated Surfaces

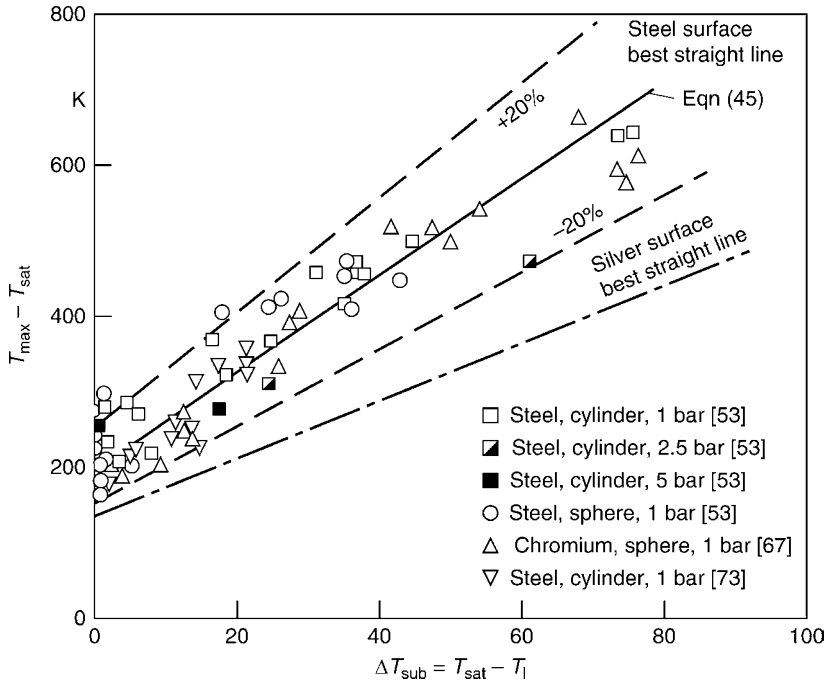
Henry [73] recommended the following equation for the determination of the maximum temperature for the case of clean



H3.6. Fig. 10. Dependence of the factor $f(\dot{m})$, Eq. (44) on the mass flow rate. Measured data from Feng [65].



H3.6. Fig. 11. Measured data from Feng [65] compared to Eq. (44), in °C.



H3.6. Fig. 12. Leidenfrost-point as a function of liquid subcooling with the material or construction as parameter [47,48,55,72].

surfaces and liquids with a high surface tension, e.g., molten metals and water at near-atmospheric pressure:

$$\frac{T_{max} - T_{max-iso}}{T_{max-iso} - T_l} = 0.42 \left[\sqrt{\frac{(\lambda\rho c_p)_l}{(\lambda\rho c)_w}} \frac{\Delta h_v}{c_w \Delta T_{L-iso}} \right]^{0.6}, \qquad (47)$$

where $T_{max-iso}$ is the maximum temperature for an isothermal surface and is given by the Berenson equation [74], i.e.,

$$\Delta T_{max-iso} = T_{max-iso} - T_{sat} = 0.127 \frac{\rho_g \Delta h_v}{\lambda_g} \cdot \left[\frac{g(\rho_l - \rho_g)}{\rho_l + \rho_g} \right]^{2/3} \cdot \left[\frac{\sigma}{g(\rho_l - \rho_g)} \right]^{1/2} \left[\frac{\eta_g}{g(\rho_l - \rho_g)} \right]^{1/3}. \qquad (48)$$

The properties of the vapor must be referred to the average temperature of the vapor film $T_g = 0.5(T_w + T_l)$.

Kalinin et al [75] studied the effect of liquids with good wetting properties (contact angle $\beta_0 \approx 0$) within the following range of parameters:

$$0.02 \le p_r \le 0.60, \quad \frac{T_{sat} - T_l}{T_{crit} - T_{sat}} \le 1.5, \quad 10^{-3} \le \sqrt{\frac{(\lambda\rho c_p)_l}{(\lambda\rho c)_w}} \le 1.0 \qquad (49a)$$

$$d_h \sqrt{\frac{g(\rho_l - \rho_g)}{\sigma}} \ge 10.0, \quad u_l \left[\frac{\rho_l - \rho_g}{g\sigma} \right]^{1/4} \le 160, \quad \frac{\rho_l u_l d_h}{\eta_l} \le 1.4 \cdot 10^6 \qquad (49b)$$

The correlation that he recommended is

$$\frac{T_{max} - T_{sat}}{T_{crit} - T_l} = 1.65\left\{0.1 + 1.5\left[\frac{(\lambda\rho c_p)_l}{(\lambda\rho c)_w}\right]^{0.25} + 0.6\frac{(\lambda\rho c_p)_l}{(\lambda\rho c)_w}\right\} \quad (50)$$

It has been checked against measurements [75] in vertical tubes and annular gaps constructed from various materials (copper, Duralumin, stainless steel, magnesium alloys, titanium alloys, steel, and fluorocarbon polymers). The geometric configuration (tubes and rod bundles of various diameters) and the roughness were varied. The fluids were nitrogen, R 12, R 13, R 22, and water in free and forced convection. The scatter between the measured values and the figures calculated from Eq. (50) was ±30%. According to the publication [75], Eq. (50) is also valid for rod bundles.

Figure 13 presents a comparison between the values calculated from Eq. (50) and measurements performed by Hein [66] in R 12. The measured values are greatly scattered, particularly in the lower range of pressures. Scattering of the measurements of the Leidenfrost-temperature has been observed in all the experiments known (see Fig. 12) and can by no means be ascribed to experimental error. In view of this fact, Komnos [76] suggested that the stability of the vapor film formed before wetting occurs is of crucial importance in deciding the wetting temperature. He thus developed a mathematical model based on the mass and energy balances at the liquid/vapor film boundary. The intersect of the curves for these balances is regarded as a theoretical Leidenfrost-temperature. The scatter of the measured values is thus explained as random hydrodynamic instabilities at the liquid/vapor film phase boundary. These instabilities may cause the wall to be prematurely wetted if turbulence in the vapor film is increased. Alternatively, they may be suppressed by the surface tension in the liquid phase or by an increase in the rate of evaporation, which would bring the phase boundary closer toward the heated wall. In view of the attendant increase in density and decrease in buoyancy, it may be assumed that the film becomes more stable at elevated pressures [77].

Example 5

A high-temperature steel tube of 25 mm diameter in a steam generator is heated to $T_w = 500°C = 773.1$ K by interrupting the flow of cooling water. It is then flooded by readmitting the cooling water at a mass flow rate of $\dot{m} = 500$ kg/m^2 s, a temperature of $T_l = 160°C = 433.15$ K, and a pressure of 1 MPa. At what temperature is the wall of the tube wetted by the water?

The values for the properties of the water at T_1 are [20] $h = 675.7$ kJ/kg, $c_p = 4.337$ kJ/kgK, $\lambda_l = 0.689$ W/mK, $\rho_l = 907.5$ kg/m^3, $\eta_l = 1.72.10^{-4}$ kg/ms, and $\sigma = 0.04658$ N/m. The boiling point of water at 1 MPa is $T_{sat} = 179.9°C = 453.0$ K, and the corresponding enthalpy and latent heat of vaporization are $h' = 762.6$ kJ/kg and $\Delta h_v = 2{,}013.6$ kJ/kg. The density of the steam film at T_g is $\rho_g = 3.6$ kg/m^3.

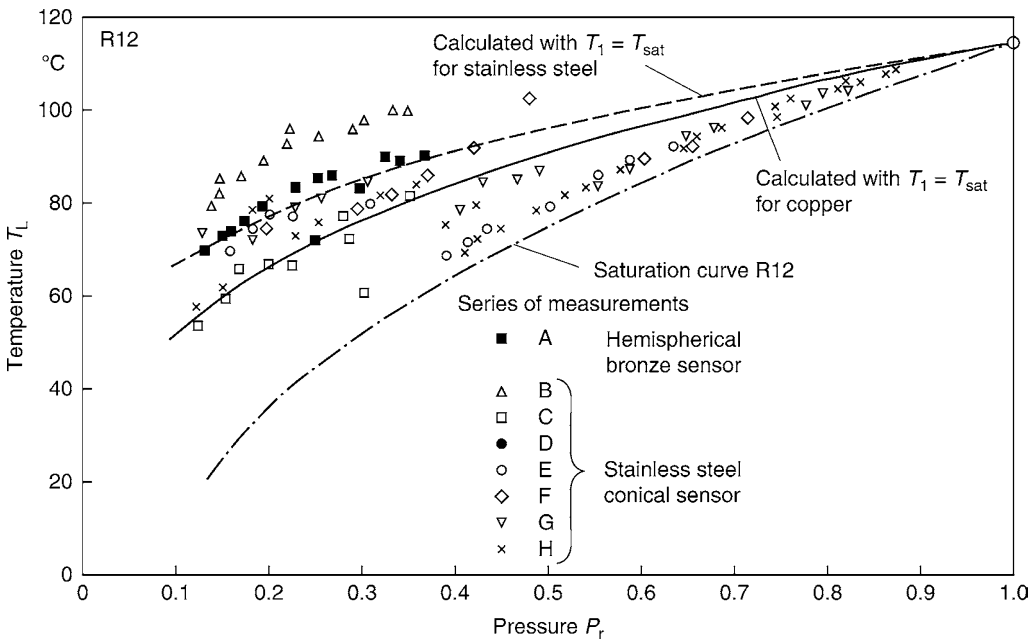
The values for the properties of the steel tube at $T_w = 500°C$ are [58] $c_w = 0.595$ kJ/kg K; $\rho_w = 7{,}800$ kg/m^3; and $\lambda_w = 37.0$ W/m K.

For water: $(\lambda\rho c_p)_l = 0.689 \cdot 907.5 \cdot 4{,}337 = 2.71 \cdot 10^6$ W^{2}s/m^4 K^2.
For steel tube: $(\lambda\rho c)_w = 37.0 \cdot 7{,}800 \cdot 595 = 1.72 \cdot 10^8$ W^{2}s/m^4 K^2.

Although $(\lambda\rho c)_w > (\lambda\rho c_p)_l$, the maximum temperature should still be determined by Eq. (50). First of all, Eqs. (49a) and (49b) must be applied to verify whether Eq. (50) is valid within the given range of parameters. Thus,

$$p_r = \frac{1}{22.12} = 0.045, \quad \text{i.e., } p_r > 0.02,$$

$$\frac{T_{sat} - T_l}{T_{crit} - T_{sat}} = \frac{453.0 - 433.1}{647.3 - 453.0} = 0.102 < 1.5,$$



H3.6. Fig. 13. Equation (50) in comparison to data measured by Hein [66].

$$10^{-3} \le \sqrt{\frac{2.71 \cdot 10^6}{1.72 \cdot 10^8}} \le 1,$$

$$0.025\sqrt{\frac{9.81(907.5-3.6)}{46.58 \cdot 10^{-3}}} = 10.9 > 10,$$

$$u_l = \frac{500}{907.5} = 0.55 \text{ m/s},$$

$$0.55\left[\frac{907.5-3.6}{9.81 \cdot 0.04658}\right]^{1/4} = 3.6 < 160,$$

$$\frac{907.5 \cdot 0.55 \cdot 0.025}{1.72 \cdot 10^{-4}} = 7.25 \cdot 10^4 < 1.4 \cdot 10^6.$$

Hence, all the conditions stipulated in Eq. (49) are satisfied, and Eq. (50) may be applied for the determination of the maximum temperature. Thus,

$$\frac{T_{max}-T_{sat}}{T_{crit}-T_l} = 1.65\left[0.1 + 1.5\left(\frac{2.71 \cdot 10^6}{1.72 \cdot 10^8}\right)^{1/4} + 0.6 \cdot \left(\frac{2.71 \cdot 10^6}{1.72 \cdot 10^8}\right)\right] = 1.65 \cdot 0.641 = 1.057.$$

The maximum temperature is, therefore,

$$T_{max} = 453.0 + 1.057(647.3 - 433.1) = 679.4 \text{ K}.$$

The maximum temperature can also be determined from Eq. (44) to allow a comparison. The check for validity yields

$$\frac{h - h'(p)}{\Delta h_v} = \frac{675.7 - 762.6}{2,013.6} = -0.043.$$

This value lies within the verified range. Thus,

$$T_{max} = 557.6 + 44.1 \cdot 1 - 3.72 \cdot 1^2 - \frac{10^4}{2.82 + 1.22 \cdot 1}\left[\frac{675.7 - 762.6}{2,013.6}\right] = 704.4 \text{ K}.$$

Therefore, the maximum temperature determined by the two methods differ by 25 K, i.e., by only about 3.5%, and the tube is rewetted at about 700 K or 427°C.

The calculation of the maximum temperature is done with and without taking into account the influence of the mass flow according to Eq. (44) with $f(\dot{m}) = 0.943 + 5.87 \cdot 10^{-4}$ m² s/kg· 500 kg/m² s = 1.236. With $p_r = 1.0/22.12 = 0.04521$ follows

$$\frac{T_{max}(\text{in°C})}{T_{crit}(\text{in°C})} \cdot \frac{1}{f(\dot{m})} = \left[0.760 - 2.607 \cdot 0.04521 - 4.865 \cdot 0.04521^2 - \frac{26.727 \cdot (-0.043)}{2.82 + 26.986 \cdot 0.04521}\right] = 1.153.$$

When neglecting the influence of the mass flow rate according to Eq. (50), the maximum temperature is calculated to T_{max} = 0.917·374.15 = 343.1°C (= 616.1 K). This value differs by 63 K to the value according to Eq. (50), which means that in this case the difference is rather big. But, accounting for the influence of the mass flow rate according to Eq. (44), then T_{max}/T_{crit} = 0.917·1.236 = 1.133, or T_{max} = 1.133·374.15 = 423°C (= 697 K). Now, the difference between both calculations is only 18 K.

Example 6

A tantalum sphere heated to 1,700 K comes into contact with liquid sodium at 1,150 K and 0.1 MPa. At what temperature is the sphere wetted by the sodium?

The values for the properties of sodium at T_l = 1,150 K and p = 0.1 MPa are [53] $\lambda_l = 49.9$ W/m K, $\rho_l = 743.0$ kg/m³, $c_p = 1.28$ kJ/kg K, and $\sigma = 0.092$ N/m. The values relating to $T_g = 0.5(1,700 + 1,150) = 1,425$ K are $\rho_g = 0.199$ kg/m³, $\eta_g = 3.03 \cdot 10^{-5}$ kg/m s, $\lambda_g = 0.0456$ W/m K, and $\Delta h_v = 3,896.6$ kJ/kg. The critical pressure and the corresponding temperature of the sodium are p_{crit} = 37 MPa and T_{crit} = 2,500 K. The saturation temperature of sodium at 0.1 MPa is T_{sat} = 1,153 K.

The values for the properties of tantalum at the temperature at the surface of the sphere are $\lambda_w = 72.2$ W/m K, $\rho_w = 16,650$ kg/m³, and $c_w = 0.15$ kJ/kg K [52].

For sodium: $(\lambda\rho c_p)_l = 49.9 \cdot 743.0 \cdot 1,280 = 4.74 \cdot 10^7$ W² s/m⁴ K².
For tantalum: $(\lambda\rho c)_w = 72.2 \cdot 16,650 \cdot 150 = 1.8 \cdot 10^8$ W² s/m⁴ K².

Thus, $(\lambda\rho c_p)_l$ and $(\lambda\rho c)_w$ are of the same order, i.e., $(\lambda\rho c_p)_l \approx (\lambda\rho c)_w$. Since, in addition, $p_r = 0.1/37 < 0.02$, i.e., <0.02, and the liquid has a high surface tension; Eqs. (47) and (48) should be taken to calculate the maximum temperature. Equation (48) becomes

$$T_{max-iso} = T_{sat} + 0.127\frac{0.199 \cdot 3,896.6 \cdot 10^3}{0.04556} \cdot \left[\frac{9.81 \cdot (743.0 - 0.199)}{743.0 + 0.199}\right]^{2/3} \cdot \left[\frac{0.092}{9.81 \cdot (743.0 - 0.199)}\right]^{1/2} \cdot \left[\frac{3.03 \cdot 10^{-5}}{9.81 \cdot (743.0 - 0.199)}\right]^{1/3},$$

$$T_{max-iso} = 1153 + 56.5 = 1,209.5 \text{ K}.$$

The maximum temperature then follows from Eq. (47), i.e.,

$$\frac{T_{max} - T_{max-iso}}{T_{max-iso} - T_l} = 0.42\left[\sqrt{\frac{4.74 \cdot 10^7}{1.8 \cdot 10^8}} \cdot \frac{3,896.6}{0.15 \cdot 56.5}\right]^{0.6} = 11.14,$$

or

$$T_{max} = 1,209.5 + 11.14(1,209.5 - 1,150) = 1,872.3 \text{ K} = 1,599°\text{C}.$$

It can be derived from tables compiled by various authors [22] that the value of T_{max} thus calculated differs by no more than ±15% from the measured values. Accordingly, the tantalum sphere will be wetted immediately on its immersion in the sodium.

H3.7 Flow Boiling of Mixtures

Dieter Steiner[1,†] · *Matthias Kind*[1] · *Yasushi Saito*[2]
[1]Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany
[2]Kyoto University, Osaka, Japan

The heat transfer coefficient for mixtures *without miscibility gap* is defined by

$$\alpha(z) = \frac{\dot{q}(z)}{\overline{T}_w(z) - T_{sat}(p(z))} \qquad (1)$$

(identical to Eq. (3) in Chap. H3), in which the boiling point T_{sat} is the equilibrium temperature at pressure p of the system when the molar composition of the liquid phase is $\underline{\tilde{x}}$ at a point z in an evaporator tube.

If due consideration is given to the real behavior of the components j in the mixed phase, the term $T_{sat}(z) = T_{sat}(p, \underline{\tilde{x}})$ can be obtained by iteration as described in Subchap. D5.1 (see also Example 2). The boiling temperature of pure substances steadily decreases as a result of the pressure drop; however, $T_{sat}(z)$ for mixtures may even increase, because the less volatile components become more concentrated along the length of the flow path z.

1 Convective Flow Boiling of Mixtures

It has been established by various studies [1–26] (see Subchap. H3.8) that convective and nucleate boiling occur together in mixtures. Niederkrüger [23] and Wettermann [24] demonstrated this most clearly by local measurements. The results obtained by Wettermann on a binary mixture for mass velocities between 80 and 400 kg/m^2 s are presented in Fig. 1.

In the light of these results, both the heat transfer coefficient in the convective boiling regime $\alpha(z)_{conv}$ and the local single-phase heat transfer coefficients $\alpha(z)_{L0}$ and $\alpha(z)_{G0}$ can be determined from the equations given in Subchap. H3.4. The appropriate properties for the mixture to be inserted in the equations can be obtained from Chap. D1. The composition of the mixture is calculated as described in Sect. 4. Methods for determining the values for the properties of refrigerant–oil mixtures without miscibility gaps [27–31] are presented in Chap. D1. In this case, the values to insert for the refrigerant are those corresponding to saturation at the system pressure; and the values for the oil are those at the boiling point $T_{sat}(p)$ of the refrigerant.

1.1 Vertical Tubes

All points on the inner wall of the tube are wetted, and $\alpha(z)_{conv}$ can be calculated from Subchap. H3.4, Eq. (1).

1.2 Horizontal Tubes

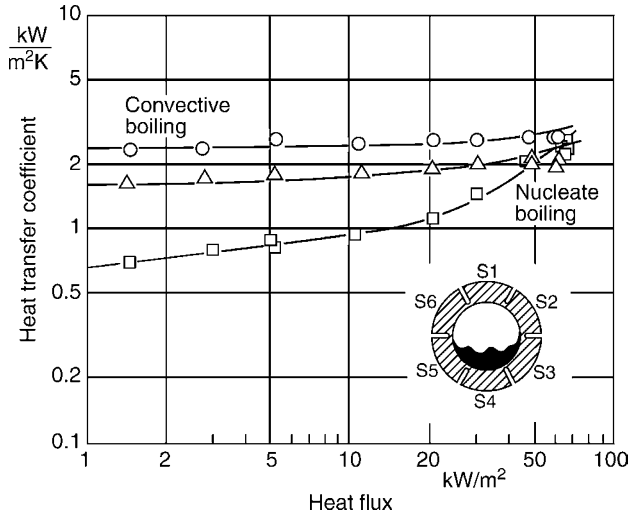
Subchap. H3.4, Eq. (3) is used to determine $\alpha(z)_{conv}$ for all flow patterns with the exception of stratified and stratified-wavy flows. In the latter two cases, incomplete wetting must be taken into consideration and therefore, Subchap. H3.4, Eqs. (3–11) for the boundary conditions $\dot{q}$ = constant and T_w = constant are used. The *flow pattern* is determined from the flow pattern map (see Subchap. H3.1) and the boundary conditions that define them. The values to be inserted for the properties in all the dimensionless numbers and equations are those for the mixture.

It was demonstrated by Gropp [20] that the resistance to mass transfer on the liquid side has comparatively little effect in convective boiling of mixtures with normal viscosity. If the mixture has a high viscosity, the resistance to mass transfer on the liquid side exerts a significant effect, even in convective boiling, as has been demonstrated by Palen [21] with mixtures of ethylene glycol/water and propylene glycol/water. In this case the measured heat transfer coefficients are considerably lower than the coefficients estimated by linear averaging the coefficients calculated for the pure substances according to Eq. (2), see below. Nevertheless, Numrich [25] shows that a good agreement between experiment and calculation can be obtained, if $\alpha(z)_{conv}$ is estimated by Subchap. H3.4, Eqs. (1–8), and if properties of the mixture are used in these equations.

2 Nucleate Boiling of Mixtures in Pipe Flow

The upper limit in nucleate boiling of mixtures is the critical boiling state (cf. Subchap. H3.5). Vertical tubes in evaporators are always completely wetted up to this point, whereas

[†]Deceased



H3.7. Fig. 1. Local heat transfer coefficient in segment S4 as a function of the heat flux. System $C_2F_6/C_2H_2F_4$, $p = 11$ bar, vapor mass fraction 0.65, composition 23 mol% C_2F_6.

horizontal tubes may already be incompletely wetted before the critical boiling state is reached. Consequently, the heat transfer equations for vertical tubes differ from those for horizontal. In both cases, it is essential to arrange the components of the mixture in the sequence of their boiling points, i.e., the subscript $j = 1$ is allotted to the component with the lowest boiling point, and the subscript $j = K$, to the component with the highest boiling point.

2.1 Nucleate Boiling in Vertical Tubes

According to the literature [3–21] and according to own results of extensive systematic measurements [22–24], the best agreement between mathematical models given by [2,26] and experimental data is obtained with the help of the following equations:

$$\frac{1}{\alpha(z)_{\mathrm{id,B}}} = \sum_{j=1}^{K} \frac{\tilde{x}_j}{\alpha_{\mathrm{B},j}}. \tag{2}$$

The heat transfer $\alpha_{\mathrm{B},j}$ for the pure substances j at the point z are obtained by inserting the local parameters in Eq. (21), Subchap. H3.4.

Mixtures at their azeotropic composition boil like pure substances. Therefore, $\alpha_{\mathrm{id,B}}$ -values of azeotrope forming mixtures, which are not at their azeotropic composition, have to be estimated from Eq. (1) using $\alpha_{\mathrm{B},j}$ -values for the azeotrope and for the pure substance.

Using Eq. (2) the heat transfer coefficient of a mixture at nucleate boiling is estimated from

$$\frac{\alpha(z)_{\mathrm{B}}}{\alpha_{\mathrm{id,B}}} = \frac{1}{1 + \frac{\alpha_{\mathrm{id,B}}}{\dot{q}} \left[\sum_{j=1}^{K-1} \left(T_{\mathrm{sat},K} - T_{\mathrm{sat},j}\right)\left(\tilde{y}_j - \tilde{x}_j\right)\left(1 - \exp\frac{-B_0 \dot{q}}{\beta_{\mathrm{L}} \tilde{\rho}_{\mathrm{L}} \Delta\tilde{h}_{\mathrm{v}}}\right) \right]}. \tag{3}$$

In this model, which was proposed by Schlünder [2], B_0 is a parameter, which considers the fraction of heating power, required for nucleate boiling, with respect to the total heating power. β_{L} is the mass transfer coefficient on the liquid side of the phase boundary.

The terms in Eq. (3) are defined by the following equations:

$$\tilde{\rho}_{\mathrm{L}} = \left(\sum_{j=1}^{K} \tilde{x}_j \tilde{v}_j \right)^{-1}. \tag{4}$$

The molar volumes for the pure substances $\tilde{v}_j$ are determined at $T_{\mathrm{sat}}(z)$ and p. If the molar densities of the pure substances at $T_{\mathrm{sat}}(z)$ and p are known, which is often the case, the following applies:

$$\tilde{v}_j = \left(\tilde{\rho}_j\right)^{-1}. \tag{5}$$

The molar enthalpies for the liquid $\tilde{h}'_j$ and the vapor $\tilde{h}''_j$ must also be determined for the pure substances in the saturated state at $T_{\mathrm{sat}}(z)$ and p. Thus, the molar enthalpy of vaporization is given by

$$\Delta\tilde{h}_{\mathrm{v}} = \sum_{j=1}^{K} \tilde{y}_j \tilde{h}''_j - \sum_{j=1}^{K} \tilde{x}_j \tilde{h}'_j \tag{6}$$

with $\tilde{y}_j$ the mole fraction corresponding to $\tilde{x}_j$ at equilibrium.

If the saturation enthalpies $\tilde{h}'$ and $\tilde{h}''$ are unknown, the following approximation can be used:

$$\Delta\tilde{h}_{\mathrm{v}} = \sum_{j=1}^{K} \Delta\tilde{h}_{\mathrm{v}j}\left(T_{\mathrm{sat},j}(p)\right)\tilde{x}_j. \tag{7}$$

For mixtures of halogenated hydrocarbons and for mixtures of a halogenated hydrocarbon with an organic substance, the following relation is confirmed for a wide parameter range [22–24]:

$$\frac{B_0}{\beta_{\mathrm{L}}} \cdot \frac{\alpha_{\mathrm{id,B}}}{c_{\mathrm{pL}}\rho_{\mathrm{L}}} = 40.6 \left(\frac{\dot{q}}{\dot{q}_0}\right)^{1.19} \left(\frac{\dot{m}}{\dot{m}_0}\right)^{-0.77} \dot{x}^{-0.15} \tag{8}$$

with $\dot{q}_0 = 20,000\ \mathrm{W/m^2}$ and $\dot{m}_0 = 100\ \mathrm{kg/m^2\,s}$. Good agreement is shown with literature data [11,17,18]. For rough estimations, the value $B_0/\beta_{\mathrm{L}} = 5 \cdot 10^3\ \mathrm{s/m}$ may be assumed.

Because the above equations are derived in general terms, it is reasonable to assume that they can also be applied to ternary and multicomponent mixtures.

2.2 Nucleate Boiling in Horizontal Tubes

According to the current knowledge on the subject, incomplete wetting is to be treated with the help of perimeter-averaged heat transfer coefficient $\alpha_{\mathrm{B},j}$ of the pure substances. A more physical prediction of heat transfer coefficients would have to consider local conditions at the incompletely wetted surfaces. This method has been elaborated for a limited number of mixtures by Wettermann [24]. The following applies for a horizontal tube:

$$\frac{1}{\alpha_{\mathrm{id,B}}} = \sum_{j=1}^{K} \frac{\tilde{x}_j}{\alpha_{\mathrm{B},j}}. \tag{9}$$

The heat transfer coefficients $\alpha_{\mathrm{B},j}$ for the pure substances j are obtained from the local parameters at the point z, as defined by

Subchap. H3.4, Eqs. (30), (31), and (33–37), with due allowance for the flow pattern and boundary conditions ($\dot{q}$ = constant; T_w = constant).

Studies by Niederkrüger [23] and Wettermann [24] on binary mixtures in various states demonstrated that the flow pattern map, see Subchap. H3.1, and the boundary conditions that define them also permit useful predictions for mixtures, provided that the values inserted for the properties in all the dimensional numbers and equations are those for the mixture (cf. Chap. D1). Thus, the flow pattern determined for the mixture at the point z must be used to calculate the value of $\alpha_{B,j}$ for the pure substances j.

The *heat transfer coefficient for the mixture* $\alpha(z)_B$ can then be obtained from Eq. (3). The value of $\alpha_{id,B}$ that is used on both sides of Eq. (3) is determined from Eq. (9).

Experimental studies have allowed the above equations to be checked only for binary and ternary mixtures. It can be assumed from the results obtained by Zizyukin and Aèrov [6] on ternary mixtures that the equations can also be applied to multicomponent mixtures.

3 Total Heat Transfer Coefficient in Flow Boiling of Mixtures

As was previously stated, a given wall superheat or a given heat flux $\dot{q}_{onb}$ is required for onset of nucleate boiling. This also pertains to mixtures, and the following equation approximately applies for T_{sat} at $z = 0$:

$$\dot{q}_{onb} = \frac{2\,\sigma\,T_{sat}\,\alpha_{L0}}{r_{cr}\,\tilde{\rho}''\,\Delta\tilde{h}_v}. \tag{10}$$

All the values to be inserted for the properties are those for the mixture, and Eq. (3) applies for the molar density of the mixed vapor $\tilde{\rho}''$. The molar enthalpy of vaporization for the mixture is calculated from Eq. (4), and the surface tension, by the method given in Chap. D1. The numerical value $r_{cr} = 0.3 \cdot 10^{-6}$ m also applies for mixtures. The term α_{L0} is the local single-phase heat transfer coefficient at the point $z = 0$ (cf. Sect. 4 of Subchap. H3.4) for the liquid mass velocity $\dot{m}$. The properties used for the determination of α_{L0} are those for the liquid mixture.

If the heat flux to be transferred at the point z is $\dot{q}(z) \geq \dot{q}_{onb}$, the total perimeter-averaged heat transfer coefficient can be calculated from

$$\alpha(z) = \sqrt[3]{\alpha(z)_{conv}^3 + \alpha(z)_B^3} \tag{11}$$

and

$$\alpha(z) = \frac{\dot{q}(z)}{T_w(z) - T_{sat}(z)}. \tag{12}$$

If $\dot{q}(z) \leq \dot{q}_{onb}$, only the convective component needs to be taken into consideration, i.e., $\alpha(z) = \alpha(z)_{conv}$.

4 Changes in the State of Mixtures

The relationship between the instantaneous composition of the liquid $\underline{\tilde{x}}$ and the mass flow rate of the remaining liquid $\dot{M}_L$ at the point z can be determined if the heat transferred per element of length Δz of evaporator tube is known. The following definitions apply.

The molar flow rates of liquid and vapor are determined from the mass flow rates $\dot{M}_L$ and $\dot{M}_G$ and the molar masses $\widetilde{M}_L$ and $\widetilde{M}_G$, i.e.,

$$\dot{N}_L = \frac{\dot{M}_L}{\widetilde{M}_L(\underline{\tilde{x}})}, \tag{13}$$

$$\dot{N}_G = \frac{\dot{M}_G}{\widetilde{M}_G(\underline{\tilde{y}})}. \tag{14}$$

If the remaining liquid at any point z in the direction of flow is assumed to be in equilibrium with the vapor at that point, the following applies

$$K_j(T_{sat}(z), \underline{\tilde{x}}) \equiv \frac{\tilde{y}_j}{\tilde{x}_j}. \tag{15}$$

The phase equilibrium constant K_j is determined by the methods described in Chap. D5. If component j is the volatile component, then $K_j > 1$; otherwise $K_j < 1$. For azeotropic mixtures $K_j = 1$.

In the case of saturated liquid entering the tube, balancing of component j is done by

$$\dot{N}_{L,in}\tilde{x}_{j,in} = \dot{N}_{L,out}\tilde{x}_{j,out} + \dot{N}_{G,out}\tilde{y}_{j,out}. \tag{16}$$

Insertion of Eqs. (13) and (14) leads to

$$\frac{\dot{M}_{L,out}}{\widetilde{M}_{L,out}}\tilde{x}_{j,out} + \frac{\dot{M}_{G,out}}{\widetilde{M}_{G,out}}\tilde{y}_{j,out} - \frac{\dot{M}_{L,in}}{\widetilde{M}_{L,in}}\tilde{x}_{j,in} = 0. \tag{17}$$

Taking into consideration, that

$$\dot{M}_{L,in} = \dot{m}A, \tag{18}$$

$$\dot{M}_{L,out} = \dot{m}A(1 - \dot{x}_{out}), \tag{19}$$

$$\dot{M}_{G,out} = \dot{m}A\dot{x}_{out}, \tag{20}$$

the following objective function OF is obtained:

$$OF = \frac{(1 - \dot{x}_{out})}{\widetilde{M}_{L,out}}\tilde{x}_{j,out} + \frac{\dot{x}_{out}}{\widetilde{M}_{G,out}}\tilde{y}_{j,out} - \frac{1}{\widetilde{M}_{L,in}}\tilde{x}_{j,in} = 0. \tag{21}$$

Using Eq. (15), this equation can be solved by iteration for a given pressure. By this at any locus z the values for $\tilde{x}_{j,out}$ and $\tilde{y}_{j,out}$ are found.

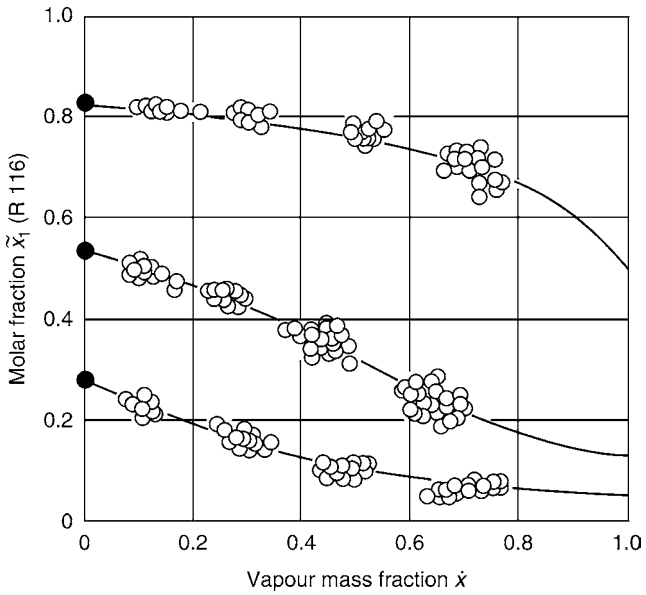
Measurements by Wettermann [24] validate the above procedure for a wide parameter range, see Fig. 2.

Example 1. Local Heat Transfer Coefficients at Forced Convection Boiling of a Binary Mixture

Consider a mixture of ethanol (1)/*n*-butanol (2) (no azeotrope) with feed composition $x_1 = 0.065$, which is partially evaporated in a 4 m long vertical tube of a forced convection evaporator. The saturated mixture enters the copper tube ($d_{out} \times s = 38$ mm $\times$ 1.5 mm) at 1.5 bar and at a mass flow rate of $\dot{m} = 560\ \mathrm{kg/(m^2\ s)}$.

The thermal conductivity of copper is 300 W/(K m). The inner wall temperature of the tube is kept constant by condensing steam which is kept 30°C above the boiling temperature of the feed mixture.

Upon neglecting pressure changes in the tube, calculate the following values in steps of 5 m tube length: local heat transfer coefficient, transferred heating power, composition, and vapor mass fraction. Furthermore, calculate the mean heat transfer coefficient $\alpha_m = \Sigma\Delta Q/(\pi d_{out} l(T_{steam} - T_{out}(p_{out}))$ averaged over the entire tube length (T_{steam} temperature of the steam at the outside of the tube, T_{out} temperature of the mixture at the outlet of the tube at p_{out}.).



H3.7. Fig. 2. Molar fraction $\tilde{x}_1$ of the low boiling component "1" as a function of vapor mass fraction $\dot{x}$ for three initial compositions (·).System $C_2F_6/C_2H_2F_4$, closed batch evaporation, p = 11 bar, $\dot{m}$ = 74 − 426 kg/m^2 s.

Results:

See Tables 1 and 2, and

$$\alpha_m = \frac{\sum \Delta\dot{Q}}{\pi \cdot d_{out} \cdot l \cdot (T_{steam} - T_{out}(p_{out}))} = \frac{126.2\ \text{kW}}{\pi \cdot 0.038\ \text{m} \cdot 4\ \text{m} \cdot (425.25\ \text{K} - 398.72\ \text{K})} = 10.0\ \text{kW}/(\text{m}^2\ \text{K}).$$

Example 2. Required Length of Evaporator Tubes for Total Evaporation at Forced Convection Boiling of a Ternary Mixture

Consider an evaporator with an horizontal heater in which a ternary mixture (no azeotrope) is to be totally evaporated, i.e., vapor mass fraction $\dot{x}_{out} = 1$.

The feed consists of C_2F_6 ($\tilde{x}_1 = 0.35$), SF_6 ($\tilde{x}_2 = 0.25$), and $C_2H_2F_6$ ($\tilde{x}_3 = 0.4$). Its mass flow density is $\dot{m} = 300$ kg/(m^2 s). It is saturated ($\dot{x}_{in} = 0$) at $p = 10$ bar. The tubes with the dimensions of $d_{out} \times s = 16$ mm × 1 mm are made of electrolyte copper with thermal conductivity of $\lambda = 394$ W/(Km).

The required length of the horizontal tubes is to be computed stepwise by applying a heat transfer coefficient which is averaged with respect to the circumference of the tubes. A constant specific heat flow rate of 30 kW/m^2 is assumed. The step width with respect to vapor mass fraction ought to be 0.1. The composition of the "last droplet" at the exit of the tubes is to be calculated.

Remarks: The effect of partial wetting at slug flow is to be taken into consideration by $\psi = 1$. Ring-slug-flow shall be treated as ring-flow.

Results:

See Tables 3 and 4, and $\tilde{x}_{1,out} = 0.097$, $\tilde{x}_{2,out} = 0.075$, $\tilde{x}_{3,out} = 0.828$.

H3.8 Special Symbols and References Used and Cited in Subchaps. H3.1–H3.7

Matthias Kind
Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany

Note: Most of the symbols used in Subchaps. H3.1–H3.7 are listed in Chap. A1 "Symbols and Units". Here only special symbols are listed.

Symbols

A	m^2	area, cross-sectional area
a	–	ratio of values for α
b	m	Laplace coefficient
B_0	–	nucleate boiling parameter
C	–	dimensionless parameter
C_F	–	factor
C_{wl}	$W/m^2\,K$	radiation coefficient
d	m	tube inner diameter
d_e	m	diameter of the inscribed circle (cf. Subchap. H3.5, Fig. 27)
d_h	m	hydraulic diameter
D_W	m	average diameter of winding in helical coil
f	m^2	cross-sectional area
f_{rel}	–	relative error
F	–	function
Δh	kJ/kg	enthalpy difference
Δh_v	kJ/kg	specific enthalpy of vaporization
K	–	equilibrium constant
K	–	subcooling parameter
K_l	–	correction factor for heated length
$\dot{m}$	$kg/(m^2\,s)$	mass flow rate
M	–	fin characteristic
n	–	exponent in term for heat flux
r_{crit}	m	parameter for heated surface
R	m	mean radius
R_a	m	arithmetic mean roughness height (ISO 4287)
s	m	wall thickness
t	m	rod spacing
U	m	periphery, or total periphery occupied by the fluid
$\dot{x}$	–	vapor mass fraction
$\dot{x}_{cr,i}$	–	critical vapor mass fraction on the assumption of thermodynamic equilibrium, when heat is applied to the inner tube of an annulus
$\dot{x}_{cr,o}$	–	critical vapor mass fraction on the assumption of thermodynamic equilibrium, when heat is applied to the outer tube of an annulus
$\dot{x}_{cr,lo}$	–	vapor mass fraction when the boiling crisis occurs on the lower surface of a horizontal or inclined tube
$\dot{x}_{cr,up}$	–	vapor mass fraction when the boiling crisis occurs on the upper surface of a horizontal or inclined tube
$\Delta\dot{x}_{cr}$	–	difference between the critical vapor mass fraction on the lower surface of a horizontal or inclined tube and that on the upper surface
$\Delta\dot{x}$	–	margin of safety against boiling crisis
$\underline{\tilde{x}}$	–	mole fraction vector $(\tilde{x}_1, \ldots, \tilde{x}_k)$ (liquid)
X	–	Martinelli parameter
$\underline{\tilde{y}}$	–	mole fraction vector $(\tilde{y}_1, \ldots, \tilde{y}_k)$ (vapor)
Y	–	mass flux ratio
z	m	coordinate in direction of flow
$\dot{q}_{uni}$	kW/m^2	heat flux if heating is uniform
Z	–	atomic number
σ	$W/m^2\,K^4$	Stephan's constant
$\dot{\omega}$	–	nonequilibrium factor $\dot{x}_{act}/\dot{x}_{eq}$
γ	l/bar	Barnett number
δ	m	thickness of tube wall
$\Delta\vartheta_u$	°C, K	subcooling at inlet
φ	°	angle of inclination to horizontal
Φ^2	–	two-phase multiplier
ψ	–	dimensionless mass flux, reduction factor
ε	–	void fraction

Θ	°	angle of inclination
κ	–	factor
ξ	–	pressure drop coefficient
$\tilde{\rho}$	kmol/m^3	molar density
σ	–	standard deviation
φ	–	unwetted arc or angle subtended by it at the centre of the tube cross-section
Φ	–	normalized unwetted arc
ψ, Ψ	–	factor
$\mathrm{Re_l} = \dfrac{\dot{m}(1-\dot{x})}{\eta_\mathrm{l}}$	–	Reynolds number for liquid phase
$\mathrm{Re_g} = \dfrac{\dot{m}\,\dot{x}\,d}{\eta_\mathrm{g}}$	–	Reynolds number for vapor phase
$\mathrm{Fr} = \left(\dfrac{\dot{m}\,\dot{x}}{\rho_\mathrm{l}}\right)^2 \dfrac{\rho_\mathrm{l}}{\rho_\mathrm{g}\,g\,d}$	–	Froude number
$\mathrm{Fr_g} = \dfrac{\dot{m}^2\,\dot{x}^2}{\rho_\mathrm{g}^2\,g\,d}$	–	Froude number for vapor phase
$\mathrm{Eu} = \dfrac{\Delta p}{\rho w^2}$	–	Euler number

Subscripts

act	actual condition
α min	location of minimum heat transfer coefficient
B	nucleate boiling
conv	convective
cr	critical boiling state
crit	critical
d	related to actual diameter
d	droplet
eq	equilibrium
G, g	vapor
h, htd	heated
hom	homogeneous model
i	interface
i	initial point of bubble formation
i	internal heating
inl	inlet conditions
iso	isothermal
j	with reference to a subchannel
K	heaviest component
K	with reference to the entire channel
lt	laminar-turbulent
L, l	liquid
L	Leidenfrost point
m	mean
max	maximum value
n	beginning of netto vapor production
o	outer heating
onb	onset of nucleate boiling
rad	radiation
sat	saturated
sub	subcooled condition
tt	turbulent-turbulent
TB	transition boiling
u	subcooled
W, w	at the wall
wet	wetted
0	normal, reference
0	at the beginning of the heated section
1, 2	any two points on the heated section
1 ph	single phase

Superscripts

HB	high-boiling
LB	low-boiling
FB	film boiling
DF	droplet flow
$'$	liquid in boiling state
$''$	vapor in condensing state
–	mean, averaged

Condensation

J1 Filmwise Condensation of Pure Vapors

Reiner Numrich[1] · *Jürgen Müller*[2]
[1]Paderborn, Germany
[2]BASF AG Ludwigshafen, Germany

1 Introduction

When a vapor comes into contact with a surface, the temperature of which is below the temperature of thermodynamic equilibrium, the vapor at this surface turns from the gaseous state to the liquid state. This process is known as condensation. Associated with the change of aggregate status is a significant production of heat.

If the condensation is caused by direct contact with the liquid phase, it is referred to as mixed or injection condensation. In the case of sufficient supercooling of the vapor and/or in the presence of condensation nuclei (e.g., tiny dust particles, small droplets), a mist can already be formed in the gas phase through spontaneous condensation.

Technically relevant in most applications is indirect condensation on cooled solid surfaces. Here, drops of liquid first start to form around individual condensation nuclei, becoming larger as the condensation process proceeds. This is known as drop condensation. If boundary layer conditions exist, which permit complete wetting of the wall, the vapor no longer condenses on the solid wall but on the surface of a liquid film. This type of condensation is known as film condensation.

The most common type under technical conditions is film condensation. This condensation type is taken as the basis for the description and calculation of condensation processes in the following. An essential feature is that the heat of condensation released at the condensation film surface must be transported to the cooled wall by the condensate film.

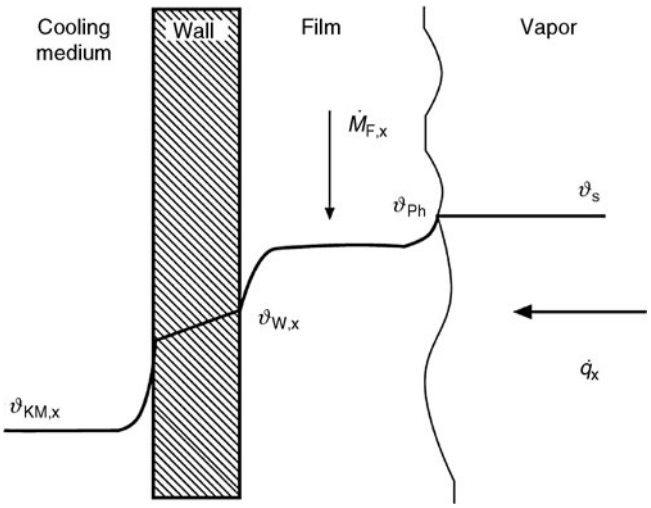
In the following, the general procedure for the design of condensers is described and information is provided on the use of material values, averaged or local reference values, and coefficient equations. According to condenser geometries used in practice, calculation methods are first described for the condensate film running down the vertical pipe due to gravitation. If necessary, the influence of the vapor flow on the heat transfer in the condensate film must be taken into account. The second classic setup is the horizontal or slightly inclined pipe where the condensation takes place on the outside of the pipe, usually in the mantle space of a horizontal tube nest apparatus, or inside the externally cooled pipe. In conclusion, special questions regarding the film condensation of metal vapors and superheated vapors are dealt with.

2 Calculation Methods

2.1 Definition of Heat Transfer Coefficients

The local temperature profile in a condensate film is shown in Fig. 1.

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_36,



J1. Fig. 1. Schematic temperature profile for condensation of pure vapors.

The local heat transfer coefficient of the condensate film $\alpha_{F,x}$ is defined as

$$\alpha_{F,x} = \frac{\dot{q}_x}{\vartheta_{Ph} - \vartheta_{W,x}} \tag{1}$$

with the local heat flux density $\dot{q}_x$ transferred vertical to the wall, and the temperatures at the film surface ϑ_{Ph}, corresponding to the case of the condensation of pure vapors with the boiling temperature ϑ_S at the relevant system pressure, and at the wall $\vartheta_{W,x}$.

The local heat transfer coefficient is presented nondimensionally as a Nusselt number

$$\mathrm{Nu}_{F,x} = \frac{\alpha_{F,x}\mathcal{L}}{\lambda_F} \tag{2}$$

formed with the characteristic length of the film flow

$$\mathcal{L} = \sqrt{\frac{\nu_F^2}{g}}. \tag{3}$$

2.2 Calculation Using Local Data

The differential energy balance for a volume element of the condenser is

$$k_x(\vartheta_S - \vartheta_{KM,x})\mathrm{d}A = \Delta h_v \mathrm{d}\dot{M}_F. \tag{4}$$

The heat condensation of released at the phase boundary must be conducted to the cooling medium KM. The condensation area required A follows from the integration of Eq. (4) to

$$A = \int_0^{\dot{M}_{F,L}} \frac{\Delta h_V \mathrm{d}\dot{M}_F}{k_x(\vartheta_S - \vartheta_{KM,x})} \tag{5}$$

with the heat transfer coefficient k_x according to Chap. C2.

For a surface without curves, this is

$$\frac{1}{k_x} = \frac{1}{\alpha_{F,x}} + \frac{s}{\lambda_W} + \frac{1}{\alpha_{KM,x}} + R_f. \tag{6}$$

Here, s/λ_w is the heat transfer resistance of the wall, $\alpha_{KM,x}$ is the heat transfer coefficient on the coolant side, and R_f is the fouling resistance. All values must be assigned in relation to the axial coordinate x.

During condensation, the fouling resistance can have a significant influence on the heat transfer area required. Calculation in advance is currently not possible. Empirical values are known from the literature. Indicative values are shown in Chap. O1.

2.3 Calculation Using Average Data

If the heat transfer coefficient is only weakly dependent on the axial coordinate, Eq. (5) can be directly integrated at constant boiling temperature ϑ_S and, for area A of the condenser

$$A = \frac{\Delta h_v \dot{M}_F \langle x = L \rangle}{k(\vartheta_S - \vartheta_{KM})_{log}} \tag{7}$$

with the overall heat transfer coefficient k we obtain

$$\frac{1}{k} = \frac{1}{\alpha_F} + \frac{s}{\lambda_W} + \frac{1}{\alpha_{KM}} + R_f \tag{8}$$

and the mean temperature difference

$$(\vartheta_S - \vartheta_{KM})_{log} = \frac{(\vartheta_S - \vartheta_{KM,ein}) - (\vartheta_S - \vartheta_{KM,aus})}{\ln \dfrac{\vartheta_S - \vartheta_{KM,ein}}{\vartheta_S - \vartheta_{KM,aus}}}. \tag{9}$$

The condensate mass flow $\dot{M}_F$ must be assigned at the point $x = L$, i.e., at the outlet of the condenser. This procedure is suitable for a preliminary rough estimate of the transfer area of a condenser. For precise design, a calculation on the basis of local values is usually necessary.

3 Condensation in Vertical Tubes

3.1 Local Heat Transfer Coefficients Without Vapor Flow

In the *laminar flow area*, the local Nusselt number for the smooth film is calculated ignoring the vapor shear stress according to Nusselt [1]

$$\mathrm{Nu}_{F,x,1} = \frac{a_{F,x,1}\mathcal{L}}{\lambda_F} = 0.693 \left(\frac{1 - \rho_D/\rho_F}{\mathrm{Re}_{F,x}}\right)^{1/3}. \tag{10}$$

Here, the Reynolds number is obtained:

$$\mathrm{Re}_{F,x} = \frac{\dot{\Gamma}_X}{\eta_F} = \frac{\dot{M}_{F,x}}{\pi\, d\, \eta_F} = \frac{\dot{M}_{F,x}}{b\, \eta_F} \tag{11}$$

with the local trickle density Γ_x, i.e., the mass flow of film liquid in relation to the pipe circumference πd or to the width of the

cooling area b. The material properties must be assigned for the temperature of the phase boundary (boiling temperature) of the condensate film.

The *waviness of the film flow* at the surface improves the heat transfer. This effect is taken into account by a waviness correction f_{well}. Various approaches exist from different authors, which do not differ greatly. At this point, the approach of Kutateladze and Gogonin [2] is recommended:

$$f_{well} = \frac{Nu_{F,x,l,well}}{Nu_{F,x,l}} = \begin{cases} 1 & \text{for } Re_{F,x} < 1, \\ Re_{F,x}^{0.04} & \text{for } Re_{F,x} \geq 1. \end{cases} \quad (12)$$

In the case of *turbulent flow*, the Nusselt number of the condensate film is obtained from the arrangement in series of a heat transfer resistance near the wall and phase boundary [3, 4]. Experimental data for this have been measured by Yüksel [5] and Müller [3] in a Prandtl number range from 3 to 52 and, with the help of analogy observations applied to the basic processes of film evaporation and absorption. The local Nusselt number for the turbulent condensate film, according to Müller [3], is

$$Nu_{F,x,t} = \frac{\alpha_{F,x,t}\mathcal{L}}{\lambda_F} = \frac{0.0283 Re_{F,x}^{7/24} Pr_F^{1/3}}{1 + 9.66 Re_{F,x}^{-3/8} Pr_F^{-1/6}}. \quad (13)$$

3.1.1 Influence of Temperature-Dependent Properties

The influence of temperature-dependent material properties can be taken into account, according to Müller [3], by a correction factor f_η:

$$f_\eta = \left(\frac{\eta_{F,S}}{\eta_{F,W}}\right)^{1/4}. \quad (14)$$

It is valid for the laminar and the turbulent flow region and has a pronounced effect when the temperature difference in the film is large, e.g., in the case of intensive condensation processes of substances with high Prandtl numbers.

3.1.2 Combined Presentation

The equations shown above can be superimposed as follows:

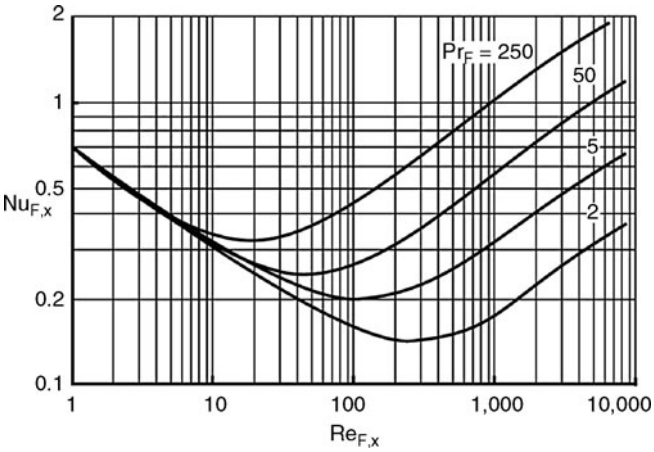
$$Nu_{F,x} = \sqrt[2]{(f_{well} Nu_{F,x,l})^2 + Nu_{F,x,t}^2} \cdot f_\eta \quad (15)$$

This quadratic superimposition describes the equations of Müller [3] very well.

Figure 2 shows the local Nusselt number for the condensate film in relationship to the Reynolds number. The Prandtl number is shown as a parameter. The calculations were carried out according to Eq. (15) with $f_\eta = 1$.

Range of validity:

$Nu_{F,x}$ acc. to Eq. (15), $Re_{F,x} < 10{,}000, 0.5 < Pr_F < 500, 0.2 < \eta_{F,S}/\eta_{F,W} < 5$.



J1. Fig. 2. Local Nusselt number for filmwise condensation in a vertical tube as a function of Reynolds number and Prandtl number.

3.2 Mean Heat Transfer Coefficients Without Vapor Flow

Nusselt numbers averaged over the cooling area length are obtained by integration of the local values from the previous section. The following equations result for the average Nusselt numbers.

Laminar range:

$$Nu_{F,l} = \frac{\alpha_{F,l}\mathcal{L}}{\lambda_F} = \frac{4}{3} Nu_{F,x=L,l} = 0.925 \left(\frac{1 - \rho_D/\rho_F}{Re_{F,L}}\right)^{1/3}. \quad (16)$$

Turbulent range:

$$Nu_{F,t} = \frac{\alpha_{F,t}\mathcal{L}}{\lambda_F} = \frac{0.020 Re_{F,L}^{7/24} Pr_F^{1/3}}{1 + 20.52 Re_{F,L}^{-3/8} Pr_F^{-1/6}}. \quad (17)$$

Here, the Reynolds number is obtained with the trickle density Γ_L or the condensate mass flow $\dot{M}_{F,L}$ at the outlet of the condenser:

$$Re_{F,L} = \frac{\dot{\Gamma}_L}{\eta_F} = \frac{\dot{M}_{F,L}}{\pi d \eta_F} = \frac{\dot{M}_{F,L}}{b \eta_F}. \quad (18)$$

3.2.1 Combined Presentation

Laminar and turbulent regions can be superimposed as follows:

$$Nu_F = \sqrt[1,2]{(f_{well} Nu_{F,l})^{1,2} + (Nu_{F,t})^{1,2}} \cdot f_\eta \quad (19)$$

In the calculation of the average heat transfer coefficients, Eq. (12) can also be used as *waviness correction* f_{well}. The deviation can be ignored.

In order to take account of the *influence of temperature-dependent material properties*, Eq. (14) is also recommended in the case of average heat transfer coefficients.

The validity range of the equations for the local heat transfer applies here as well.

3.3 Heat Transfer with Significant Vapor Flow

In the case of high vapor velocities, there is a significant interaction between the gas and the fluid phases, expressed by the shear stress τ_D acting on the condensate film surface, which can have a considerable influence on the heat transport in the condensate film. For design in such cases, a general distinction must be made between flow with the current and counterflow.

3.3.1 Cocurrent Flow of Gaseous and Liquid Phases

Heat Transfer

If the gas and the fluid phases are both flowing in the same direction, the transport resistance is reduced in principle as a result of two different physical processes: first, through modification of the laminar sublayer near the wall and, second, through the excitation of turbulences in the boundary layer near the surface.

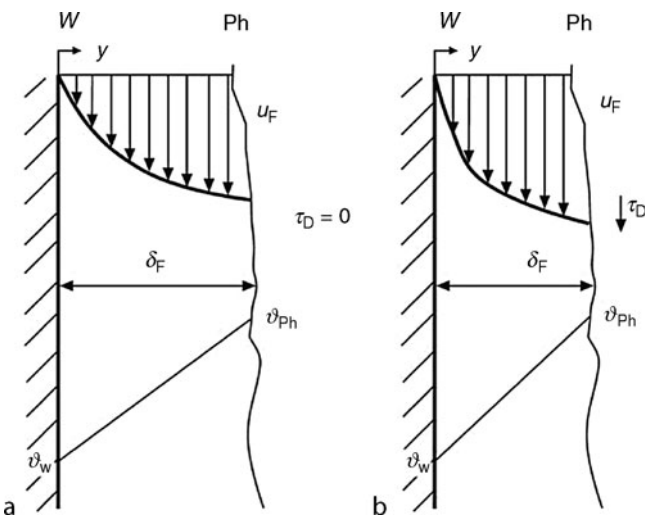
First, the effect of the shear stress at the phase boundary area on the heat transfer in the layer near the wall is considered (shown by the exponent +). The shear stress increases the mean velocity $\bar{u}_F$ in the liquid phase. As a result, the condensate film becomes thinner, as the Reynolds number Re_F remains constant locally, i.e., $\bar{u}_F \cdot \delta_F = \text{const}$. (Fig. 3).

The relationship of the Nusselt numbers with (exponent +) and without consideration of the shear stress can be represented by

$$\frac{Nu^+_{F,x,l}}{Nu_{F,x,l}} = K_W = \left(1 + 1.5\tau^*_D\right)^{1/3}. \tag{20}$$

Here, τ^*_D is a nondimensional shear stress in the form

$$\tau^*_D = \frac{\tau_D}{\rho_F g \delta^+_F} \text{ with } \tau_D = \frac{\xi_r}{8}\rho_D \bar{u}^2_D. \tag{21}$$



J1. Fig. 3. Velocity and temperature profiles with and without superimposed vapor flow at laminar film flow.

The calculation of the shear stress τ_D at the condensate film surface and the film thickness δ^+_F is explained under *pressure loss and shear stress*. In the turbulent flow region, the existing laminar sublayer is similarly influenced by the higher average condensate film velocity. From Numrich [8], we obtain the relationship (22)

$$\frac{Nu^+_{F,x,t}}{Nu_{F,x,t}} = K_{W,t} = \left(1 + \tau^*_D\right)^{1/3}. \tag{22}$$

Equation (22) has been confirmed by Müller [3] in a later work.

The description of the shear stress influence in Eq. (22) is sufficiently accurate for the whole flow region, using the superimposition function of Eq. (15). It is recommended to calculate uniformly in the whole flow region with

$$K_{W,l} = K_{W,l} = K_W = \left(1 + \tau^*_D\right)^{1/3} \tag{23}$$

so that, generally,

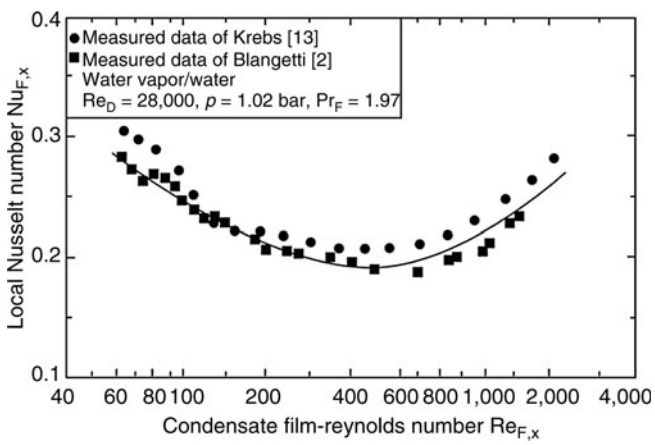
$$Nu^+_{F,x} = Nu_{F,x}\left(1 + \tau^*_D\right)^{1/3}. \tag{24}$$

Figure 4 shows a comparison of Nusselt numbers measured and calculated according to Eq. (24).

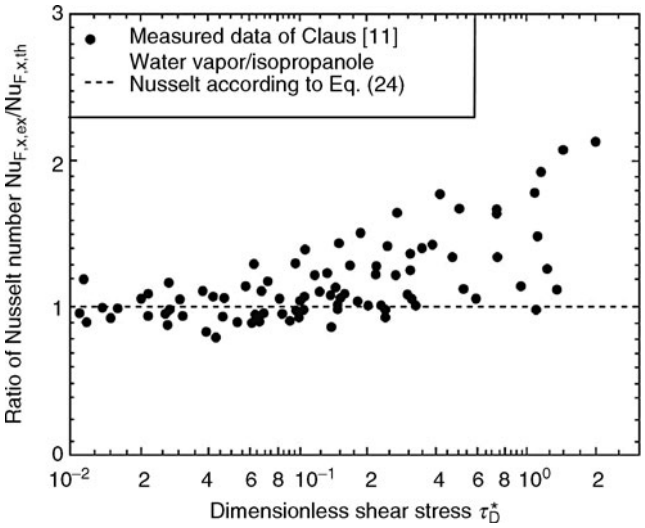
In systems with material properties other than water or water vapor, e.g., hydrocarbons with higher Prandtl numbers, the equations shown are inadequate for showing the influence of the shear stress. A comparison with experiments by different authors [9–11] shows that, as the Prandtl number rises, i.e., as the thermal conductivity of the fluid used falls, the heat transfer is up to 100% greater than that obtained with Eq. (24).

Figure 5 shows the relationship of measured Nusselt numbers to values calculated according to Eq. (24) as a function of the nondimensional shear stress.

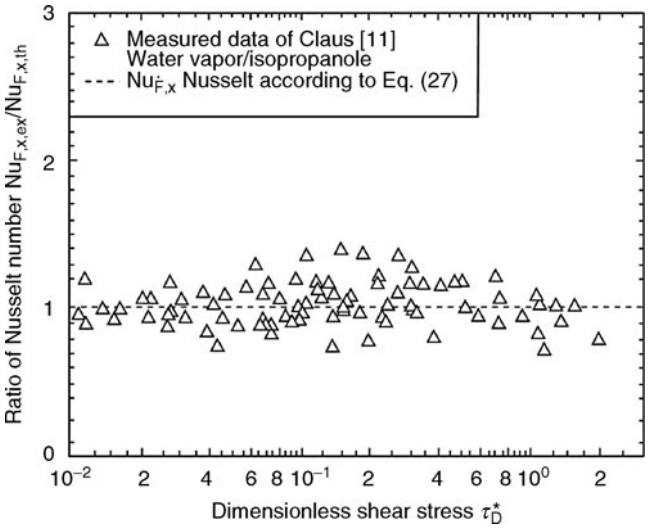
The additional increase in the heat transfer with rising shear stress can be explained by a modification of the quasi-laminar layer at the phase boundary. The shear stress intensifies the exchange of impulses at the phase boundary which leads to the amplification of turbulent fluctuations in the condensate film. In the laminar flow region, the exchange of impulses increases the surface roughness of the condensate films, i.e., additional



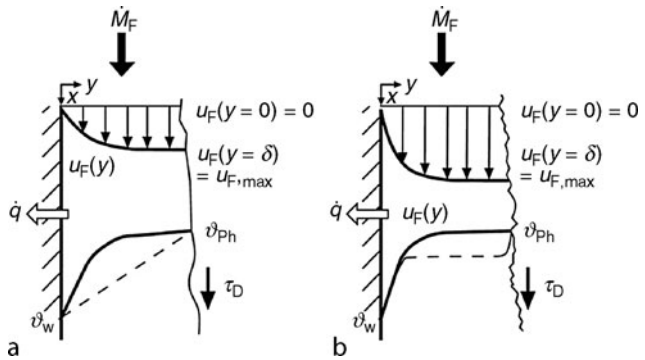
J1. Fig. 4. Comparison of measured data from Blangetti and Krebs with data according to Eq. (24) calculated Nusselt numbers.



J1. Fig. 5. Comparison of measured Nusselt numbers with Eq. (24).



J1. Fig. 7. Comparison of measured Nusselt numbers with Eq. (27).



J1. Fig. 6. Velocity and temperature profiles in the presence of significant vapor flow.

turbulent fluctuations are excited on the surface (Fig. 6a). In the turbulent flow region, the laminar boundary layer near the surface is so influenced that the thickness of this layer is reduced in dependence on the shear stress and the heat transfer is also improved in this way (Fig. 6b).

As the influence of the shear stress between laminar and turbulent flow conditions in the condensate film differs significantly, two correction factors K_{Ph} must be introduced [12]:

- laminar flow regime:

$$K_{Ph,l} = 1 + \left(Pr_F^{0.56} - 1\right) \tanh \tau_D^*, \tag{25}$$

- turbulent flow regime:

$$K_{Ph,t} = 1 + \left(Pr_F^{0.08} - 1\right) \tanh \tau_D^*. \tag{26}$$

The following method is recommended:

$$Nu_{F,x}^{\bullet} = \sqrt{\left[\left(K_{Ph,l} Nu_{F,x,l}^{+}\right)^2 + \left(K_{Ph,t} Nu_{F,x,t}^{+}\right)^2\right]}. \tag{27}$$

Figure 7 shows the comparison from Fig. 5 with Eq. (27).

Pressure Loss and Shear Stress

As a rule, a downward directed two-phase ring flow exists in practice, in which the gas and liquid phases are separated. In the vertical pipe, assuming an adiabatic ring flow (represented by the exponent °), the relationship between friction pressure drop per length $(dp/dx)^\circ$ and the shear stress τ_D° at the condensate film surface ($\delta_F^+ \ll d$):

$$\left(\frac{dp}{dx}\right)^\circ = -\tau_D^\circ \frac{4}{d}. \tag{28}$$

The shear stress is defined by

$$\tau_D^\circ = \frac{\xi_r^\circ}{8} \rho_D \bar{u}_{D-F}^2. \tag{29}$$

Here, ξ_r° is the resistance coefficient of the condensate film surface and $\bar{u}_{D-F}$ is the average velocity of the gas phase in relation to the liquid phase. While, in the case of low pressures and the associated low condensation rates, it is often possible to calculate with the average gas velocity $\bar{u}_D = \bar{u}_{D-F}$, this results in very considerable deviations at higher pressures and high condensation rates, so that an estimate of the speeds is always necessary.

For calculation of the resistance coefficient ξ_r°, which governs the shear stress and the pressure loss, numerous approaches exist, some of which differ greatly under certain process conditions. A comparison with extensive experimental data shows that a modified approach in accordance with Andreussi [13] gives the best agreement [14]:

$$\xi_r^\circ = \xi_g^\circ \left(1 + 550F \cdot \tau_D^{*a}\right). \tag{30}$$

Herein are

$$\xi_g^\circ = 0.184 Re_{D-F}^{-0.2} \text{ with } Re_{D-F} = \frac{\bar{u}_{D-F} \cdot d_h}{\nu_D}. \tag{31}$$

The friction factor of a smooth tube,

$$F = \frac{\max\left\{\left(2Re_{F,x}\right)^{0.5}; 0.132 Re_{F,x}^{0.9}\right\}}{Re_{D-F}^{0.9}} \frac{\eta_L}{\eta_D} \sqrt{\frac{\rho_D}{\rho_L}} \tag{32}$$

a flow parameter

$$a = 0.85 \text{ for } \tau_D^* \le 1,$$
$$a = 0.3 \text{ for } \tau_D^* > 1 \tag{33}$$

an exponent for the description of the relationship between shear stress and gravity of the film. The required film thickness is also determined with the flow parameter F as

$$\frac{\delta_F^+}{d} = \frac{6.59F}{\sqrt{1 + 1,400F}}. \tag{34}$$

This is a calculated value which is only valid in combination with Eqs. (30–33) [15]. Strictly speaking, this should be δ_F^+, but in practice, $d_h \approx d$ is sufficiently accurate. Figure 8 shows qualitatively the relationships between ξ_r^o and the Reynolds numbers of the gas and liquid phases, taking as an example the system isopropanol–carbon dioxide.

The wall normal mass transport $\dot{m}_n$ toward the condensate film surface leads to an additional increase in the exchange of impulses. This is taken into account by the factor C_τ:

$$\xi_r = C_\tau \xi_r^o. \tag{35}$$

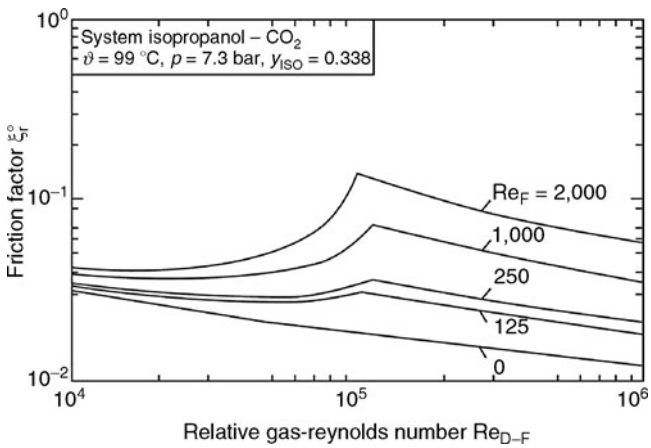
According to the ideas of film theory, this factor results in

$$C_\tau = \frac{a_\tau}{1 - e^{-a_\tau}} \text{ with } a_\tau = \frac{\dot{m}_n \cdot \bar{u}_{D-F}}{\tau_D^o}. \tag{36}$$

As the incorporation of this factor means a great deal of calculation work and the value of C_τ only plays a role with regard to pressure loss at high condensation rates, a prior estimate is recommended. In most cases, $C_\tau = 1$ can be set, so that $\xi_r = \xi_r^o$ or $\tau_D = \tau_D^o$. This simplification results in larger dimensioning than necessary.

Incidentally, when determining the whole pressure gradient, it is important that, in addition to friction pressure loss and gravity, the impulse gain due to the deceleration of the vapor flow is taken into account. While the gravity portion may be significant at very high gas densities, the deceleration portion of the total pressure drop

$$\left(\frac{dp}{dx}\right)_v \approx \frac{d(\rho_D \bar{u}_D)^2}{dx} \tag{37}$$



J1. Fig. 8. Friction factor ξ_r^o of gas flow at different Reynolds numbers of liquid phase for isopropanol und carbon dioxide.

may be of the same magnitude as the friction pressure loss, particularly in the case of almost complete condensation.

Limits, Entrainment

In the literature, e.g., [13], it is often pointed out that, when a limit value is exceeded for high vapor and liquid loading, droplet entrainment may occur. In the case of film condensation of pure vapors flowing in the same direction, this is of minor importance. The reason is that although, on entry into the condenser, the vapor velocity is at its highest, the condensate film has not yet formed or is very thin. Only from a specific Reynolds number of the liquid phase entrainment does occur, even at the highest vapor velocities [16]. While, as the condensation progresses, the quantity of condensate increases, the quantity of vapor and thus the square of the shear stress decrease. The rapid reduction of the flow velocity causes quick accumulation of the dispersed droplets. So this effect can usually be ignored, as its influence on heat transfer is negligible.

3.3.2 Countercurrent Flow of Gaseous and Liquid Phases

Heat Transfer

In the case of counterflow, the influence on the near-wall laminar sublayer and the intensification of the heat transfer in the near-surface layer act in exactly the opposite direction. In the case of counterflow, the gas phase causes the liquid film to slow down, thus increasing the thickness of the condensate film. We thus obtain the relationship according to Eq. (24) for $\tau_D^* < 2/3$:

$$Nu_{F,x}^+ = K_W \cdot Nu_{F,x} = Nu_{F,x}\left(1 - \tau_D^*\right)^{1/3}. \tag{38}$$

For $\tau_D^* > 2/3$, the unidirectional upward flow case exists. The influence on the layer near the surface can be shown in an analogue manner as in Eqs. (25) and (26). Equation (27) is correspondingly applicable. Altogether, the influence of the gas flow is first smaller in the case of counterflow. It must be remembered, however, that the interaction, i.e., the shear stress, is already many times greater at low vapor flow velocities than it is in the case of unidirectional flow.

Pressure Loss and Shear Stress

In analogy to Sect. 3.3.1, the pressure loss (Eq. (28)) and the shear stress (Eq. (29)) can be determined, remembering that, in addition to the changed coordinate direction, $\bar{u}_{D-F}$ no longer represents the difference between gas and liquid phases, but the sum

$$\bar{u}_{D-F} = \bar{u}_D + \bar{u}_F.$$

Even at low vapor velocities, the shear stress can be very high. This is due to the resistance coefficient ξ_r^o which, according to Henstock and Hanratty [15], is determined as

$$\xi_r^o = \xi_g^o(1 + 1,400F). \tag{39}$$

Limits, Entrainment, Backups

The maximum condensation performance that can be achieved does not depend on the heat transfer, but is limited by the hydrodynamics. In the case of counterflow, in contrast to

unidirectional flow, the greatest condensate mass flow and the greatest vapor mass flow occur at the same time at the lower inlet of the pipe. At this point, the influence on the condensate films of the flowing vapor phase is correspondingly at its greatest. As a backup or discharge of liquid must be avoided, the backup point must not be exceeded at this point. Before this point is reached, however, entrainment starts, the occurrence of which can be estimated with the modified Weber number

$$\mathrm{We}^* = \frac{\tau_D^o \cdot \delta_F^+}{\sigma_F}$$

τ_D^o can be obtained in accordance with Eq. (29). For δ_F^+, as an approximation, equations for the freely running trickle film can be used. As a critical limit value, which should not be exceeded in the design, the value $\mathrm{We}_C^* = 0.017$ is recommended, below which entrainment is not to be expected [13].

4 Condensation at Horizontal Tubes

4.1 Single Tube

For the condensation on horizontal pipes, Nusselt [1] has given circumferentially averaged heat transfer coefficients for the laminar region. At constant temperature of the outer wall of the condenser pipe and negligible vapor flow

$$\mathrm{Nu}_{F,1} = \frac{\alpha_{F,1}\mathcal{L}}{\lambda_F} = 0.959\left(\frac{1-\rho_D/\rho_F}{\mathrm{Re}_F}\right)^{1/3}. \quad (40)$$

The Reynolds number is also obtained here with the trickle density Γ:

$$\mathrm{Re}_F = \frac{\dot{\Gamma}}{\eta_F} = \frac{\dot{M}_F}{L\eta_F}, \quad (41)$$

in which the condensate mass flow $\dot{M}_F$ is related to the pipe length L. The material data should be inserted here at the average film temperature $(\vartheta_S + \vartheta_W)/2$.

4.2 Tube Bundle

According to Nusselt [1], for a vertically aligned row of pipes in which the condensate from the upper pipe drops on the next pipe below, there exists the following relationship of the average Nusselt number of row $\mathrm{Nu}_{F,1,RR}$ with η_R pipes with the circumferentially averaged Nusselt number of a single pipe $\mathrm{Nu}_{F,1}$:

$$\frac{\mathrm{Nu}_{F,1,RR}}{\mathrm{Nu}_{F,1}} = n_R^i \quad (42)$$

with $i = -1/4$. The heat transfer thus becomes worse as the number of pipes rises, since the liquid film becomes thicker below and the heat transfer resistance also becomes greater.

On the other hand, experimental data show a weaker relationship with the number of pipes in a row. The reasons for this are, for example:

- effects of the vapor shear stress on the heat transfer and
- splashing of the condensate from the pipes.

The experimentally determined exponents for Eq. (42) range from $i = -1/6$ to 0. For the practical calculation of heat transfer coefficients, the value $i = -1/6$ is recommended.

4.3 Tube Bundle, Influence of Gas Flow

In the case of tube bundles, the influence of the vapor shear stress on the heat transfer in the horizontal pipe must normally also be taken into account. Methods from various authors exist in the literature for taking account of the vapor flow.

For a single horizontal pipe with vapor flow from top to bottom, Fujii et al. [17] have published the equation

$$\mathrm{Nu}_{F,1} = \frac{\alpha_{F,1}\mathcal{L}}{\lambda_F} = C\chi\left(1 + \frac{0.276\ \mathrm{Pr}_F}{\chi^4 \mathrm{Fr}\,\mathrm{Ph}}\right)^{1/4}\sqrt{\mathrm{Re}_{GS}}\cdot\frac{\mathcal{L}}{d}. \quad (43)$$

Here $\chi = 0.9(1+G^{-1})^{1/3}$,

$$G = \frac{\mathrm{Ph}}{\mathrm{Pr}_F}\left(\frac{\rho_F\eta_F}{\rho_D\eta_D}\right)^{0,5}, \qquad \mathrm{Ph} = \frac{C_{\rho F}(\vartheta_S - \vartheta_W)}{\Delta h_v},$$

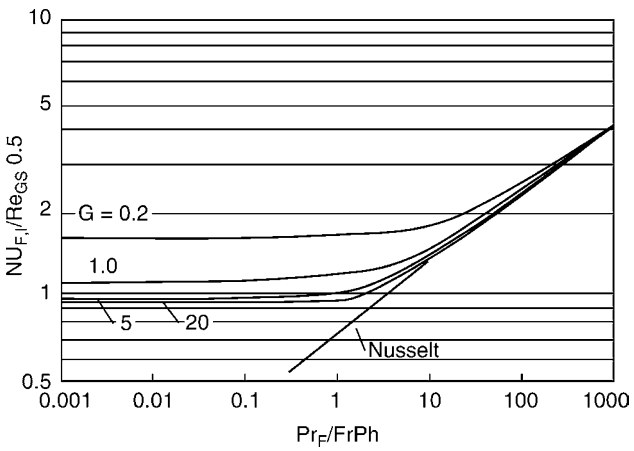
$$\mathrm{Re}_{GS} = \frac{\bar{u}_D d}{\nu_F}, \qquad \mathrm{Fr} = \frac{\bar{u}_D^2}{gd}, \quad C = 1.$$

In Fig. 9 the expression $\mathrm{Nu}_{F,1}/\sqrt{\mathrm{Re}_{GS}}$ is represented as a function of the parameter G. In the case of high values for $\mathrm{Pr}_F/\mathrm{Fr}\,\mathrm{Ph}$, i.e., at low gas flow velocities, the relationship according to Nusselt [1] (Eq. (40)) is reached.

The influence of the angle of incidence of the vapor flow on to the condenser pipe is variously discussed in the literature. Fujii [18] finds almost no influence on the heat transfer in a horizontal pipe. The equations given are also suitable for the calculation of pipe nests. In the case of Fujii et al. [19], calculation according to Eq. (43) is recommended for an offset array of pipes, and a reduction by 20% of the values calculated according to Eq. (43) is recommended for an aligned array:

$$C = \begin{cases} 0.8 & \text{in row,} \\ 1 & \text{displaced.} \end{cases}$$

For more precise calculations, multidimensional treatments must be drawn upon. As a result of condensation, the vapor



J1. Fig. 9. Influence of vapor flow on the heat transfer at horizontal tubes.

velocity and the system pressure are subject to strong variations which can be studied by splitting the condenser, according to incident flow, into individual lines or rings with constant flow conditions and monitoring these using balance sheets. In any case, however, it must be ascertained whether the work involved in more extensive calculations is justified, particularly with regard to uncertainties in the determination of the fouling resistance.

5 Condensation in Horizontal Tubes

The condensation process and, thus, the calculation of the heat transfer in the horizontal or slightly inclined pipe are essentially determined by the constant change in the flow distribution of the vapor and the liquid phase along the condensation section. Assuming pure vapor on entry at a relatively high velocity, an almost uniformly thin condensate film will form around the circumference. This liquid film becomes continuously thicker as the condensation progresses and, because of gravity, becomes more unevenly distributed. At the same time, the vapor velocity and, thus, the interaction between the vapor and the liquid phase are reduced. A mixture of annular and stratified flow forms which, according to condensation conditions, develops into a surge flow, a slug flow, or even a single phase (liquid) flow.

In order to assess the flow distribution, flow maps are employed, which are presented in many different ways. Figure 10 shows a simplified flow map according to Breber et al. [20], in which a modified Froude number (44)

$$\mathrm{Fr}_{\mathrm{G}}^{*} = \sqrt{\frac{\rho_{\mathrm{D}}}{\rho_{\mathrm{F}} - \rho_{\mathrm{D}}}} \frac{\bar{u}_{\mathrm{D},0}}{\sqrt{d \cdot g}}. \tag{44}$$

is shown in relation to the flow parameter F according to Eq. (32).

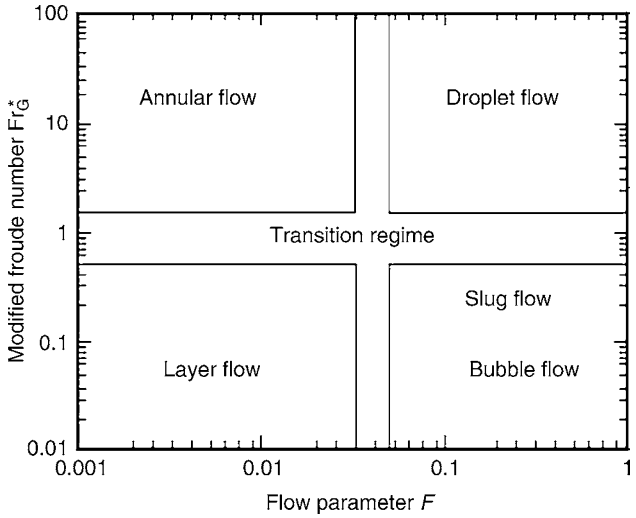
It is essential for the practical calculation that, on the basis of this map, a distinction is made between separated flows (annular, stratified, or wavy stratified flow) and purely discontinuous flow forms (bubble, surge, and slug flows). For assessment, the distribution of the gas and liquid phases in the pipe is still important, as described by the volumetric vapor content $\varepsilon = V_{\mathrm{D}}/(V_{\mathrm{D}} + V_{\mathrm{F}})$. The value of ε is given, according to Owen and Lee [21], as a function of the flow parameter F

$$\varepsilon = 1 - \frac{1}{1 + \dfrac{1}{8.48\,F}}. \tag{45}$$

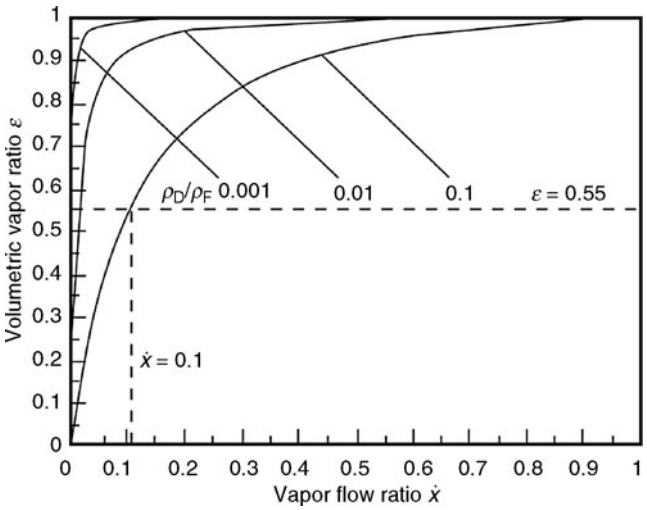
As F is, in fact, a function of the flow vapor content $\dot{x} = \dot{M}_{\mathrm{D}}/(\dot{M}_{\mathrm{D}} + \dot{M}_{\mathrm{F}})$, the result is the relationship between ε and x in Fig. 11 for different density conditions $\rho_{\mathrm{D}}/\rho_{\mathrm{F}}$. Equation (45) has been verified for a large number of substance pairs [21].

5.1 Heat Transfer

On the basis of previous statements on the vertical pipe, the transfer resistance also exists only in the condensed phase, so that, in principle, the equations in Sect. 3 can be used for the laminar and turbulent Nusselt number according to Eqs. (10) and (13) together with the corresponding coefficients.



J1. Fig. 10. Flow map according to Breber et al. [20].



J1. Fig. 11. Volumetric vapor content ε as a function of vapor flow x with various density ratios $\rho_{\mathrm{D}}/\rho_{\mathrm{F}}$.

It should be noted here that the shear stress in the condensate film is eliminated by the gravitational force. The Nusselt numbers and the heat transfer coefficients of the vertical condensate film must be correspondingly modified. This is carried out by a shear stress correction K_{W}, which, for the horizontal pipe, derived from a simple balance of forces, gives

$$K_{\mathrm{W}} = \tau_{\mathrm{D}}^{*1/3}. \tag{46}$$

This approach takes into account the improvement in heat transfers at high shear stresses and the deterioration of the heat transfers for the case where the shear stress τ_{D} acting on the condensate film is smaller than the comparable gravitational stress in the vertical case.

It should also be noted that, for the relative shear stress τ_D^*, the film thickness δ_F^+ must be substituted by the circumferentially averaged thickness of the liquid cross section δ_A^+, which, with a good approximation for $\varepsilon \geq 0.67$, gives

$$\delta_A^+ = \frac{1-\varepsilon}{4} d \tag{47}$$

especially as the shear stress is only significant in the case of very high volumetric vapor contents. The relative shear stress is therefore

$$\tau_D^* = \frac{\tau_D}{\rho_F g \delta_A^+}. \tag{48}$$

The improvement in the heat transfer due to the increase in turbulence in the liquid phase resulting from the vapor shear stress τ_D can be described in analogy to Eqs. (25) and (26). For die, Nusselt number in the laminar flow region:

$$\mathrm{Nu}_{F,x,l}^{\bullet} = K_{Ph,l} \cdot \mathrm{Nu}_{F,x,l}^{+} \tag{49}$$

or in the turbulent region

$$\mathrm{Nu}_{F,x,t}^{\bullet} = K_{Ph,t} \cdot \mathrm{Nu}_{F,x,t}^{+}. \tag{50}$$

$\mathrm{Nu}_{F,x}^{+}$ is obtained in both equations with the correction factor according to Eq. (46).

Here, the superimposition according to Eq. (27) also applies.

5.2 Pressure Loss and Shear Stress

Under the assumption of separated flow, the aforementioned statements on shear stress and pressure loss are valid. The resistance coefficient required is calculated according to Henstock and Hanratty [15] as

$$\xi_r^{\circ} = \xi_g^{\circ}(1 + 850\, F), \tag{51}$$

where ξ_g° and F are obtained according to Eqs. (31) and (32) The shear stress τ_D° is obtained in analogy to Eq. (29) (also see the calculation examples). As far as entrainment is concerned, the same statements apply in principle as for unidirectional flow, with the possibility of occurrence already shown in the flow maps.

6 Special Points

6.1 Additional Resistance at Phase Layer Between Vapor and Liquid Phases

In the case of metal vapor, highly superheated vapor, or nonvolatile substances, an additional molecular heat transfer resistance may occur at the liquid–vapor phase boundary. The mass flow density at the phase boundary, according to Rohsenow et al. [22], is

$$\dot{m} = \frac{\sigma_{Akk}}{1 - 0.5\sigma_{Akk}} \sqrt{\frac{\widetilde{M}}{2\pi\tilde{R}}} \left(\frac{p_D}{T_D^{1/2}} - \frac{p_{Ph}}{T_{Ph}^{1/2}} \right). \tag{52}$$

For the accommodation coefficient, $\sigma_{Acc} = 1$ can be used.

By taking a balance at the phase boundary, the unknown temperature T_{Ph} can be determined iteratively:

$$\alpha_F(\vartheta_{Ph} - \vartheta_W) = \frac{\sigma_{Akk}}{1 - 0.5\,\sigma_{Akk}} \sqrt{\frac{\widetilde{M}}{2\pi\tilde{R}}} \left(\frac{p_\infty}{T_\infty^{1/2}} - \frac{p_{Ph}}{T_{Ph}^{1/2}} \right) \Delta h_v. \tag{53}$$

The deterioration in the condensation performance on the occurrence of a significant phase boundary resistance (PBR) is then given by

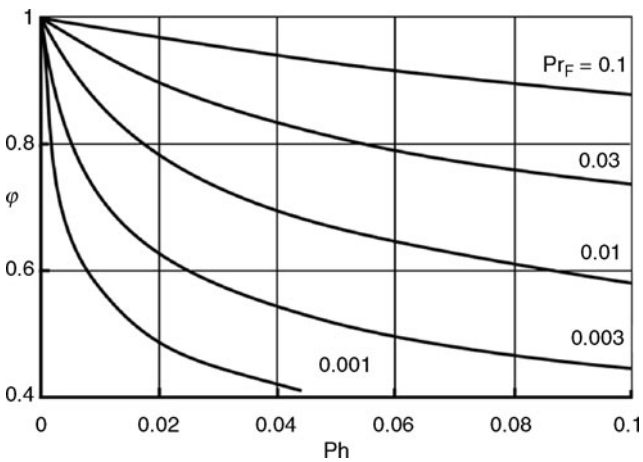
$$\frac{\dot{q}_{PGW}}{\dot{q}s} = \frac{\vartheta_{Ph} - \vartheta_W}{\vartheta_\infty - \vartheta_W}. \tag{54}$$

6.2 Condensation of Metal Vapors

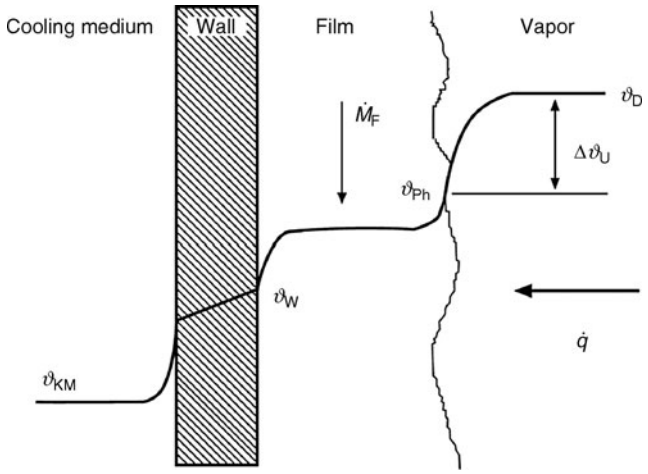
In the case of the condensation of metal vapors, with their high thermal conductivity in the liquid ($\mathrm{Pr}_F < 0.1$), the acceleration elements in the balance equations of the laminar film condensation can no longer be ignored. A correction of the heat transfer coefficient obtained according to *Nusselt* is therefore necessary. According to Chen [23], this correction φ is dependent on the phase transition number $\mathrm{Ph} = c_{p,F}(\vartheta_D - \vartheta_W)/\Delta h_v$ and the Prandtl number $\mathrm{Pr}_F = \eta_F c_{p,F}/\lambda_F$

$$\varphi = \frac{\mathrm{Nu}_{F,x,l,\,Pr\to 0}}{\mathrm{Nu}_{F,x,l}} = \left(\frac{1 + 0.68\,\mathrm{Ph} + 0.02\,\mathrm{Ph}^2/\mathrm{Pr}_F}{1 + 0.85\,\mathrm{Ph}/\mathrm{Pr}_F - 0.15\,\mathrm{Ph}^2/\mathrm{Pr}_F} \right). \tag{55}$$

Figure 12 shows the correction term φ in relation to the Prandtl and the phase transition numbers. In some cases, an additional resistance at the liquid–vapor phase boundary has to be taken into account (Sect. 6.1).



J1. Fig. 12. Influence of small Prandtl numbers ($\mathrm{Pr}_F < 0.1$) on heat transfer during filmwise condensation.



J1. Fig. 13. Schematic temperature profile during condensation of superheated vapor.

6.3 Condensation of Superheated Vapor

When superheated vapor comes into contact with a cold surface, condensation occurs if the temperature of the surface is below the saturation value at the corresponding system pressure. Figure 13 shows a qualitative temperature profile.

In addition to the latent heat, sensible heat is also transferred. For calculation of the heat transfer, instead of the evaporation enthalpy, the total difference of the specific enthalpies of vapor and liquid must be used:

$$\Delta h = \Delta h_v + C_{pD}(\vartheta_D - \vartheta_S) = \Delta h_v + c_{pD}\Delta\vartheta_{\ddot{U}}. \qquad (56)$$

Thus, the condensation area required according to Eq. (5)

$$\frac{A_{\ddot{U}}}{A} = \left(1 + \frac{c_{pD}\Delta\vartheta_{\ddot{U}}}{\Delta h_v}\right) \qquad (57)$$

generally increases only slightly in comparison with the condensation of dry saturated vapors, so this may normally be ignored.

In the case of strong superheating, the heat and material transfer processes in the gas–vapor phase must be taken into account. Here, the reader is referred to Subchap. J2.1 (particularly Sect. 3.4.4), which also applies correspondingly for the condensation of pure vapors.

7 Calculation Examples

Example 1

Condensation of isopropanol vapor in a vertical tube

Inlet conditions (saturation state)

Vapor flow	$\dot{M}_{D,E} = 0.04$ (kg/s) $\hat{=}$ 144 (kg/h)
Pressure	$p = 2.0$ bar = const
Temperature	$\vartheta = 100°C$ = const

Cooling conditions

Heat transfer coefficient	$a_{KM} = 6{,}500$ W/m^{2}K
Heat transfer wall	$\left(\frac{\lambda}{s}\right)_W = 10{,}000$ W/m^{2}K
Temperature of cooling fluid	$\vartheta_{KM} = 50°C \approx$ const

Properties at saturation state

Liquid	Density	$\rho_F = 712.7$ (kg/m^3)
	Dynamic viscosity	$\eta_F = 0.376{\cdot}10^{-3}$ Pa s
	Specific heat capacity	$c_{p,F} = 3{,}550$ J/(kg K)
Vapor	Density	$\rho_D = 4.15$ kg/m^3
	Dynamic viscosity	$\eta_D = 9.8{\cdot}10^{-6}$ Pa s
Condensation enthalpy		$\Delta h_v(\vartheta = 100\,°C) = 627.9$ kJ/kg

Solution

The calculation of the heat exchange area A and the tube length L is done by using local data according to Sect. 3 with following consumptions:

$$1 - \frac{\rho_D}{\rho_F} \approx 1; \quad f_\eta \approx 1; \quad \delta_F^+ \ll d.$$

The relative velocity between vapor and condensate is approximately the absolute velocity of the vapor, and the shear stress of vapor is neglected.

Mass flux normal to the wall is neglected.

Local condensate flow rates $\dot{M}_{F,x}$

$$\dot{M}_{F,1} = 1 \text{ kg/h}; \quad \dot{M}_{F,2} = 25 \text{ kg/h};$$
$$\dot{M}_{F,3} = 75 \text{ kg/h}; \quad \dot{M}_{F,4} = 144 \text{ kg/h}.$$

The way of calculation is shown at the local value $\dot{M}_{F,2}$. The results are presented in Table 1. The calculation neglects the influence of vapor flow to liquid phase

- Local condensate Reynolds numbers $Re_{F,x}$

$$Re_{F,x} = \frac{\dot{M}_F}{\pi d \eta_F} = \frac{25}{3{,}600 \cdot \pi \cdot 0.03 \cdot 3.76 \cdot 10^{-4}} = 196, \quad \text{Eq. (11)}$$

- Local Nusselt numbers $Nu_{F,x}$

$$\text{laminar: } Nu_{F,x,l} = 0.7 Re_{F,x}^{-0.29} = 0.7 \cdot 196^{-0.29} = 0.151, \quad \text{Eqs. (10, 12)}$$

$$\text{turbulent: } Nu_{F,x,t} = \frac{0.0283 Re_{F,x}^{-0.292} Pr_F^{0.333}}{1 + 9.66 Re_{F,x}^{-0.375} Pr_F^{-0.167}}, \quad \text{Eq. (13)}$$

- Prandtl number

$$Pr_F = \frac{\eta_F c_{p,F}}{\lambda_F} = \frac{3.76 \cdot 10^{-4} \cdot 3{,}550}{0.124} = 10.76,$$

$$Nu_{F,x,t} = \frac{0.0283 \cdot 196^{0.292} \cdot 10.76^{0.333}}{1 + 9.66 \cdot 196^{-0.375} \cdot 10.76^{-0.167}} = 0.152,$$

$$Nu_{F,x} = \sqrt{Nu_{F,x,t}^2 + Nu_{F,x,t}^2} = \sqrt{0.151^2 + 0.152^2} = 0.214, \quad \text{Eq. (15)}$$

J1. Table 1. Example: vertical tube

Condensate flow rate	Condensate film Reynolds number	Nusselt numbers			Heat transfer coefficient	Overall heat transfer coefficients		Tube length
						Local	Between 2 coordinates	
$\dot{M}_{F,x}$ in $\frac{kg}{h}$	$Re_{F,x}$	$Nu_{F,x,l}$	$Nu_{F,x,t}$	$Nu_{F,x,t}$	$\alpha_{F,x}$ in $\frac{W}{m^2K}$	k_x in $\frac{W}{m^2K}$	k_x in $\frac{W}{m^2K}$	ΔL in m
1	8	0.383	0.029	0.384	1561	1118	916	0.97
15	196	0.151	0.152	0.214	870	713	790	2.34
75	588	0.110	0.250	0.273	1110	866	949	2.69
144	1129	0.091	0.332	0.344	1398	1032	$L = \Sigma\Delta L = 6.0$ m	

- Local heat transfer coefficient $\alpha_{F,x}$

$$Nu_{F,x,t} = \frac{a_{F,x} \cdot \mathcal{L}}{\lambda_F}.$$

- Characteristic length

$$\mathcal{L} = \left(\frac{\eta_F^2}{\rho_F^2 g}\right)^{1/3},$$

$$\mathcal{L} = \left(\frac{(3.76 \cdot 10^{-4})^2}{712.7^2 \cdot 9.81}\right)^{1/3} \text{m} = 3.05 \cdot 10^{-5} \text{ m}$$

$$a_{F,x} = \frac{Nu_{F,x} \cdot \lambda_F}{\mathcal{L}} = \frac{0.214 \cdot 0.124}{3.05 \cdot 10^{-5}} \text{ W/m}^2\text{K} = 870 \text{ W/m}^2\text{K}.$$

- Local overall heat transfer coefficient k_x:

$$\frac{1}{k_x} = \frac{1}{\alpha_{F,x}} + \left(\frac{s}{\lambda}\right)_W + \frac{1}{\alpha_{KM}},$$

$$\frac{1}{k_x} = \left(\frac{1}{870} + \frac{1}{10{,}000} + \frac{1}{6{,}500}\right) \text{m}^2\text{K/W} = 1.4 \cdot 10^{-3} \text{ m}^2\text{K/W}$$

$$\Rightarrow k_x = 713 \text{ W/m}^2\text{K}.$$

- Heat transfer coefficient between 1 and 2:

$$\bar{k}_{1,2} = \frac{1}{2}(k_1 + k_2) = \frac{1}{2}(1{,}118 + 713) \text{ (W/m}^2\text{ K)}$$
$$= 916 \text{ (W/m}^2\text{ K)}.$$

- Necessary length $\Delta L_{1,2}$ between 1 and 2 according to Eq. (7):

$$\Delta L_{1,2} = \frac{1}{\pi d} \cdot \frac{(\dot{M}_{F,2} - \dot{M}_{F,1}) \cdot \Delta h_v}{\bar{k}_{1,2} \cdot \Delta\vartheta}.$$

Due to the assumption of $\Delta\vartheta = 50$ K = constant it is valid

$$\Delta L_{1,2} = \frac{1}{\pi \cdot 0.03} \cdot \frac{(25 - 1) \cdot 627.9 \cdot 10^3}{3{,}600 \cdot 916 \cdot 50} \text{m} = 0.97 \text{ m}$$

- The total length is given by summation of the different elements to $L = 6.00$ m. The length from 0 to 1 is neglected.

Example 2

Condensation of water vapor at horizontal tubes.

Saturated water vapor with $\vartheta_D = 100°C$ flows outside over a cooled horizontal single tube.

- Influence of gas velocity is negligible.
- Geometry: $d_a = 25$ mm, $s = 1$ mm, $\lambda_R = 21$ W/(mK), $L = 1$ m.
- Cooling water: $\bar{u}_{KW} = 2$ m/s, $\vartheta_{KW,ein} = 20°C$,
  properties: $\rho_{KW} = 998$ kg/m^3, $c_{p,KW} = 4{,}180$ J/(kg K),
  $\nu_{KW} = 0.9 \cdot 10^{-6}$ m^2/s, $\lambda_{KW} = 0.60$ W/(mK),
  fouling factor $R_{f,KW} = 0.09$ K m^2/kW acc. to Chap. O1
- Condensate:
  Properties: $\rho_F = 965$ kg/m^3,
  $c_{p,F} = 4{,}205$ J/(kg K), $\nu_F = 0.29 \cdot 10^{-6}$ m^2/s,
  $\lambda_F = 0.68$ W/(mK), $\Delta h_v = 2{,}250$ kJ/kg.

Solution

- Geometry: $A_a = \pi d_a L = 0.079$ m^2, $A_i = \pi(d_a - 2s)$ $L = 0.072$ m^2.
- Calculation of cooling fluid acc. to Part G:

$$\dot{M}_{KW} = \rho_{KW} \frac{\pi}{4} d_i^2 \bar{u}_{KW} = 0.829 \text{ kg/s};$$

$$\text{with Re} = \frac{\bar{u}_{KW} d_i}{\nu_{KW}} = 51{,}111 \quad \text{and} \quad \text{Pr} = \frac{\rho_{KW} \nu_{KW} c_{p,KW}}{\lambda_{KW}} = 6.26;$$

it follows that

$$\text{Nu} = \frac{\alpha_{KW} d_i}{\lambda_{KW}} = 346 \text{ resp. } \alpha_{KW} = \frac{\text{Nu}\lambda_{KW}}{d_i} = 9{,}018 \text{ W/(m}^2\text{K)}.$$

- Calculation of condensate fluid:

Because the heat transfer coefficient for condensate α_F and also the outlet temperature of the cooling water $\vartheta_{KW,aus}$ is unknown, an iterative method becomes necessary.

Starting value: $\alpha_F = 10{,}000$ W/(m^2 K).

With balance and transfer equation we can obtain:

$$M_{KW} c_{p,KW} (\vartheta_{KW,aus} - \vartheta_{KW,ein}) = k A_a \Delta\vartheta_{log}$$

With

$$\frac{1}{kA_a} = \left(\frac{1}{\alpha_{KW}} + R_{f,KW}\right) \frac{1}{A_i} + \frac{s \ln (A_a/A_i)}{\lambda_R (A_a - A_i)} + \frac{1}{\alpha_F A_a}.$$

Now we can calculate the outlet temperature:

$\vartheta_{KW} = 24.78°C$.

Calculation of α_F:

$$\dot{Q}_F = \dot{Q}_{KW} = \dot{M}_{KW} c_{p,KW} (\vartheta_{KW,aus} - \vartheta_{KW,ein})$$
$$= 0.829 \text{ kg/s} \cdot 4{,}180 \text{ J/(kg K)} \cdot (24.78 - 20.00) \text{ K};$$
$$\dot{Q}_F = 16{,}551 \text{W};$$
$$\dot{M}_F = \dot{Q}_{KW}/\Delta h_v = 16{,}551 \text{ W}/2{,}250 \text{ kJ/kg} = 7.4 \text{ g/s};$$
$$\text{Re}_F = \dot{M}_F / L \rho_F \nu_F = 25.9;$$
$$\text{Nu}_F = 0.954 \text{Re}_F^{-1/3} \text{ according to Eq. (40)}.$$

As a first estimation, we get

$$\alpha_F = \mathrm{Nu}_F \lambda_F / \left(\nu_F^2/g\right)^{1/3} = 10{,}565\ \mathrm{W/(m^2\,K)}.$$

This value is used for the calculation of the cooling water outlet temperature.

After further iterative steps, the final result is
$\alpha_F = 10{,}519\ \mathrm{W/(m^2\,K)}$;
cooling temperature $\vartheta_{KW,aus} = 24.83°\mathrm{C}$;
condensate flow rate $\dot{M}_{KW} = 26.8\ \mathrm{kg/h}$.

Example 3

Condensation of R22 vapor in a horizontal tube.

Inlet conditions (saturation state)

Vapor flow	$\dot{M}_{D,E} = 0.1\ \mathrm{kg/s} \triangleq 360\ \mathrm{kg/h}$
Pressure	$p = 9.58\ \mathrm{bar}$
Temperature	$\vartheta = 22°\mathrm{C}$

Conditions for cooling water

Heat transfer coefficient		$\alpha_{KM} = 5{,}000\ \mathrm{W/m^2K}$
Heat transfer wall		$\left(\frac{\lambda}{s}\right)_W = 7{,}500\ \mathrm{W/m^2\,K}$
Temperature		$\vartheta_{KM} = 0°\mathrm{C}$
Properties at saturation state		
Liquid	Density	$\rho_F = 1{,}206\ \mathrm{kg/m^3}$
	Dynamic viscosity	$\eta_F = 2.04 \cdot 10^{-4}\ \mathrm{Pa\,s}$
	Thermal conductivity	$\lambda_F = 0.0866\ \mathrm{W/m\,K}$
	Heat capacity	$c_{p,F} = 1.24\ \mathrm{kJ/kg\,K}$
Vapor	Density	$\rho_D = 40.6\ \mathrm{kg/m^3}$
	Dynamic viscosity	$\eta_D = 1.32 \cdot 10^{-5}\ \mathrm{Pa\,s}$

Solution

The calculation of the heat exchange area A and the tube length L is done by using local data according to Sect. 3 with the following consumptions:

- $1 - \frac{\rho_D}{\rho_F} \approx 1; \quad f_n \approx 1; \quad \delta_F^+ \ll d.$
- The relative velocity between vapor and condensate is approximately the absolute velocity of the vapor, and the shear stress of vapor is neglected.
- Mass flux normal to the wall is neglected.

Definition of local points:
Local vapor contents $\dot{x}_1 = 0.99$; $\dot{x}_2 = 0.9$; $\dot{x}_3 = 0.5$; $\dot{x}_4 = 0.1$; $\dot{x}_5 = 0.01$.

The way of calculation is shown at the local value $\dot{x}_2$. The results are presented in Tables 2 and 3. The calculation neglects the influence of vapor flow to liquid phase according to Sect. 3.1.

The flow rates for liquid phase $\dot{M}_{F,x}$and vapor phase $\dot{M}_{D,x}$ are defined:

$$\dot{x}_2 = \frac{\dot{M}_{D,2}}{\left(\dot{M}_{F,x} + \dot{M}_{D,x}\right)} \Rightarrow \dot{M}_{D,2} = \dot{x}_2 \cdot \left(\dot{M}_{F,x} + \dot{M}_{D,x}\right)$$
$$= 0.9 \cdot 360\ \mathrm{kg/h} = 324\ \mathrm{kg/h}$$
$$\Rightarrow \dot{M}_{F,2} = 36\ \mathrm{kg/h}.$$

- Calculation of Reynolds numbers

$$\mathrm{Re}_{F,x} = \frac{\dot{M}_{F,x}}{\pi d \eta_F} = \frac{36}{3{,}600\pi \cdot 0.025 \cdot 2.04 \cdot 10^{-4}} = 624$$

$$\mathrm{Re}_{D,x} = \frac{4\dot{M}_{D,x}}{\pi d \eta_D} = \frac{4 \cdot 324}{3{,}600\pi \cdot 0.025 \cdot 1.32 \cdot 10^{-5}} = 347{,}247.$$

Simplification: $d_h = \varepsilon d \approx d$.

- Flow parameter F (Eq. (32))

$$F = \frac{\max\left(\left(2\mathrm{Re}_{F,x}\right)^{0.5}; 0.132\mathrm{Re}_{F,x}^{0.9}\right)}{\mathrm{Re}_{D,x}\,0.9}, \frac{\eta_F}{\eta_D}\sqrt{\frac{\rho_D}{\rho_F}},$$

$$F = \frac{0.132.624^{0.9}}{347{,}247^{0.9}} \cdot \frac{2.04 \cdot 10^{-4}}{1.32 \cdot 10^{-5}} \sqrt{\frac{40.6}{1{,}206}} = 1.27 \cdot 10^{-3},$$

- calculation of volumetric vapor content ε

$$\varepsilon = 1 - \frac{1}{1 + \frac{1}{8.48F}} = 1 - \frac{1}{1 + \frac{1}{8.48 \cdot 1.27 \cdot 10^{-3}}} = 0.9893,$$

Eq. (45)

- calculation of film thickness δ_F

$$\delta_F^+ = \frac{1}{4}(1-\varepsilon)d = \frac{1 - 0.9907}{4} \cdot 0.025\ \mathrm{m} = 0.067 \cdot 10^{-3}\ \mathrm{m}.$$

- Nusselt number of condensate film:
  Characteristic length

$$\mathcal{L} = \left(\frac{\eta_F^2}{\rho_F^2 g}\right)^{1/3} = \left(\frac{2.04^2 \cdot 10^{-8}}{1{,}206^2 \cdot 9.81}\right)^{1/3}\ \mathrm{m} = 1.43 \cdot 10^{-5}\ \mathrm{m},$$

- laminar Nusselt number $\mathrm{Nu}_{F,x,l}$

$$\mathrm{Nu}_{F,x,l} = 0.7 \cdot \mathrm{Re}_{F,x}^{-0.29} = 0.7 \cdot 624^{-0.29} = 0.108,$$

- turbulent Nusselt number $\mathrm{Nu}_{F,x,t}$

$$\mathrm{Nu}_{F,x,t} = \frac{0.0283 \cdot \mathrm{Re}_{F,x}^{+0.292}\,\mathrm{Pr}_F^{0.333}}{1 + 9.66 \cdot \mathrm{Re}_{F,x}^{-0.375}\,\mathrm{Pr}_F^{-0.167}}$$
$$= \frac{0.283 \cdot 624^{+0.292} \cdot 2.92^{0.333}}{1 + 9.66 \cdot 624^{-0.375} \cdot 2.92^{-0.167}} = 0.154,$$

Eq. (13)

$$\mathrm{Nu}_{F,x} = \sqrt{\mathrm{Nu}_{F,x,l}^2 + \mathrm{Nu}_{F,x,l}^2} = \sqrt{0.108^2 + 0.154^2} = 0.188,$$

Eq. (15)

- Calculation shear stress

$$\tau_D = \frac{\xi_r}{8}\rho_D u_D^2$$

  - friction factor (rough) $\xi_r = \xi_g\,(1 + 850F)$, Eq. (51)
  - friction factor (smooth)

$$\xi_g = 0.184\ \mathrm{Re}_{D,x}^{-0.2} = 0.184 \cdot 347{,}247^{-2} = 0.0143,$$

  - velocity u_D ($\delta_F < d$)

J2 Film Condensation of Binary Mixtures with and without Inert Gas

Ernst-Ulrich Schlünder
Universität Karlsruhe (TH), Institut für Thermische Verfahrenstechnik, Karlsruhe, Germany

1 Introduction

Gaseous substances in a specified thermodynamic state can be subdivided into vapors and inert gases. Vapors are condensable at the respective specified coolant temperatures, but inert gases are not. In the condensation of binary mixtures, both components may be vapors or one component may be an inert gas. In both cases, in addition to the heat transfer resistance in the condensate film, heat transfer and mass transfer resistances also occur in the gas phase, leading to a reduction of condensation.

In the following, the basic equations for calculation of the condensation curve and a general calculation method for the design of a condenser are explained.

In many cases, an estimate of the distribution of the resistances to the gas phase, to the condensate film, and to the coolant, by ignoring one or the other, permits an appreciable simplification of the calculation. The approximate design of a condenser (Sects. 3.4 and 4.3) is primarily justified if important parameters like the gas volume flow, its temperature and composition, and the material values in the condensate film and in the gas phase are also known only approximately.

2 General Principles

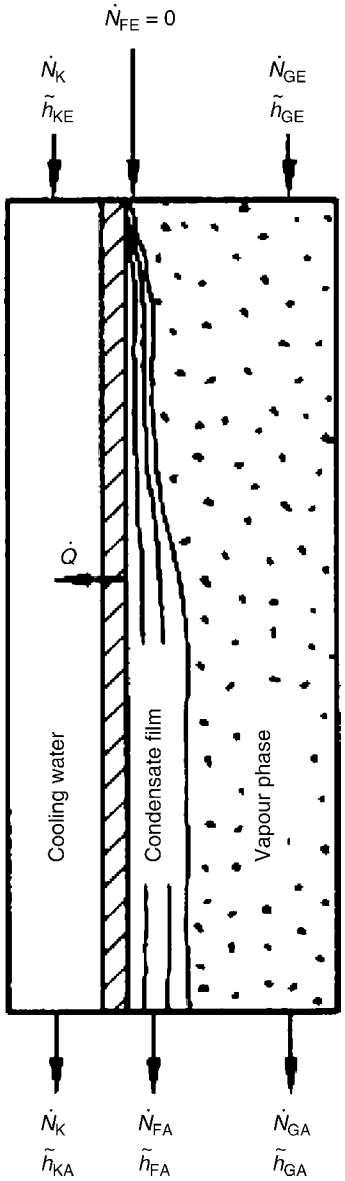
The equations describing the condensation process follow from the mass, component, and energy balance equations for the gas and liquid phases in combination with the kinetic theorems for heat and mass transfer [1].

2.1 Integral Mass and Energy Balances

According to Fig. 1, the mass balance for the overall segment shown reads

$$\dot{N}_{GE} - \dot{N}_{GA} = \dot{N}_{FA} \qquad (1)$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_37,



J2. Fig. 1. Condenser segment with cocurrent (parallel) coolant flow.

and the energy balance for the condensing phase and for the coolant (index K) reads

$$\dot{N}_{GE}\tilde{h}_{GE} - \dot{N}_{GA}\tilde{h}_{GA} = \dot{N}_{FA}\tilde{h}_{FA} + \dot{Q}, \tag{2}$$

$$\dot{Q} = \dot{N}_K(\tilde{h}_{KA} - \tilde{h}_{KE}). \tag{3}$$

If the mixture components behave ideally, the enthalpy of mixing vanishes and the enthalpy value for each substance can be normalized to be 0 at 0°C (liquid state):

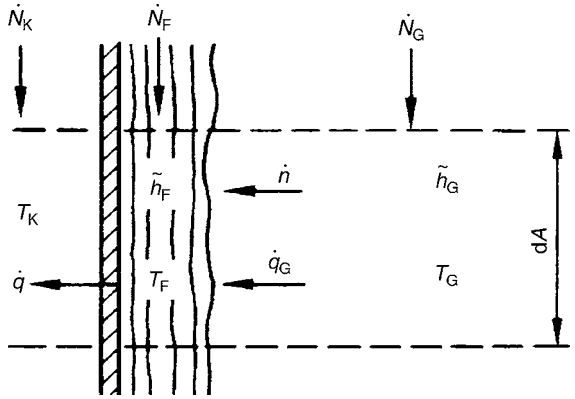
$$\tilde{h}_F = \tilde{c}_{pF} T_F, \tag{4}$$

$$\tilde{h}_G = \Delta h_v\{0°C\} + \tilde{c}_{pG} T_G, \tag{5}$$

$$\Delta\tilde{h}_v\{T\} = \Delta\tilde{h}_v\{0°C\} + (\tilde{c}_{pG} - \tilde{c}_{pF})T, \tag{6}$$

with the enthalpy of evaporation

$$\Delta\tilde{h}_v\{T\} = \tilde{h}_G\{T\} - \tilde{h}_F\{T\}. \tag{7}$$



J2. Fig. 2. Local (differential) mass, component, and energy flows.

Here the temperatures T, T_G, and T_F must be inserted in °C. From Eq. (2), it follows that

$$\dot{Q} = \dot{N}_{GE}\tilde{c}_{pG}(T_{GE} - T_{GA}) + (\dot{N}_{GE} - \dot{N}_{GA})\Delta h_v\{T_{GA}\} + \dot{N}_{FA}\tilde{c}_{pF}(T_{GA} - T_{FA}). \tag{8}$$

The total heat flow $\dot{Q}$ to be transferred to the coolant is composed of the cooling of the gas flow from T_{GE} to T_{GA}, the condensation of the vapor at T_{GA}, and the supercooling of the condensate film to T_{FA}. The energy gain of the coolant is given by Eq. (3):

$$\dot{Q} = \dot{N}_K\tilde{c}_{pK}(T_{KA} - T_{KE}). \tag{9}$$

2.2 Differential Mass and Energy Balances

The mass, the component, and energy balances according to Fig. 2 are based on a so-called single-component boundary layer of constant thickness (film model).

Mass balances

$$\dot{N}_G = \dot{N}_{G1} + \dot{N}_{G2}, \tag{10}$$

$$\dot{N}_F = \dot{N}_{F1} + \dot{N}_{F2}, \tag{11}$$

$$\dot{n} = \dot{n}_1 + \dot{n}_2, \tag{12}$$

$$d\dot{N}_G - \dot{n}\,dA = 0, \tag{13}$$

$$d\dot{N}_{G1} - \dot{n}_1\,dA = 0, \tag{14}$$

$$d\dot{N}_F - \dot{n}\,dA = 0, \tag{15}$$

$$d\dot{N}_{F1} - \dot{n}_1\,dA = 0. \tag{16}$$

Energy balances

$$d(\dot{N}_G\tilde{h}_G) + \dot{q}_G\,dA + \dot{n}\tilde{h}_G\,dA = 0, \tag{17}$$

$$d(\dot{N}_F\tilde{h}_F) + \dot{q}\,dA - \dot{q}_G\,dA - \dot{n}\tilde{h}_G\,dA = 0. \tag{18}$$

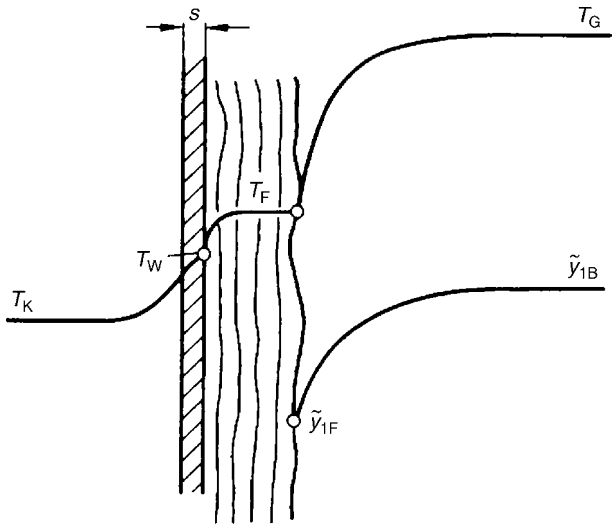
Linkage of mass and energy balances

$$\dot{N}_G\tilde{c}_{pG}\frac{dT_G}{dA} + \dot{q}_G - \dot{n}\tilde{c}_{pG}(T_G - T_F) = 0, \tag{19}$$

$$\dot{N}_F\tilde{c}_{pF}\frac{dT_F}{dA} + \dot{q} - \dot{q}_G - \dot{n}\Delta\tilde{h}_v\{T_F\} = 0. \tag{20}$$

2.3 Theorems for Heat and Mass Transfer

Figure 3 shows the driving temperature and concentration gradients for the heat and mass transfer.



J2. Fig. 3. Temperature and concentration profiles in and close to the condensate film.

2.3.1 Heat Transfer

The heat flow to be removed locally to the coolant is

$$\dot{q} = k'(T_F - T_K); \tag{21}$$

here, the heat transfer coefficient k' is composed of the heat transfer coefficients of the condensate film, the conduction resistance of the pipe wall, and the heat transfer coefficient on the coolant side:

$$\frac{1}{k'} = \frac{1}{\alpha_F} + \frac{s}{\lambda_R} + \frac{1}{\alpha_K}. \tag{21a}$$

The heat flow $\dot{q}_G$ transferred from the gas is, according to the kinetic theorem of coupled heat and mass transfer:

$$\dot{q}_G = \alpha_G E_T (T_G - T_F), \tag{22}$$

with the Ackermann correction factor [2]

$$E_T = \frac{\phi_T}{1 - \exp(-\phi_T)}, \tag{22a}$$

$$\phi_T = \frac{\dot{n}\tilde{c}_{pG}}{\alpha_G}. \tag{22b}$$

The Ackermann correction is to account for the mass transfer occurring parallel to the heat transfer. The local heat transfer coefficient α_F in the condensate film is calculated as described in Chap. J1, the heat transfer coefficients α_G and α_K in the gas or in the coolant according to the design of the condenser – e.g., in the case of a flow through pipes, as described in Chap. G1 and in the case of cross flow around pipe bundles, as described in Chap. G6.

2.3.2 Mass Transfer

In the case of condensation of a pure vapor in the presence of an inert gas, a mass transfer resistance only occurs in the gas phase, as the condensate film only consists of one component. The mass transfer resistance in the condensate film in the case of condensation of a binary vapor mixture is explained in Sect. 4.

The locally condensing mass flow is determined by the concentration gradient between the core (bulk) of the flow and the condensate film surface (Fig. 3):

$$\dot{n} = n_G \beta_G \ln\left(\frac{\dot{r}_1 - \tilde{y}_{1F}}{\dot{r}_1 - \tilde{y}_{1B}}\right), \tag{23}$$

with

$$\dot{r}_1 = \frac{\dot{n}_1}{\dot{n}} \tag{23a}$$

and

$$\tilde{y}_{1B} = \frac{\dot{N}_{G1}}{\dot{N}_G}. \tag{23b}$$

The mass transfer coefficient β_G follows from the same formal relationships with which the heat transfer coefficient α_G is calculated, if the Nusselt and Prandtl numbers are replaced by the Sh and Sc numbers. This is because of the analogy of convective heat and mass transfer, as the basic transport mechanisms are similar and the resulting differential equations have the same form.

This is also the basis for the Lewis relationship, an approximation which links the heat and mass transfer coefficients in the gas phase:

$$\alpha_G = n_G \beta_G \tilde{c}_{pG} \mathrm{Le}^{0.6}, \tag{24}$$

with the Lewis number

$$\mathrm{Le} = \frac{\kappa_G}{\delta_G} = \frac{\lambda_G}{n_G \tilde{c}_{pG} \delta_G}. \tag{25}$$

3 Condensation of a Pure Vapor in the Presence of an Inert Gas

During the condensation of pure vapor from a gas–vapor flow, the vapor fraction and the temperature of the gas–vapor flow decrease along the condensation line. This reduces the driving concentration and temperature gradients. For determination of the local mass flow $\dot{n}$ and the local heat flow $\dot{q}$, knowledge of the local condensate film temperature T_F is necessary. The determination of the transfer area of the condenser must therefore take place by a step-by-step calculation method. An estimate of the heat and mass transfer resistances in the coolant, in the condensate film, and in the gas phase shows that closed derivable, limiting cases can often be drawn for the calculation of the transfer area. This can give an appreciable reduction of the calculation work in individual cases.

3.1 Determination of the Condensate Film Temperature

During the condensation of pure saturated vapors, the whole heat transfer resistance is in the condensate film and in the coolant. If there is also an inert gas (e.g., air) in the vapor, this accumulates at the condensation boundary, entrained by the vapor flow. As a result, the partial vapor pressure p_1 or the vapor mole fraction $\tilde{y}_{1F}$ at the condensate surface is reduced. This reduces the temperature gradient $T_F - T_K$ between condensate

film and coolant and thus also the condenser's performance. The temperature of the condensate film T_F can be determined with the coupled balance equation (20):

$$\dot{N}_F \tilde{c}_{pF} \frac{dT_F}{dA} + k'(T_F - T_K) = \dot{n} \Delta \tilde{h}_{v1}(T_F) + \alpha_G E_T (T_G - T_F). \quad (26)$$

If the vapor is assigned the index 1 and the inert gas the index 2, it follows, with

$$\dot{n}_2 = 0 \quad (27)$$

the relationships $\dot{n}_1 = \dot{n}$ and $\dot{r}_1 = 1$, that

$$\dot{n}_1 = n_G \beta_G \ln\left(\frac{1 - \tilde{y}_{1F}(T_F)}{1 - \tilde{y}_{1B}}\right) \quad (28)$$

or, because $\tilde{y}_1 + \tilde{y}_2 = 1$,

$$\dot{n}_1 = n_G \beta_G \ln\left(\frac{\tilde{y}_{2F}(T_F)}{\tilde{y}_{2B}}\right). \quad (28a)$$

If there is equilibrium at the condensate film surface and the air is saturated,

$$\tilde{y}_{1F} = \frac{p_1^*(T_F)}{p}. \quad (28b)$$

The saturated vapor pressure $p_1^*(T_F)$ associated with the condensate film temperature can be calculated, for example, with the simple Antoine vapor pressure equation

$$\ln p_1^* = A - \frac{B}{C + T/°C}. \quad (29)$$

The values for A, B, and C for almost all technically important substances can be found in the literature [3, 4].

In most cases, it is permissible, in the determination of the condensate film temperature, to ignore the change in the molar enthalpy of the condensate film. So, from Eq. (26), the iterative resolution for the condensate film temperature T_F is

$$k'(T_F - T_K) = n_G \beta_G \Delta \tilde{h}_{v1} \ln\left(\frac{\tilde{y}_{2F}(T_F)}{\tilde{y}_{2B}}\right) + \alpha_G E_T (T_G - T_F) \quad (30)$$

or

$$k'(T_F - T_K) = \alpha_G \phi_T \left(\frac{\Delta \tilde{h}_{v1}}{\tilde{c}_{pG1}} + \frac{T_G - T_F}{1 - \exp(-\phi_T)}\right), \quad (31)$$

with

$$\phi_T = \frac{n_1 \tilde{c}_{pG1}}{\alpha_G} = \frac{n_G \beta_G \tilde{c}_{pG1}}{\alpha_G} \ln \frac{\tilde{y}_{2F}(T_F)}{\tilde{y}_{2B}}. \quad (31a)$$

Using the Lewis relationship (Eq. (24)), it follows that

$$\phi_T = \frac{\tilde{c}_{pG1}}{\tilde{c}_{pG} Le^{0.6}} \ln\left(\frac{\tilde{y}_{2F}}{\tilde{y}_{2B}}\right). \quad (31b)$$

If the condensate film temperature T_F is known, the locally condensing component flux $\dot{n}_1$ (Eq. (28)) and the removed heat flux $\dot{q}$ (Eq. (21)) can be calculated (Example 1).

Example 1

Part A

The condensate film temperature T_F of a water vapor/air mixture with a mole fraction of water vapor at the inlet $\tilde{y}_{1B} = 0.5$ and temperature $T_G = 100°C$ at pressure $p = 1$ bar is to be calculated. The coolant water temperature is $T_K = 20°C$.

Convective heat transfer coefficient: $\alpha_G = 20$ W/m^2 K.
Overall heat transfer coefficient: $k' = 1{,}000$ W/m^2 K.
Properties are to be inserted at a temperature of 50°C.

The temperature dependence of the material values may be ignored for the iterative determination of the condensate film temperature T_F. The values for this case are

$$\Delta \tilde{h}_{v1} = 42{,}800 \text{ J/mol}, \quad \tilde{c}_{pG1} = 34.2 \text{ J/mol K},$$
$$\tilde{c}_{pG1}/(\tilde{c}_{pG} Le^{0.6}) = 1.3.$$

The vapor pressure dependence in the case of water is described by the Antoine equation

$$\ln \frac{p_1^*}{\text{bar}} = 11.9648 - 3984.923/(233.426 + T/°C),$$

while the dewpoint temperature $T_T(\tilde{y}_{1B})$ is 81.4°C.

Iteration

Following Eq. (31), the iteratively resolved equation for T_F is

$$T_F = T_K + 25K \cdot \phi_T + 0.02\,\phi_T \cdot (T_F - T_F)/(1 - \exp(-\phi_T)),$$

with

$$\phi_T = 1.3 \ln\left[2\left(1 - \frac{p_1^*}{p}\right)\right]$$

according to Eq. (31b). In place of the mole flow $\dot{n}_1$, the mass flow $\dot{m}_1$ can also be determined from the nondimensional mass flow ϕ_T according to Eq. (31a):

$$\dot{m}_1 = \alpha_G \phi_T / c_{pG1}$$

	T_F (°C)	p_1^* (bar)	φ_T (–)	T_F' (°C)	$\dot{m}_1$ (10^{-3} (kg/m^2 s))
1. Estimate	50	0.1231	0.730	39.6	7.68
2. Estimate	40	0.0736	0.802	41.8	8.44
Result	41.5	0.0797	0.793	41.5	8.35

Part B

Influence of gas and coolant temperature: In the case of strong superheating of the gas at the inlet, while the condensate film temperature T_F rises appreciably, the locally condensing mass flow $\dot{m}_1$ nevertheless decreases only slightly in this case, as can be seen in the following table (lines 1–3).

Line	T_G (°C)	T_K (°C)	T_F (°C)	φ_T (–)	$\dot{m}_1$ (10^{-3} (kg/m^2 s))	k'/α_{GD} (Eq. (38))
1	100	20	41.5	0.793	8.35	1.86
2	200	20	44	0.777	8.18	1.56
3	500	20	51	0.721	7.59	0.98
4	$T_G = T_F$	60	70	0.417	4.39	1.14
5	$T_G = T_F$	40	56.5	0.661	6.96	1.51
6	$T_G = T_F$	20	40	0.802	8.44	2.07
7	$T_G = T_F$	0	22	0.880	9.26	2.70

In the absence of heat flow $\dot{q}_G$, i.e., at $T_G = T_B$, Eq. (31) can be simplified to Eq. (39):

$$T_F = T_K + 32.5\,\mathrm{K} \cdot \ln\left(\frac{\tilde{y}_{2F} - (T_F)}{\tilde{y}_{2B}}\right).$$

The condensing mass flow only increases by 1% (lines 6 and 1).

A reduction of the coolant temperature T_K and thus the condensate film temperature T_F causes a reduction of the vapor pressure p_1^* and thus an increase in the driving concentration gradients and the locally condensing mass flow $\dot{m}_1$. As the vapor pressure p_1^* is exponentially dependent on the condensate film temperature T_F (Eq. (29)), its influence on the condensate mass flow $\dot{m}_1$ decreases, the lower the temperature T_F is, as shown in the table.

For the vapor pressure $p_1^* = 0$, the driving concentration gradient and the locally condensing mass flow are at a maximum. This is determined by the vapor or inert gas content in the core $\tilde{y}_{1B}$:

$$\phi_{T\,max} = \frac{\tilde{c}_{pG1}}{\tilde{c}_{pG}\mathrm{Le}^{0.6}} \ln\left(\frac{1}{1-\tilde{y}_{1B}}\right) = 1.3 \cdot \ln 2 = 0.901,$$

$$\dot{m}_{1\,max} = 9.48 \cdot 10^{-3}\,(\mathrm{kg/m^2\,s}).$$

3.2 General Method for Determination of the Transfer Area

The condenser performance or the transfer area can generally only be calculated step-by-step according to the program flowchart in Fig. 4. For this purpose, the total area A of the condenser is divided into a number of small area elements ΔA. The magnitude of ΔA can be estimated, for example, with the minimum required transfer area (Eq. (44)) and the number of sampling points. On the basis of the given entry conditions, the change in the gas and condensate mass flow can then be calculated. The step-by-step procedure is stopped when the specified total area or the required residual vapor fraction is reached. Corresponding methods are described in [5, 6].

3.2.1 Determination of Local Mass Flows

The change in the gas and condensate mass flow between two consecutive sampling points i and $i + 1$ is described by the differential balance equations (Eqs. (10–20)) in the form of differential equations:

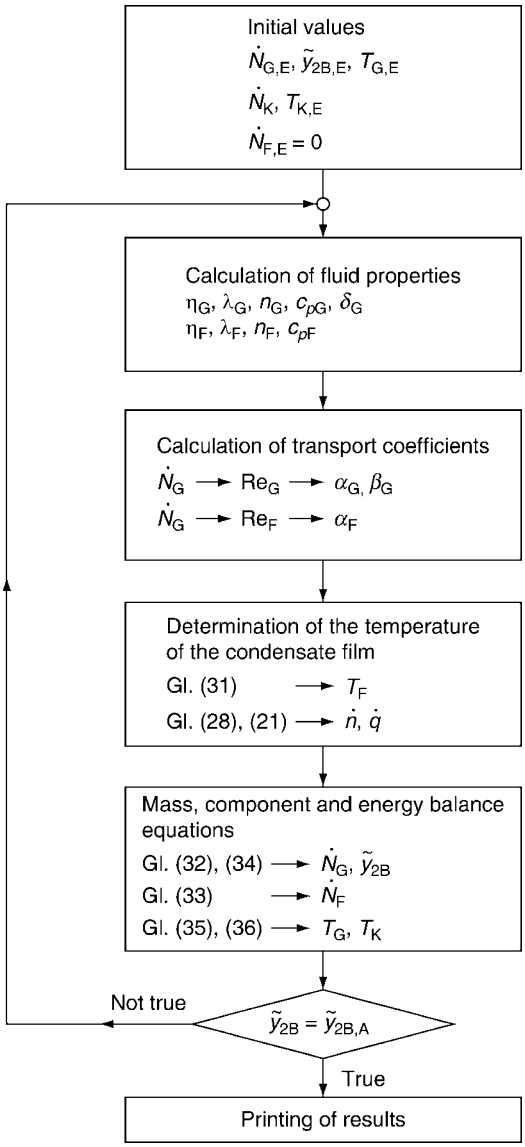
$$\dot{N}_{G,i+1} = \dot{N}_{G,i} - \dot{n}_i \Delta A, \tag{32}$$

$$\dot{N}_{F,i+1} = \dot{N}_{F,i} + \dot{n}_i \Delta A. \tag{33}$$

As the inert gas flow $\dot{N}_{G2}$ is constant in the course of the condensation, the local inert gas content is given by

$$\tilde{y}_{2B,i} = \frac{\dot{N}_{G2}}{\dot{N}_{G,i}} = \frac{\dot{N}_{G2}}{\dot{N}_{G,1,i} + \dot{N}_{G2}}. \tag{34}$$

The respective, locally condensing mass flow $\dot{n}_i$ and the heat flow to be removed $\dot{q}_i$ are calculated with the help of the iteratively determined condensate film temperature $T_{F,i}$. For this purpose, the local temperatures of the gas–vapor mixture $T_{G,i}$, the coolant $T_{K,i}$, and the local material values and transport coefficients are needed.



J2. Fig. 4. Program flowchart for the stepwise determination of the transfer area of a condenser for a pure condensate from a mixture of vapor and inert gas.

3.2.2 Determination of the Local Temperature of the Gas–Vapor Mixture T_G

If the gas–vapor mixture is saturated, the local mixture temperature $T_{G,i}$ in the bulk of the flow is equal to the dewpoint temperature $T_T(\tilde{y}_{1B,i})$ at each point corresponding with the local vapor fraction, which can be determined with the help of Eq. (29). If the mixture is superheated, the drop in the gas temperature T_G can be determined with the help of Eq. (19):

$$T_{G,i+1} = T_{G,i} - \frac{\dot{n}_i/\dot{N}_{G,i}}{\exp\,\phi_T - 1}(T_{G,i} - T_{F,i})\Delta A. \tag{35}$$

If the temperature at any point is below the dewpoint temperature T_T, small droplets may show up to form mist or fog. It is therefore recommended, when the dewpoint temperature is reached, to regard the gas–vapor mixture in the further course of the condensation as saturated and to calculate T_G according to Eq. (29).

3.2.3 Determination of the Local Coolant Temperature $T_{K,i}$

If the cooling takes place through a pure evaporating medium, the coolant temperature T_K remains constant along the condensation line. If the temperature rise is ignored in the case of cooling water, for a parallel flow between gas and coolant

$$T_{K,i+1} = T_{K,i} + \frac{\dot{q}_i}{\dot{N}_K c_{pK}} \Delta A. \tag{36}$$

If the coolant water flows in the opposite direction, i.e., countercurrent flow, the coolant water exit temperature must be calculated with the help of the total balance (Eqs. (8) and (9)), ignoring or estimating the cooling of the gas–vapor flow and the condensate film. In the case of cross-current flow, as in a pipe bundle system, for example, segment-wise constant coolant temperature may be assumed.

3.2.4 Properties

As the mixture cools down, passes through the condensation line, and the inert gas is enriched, the temperature and concentration dependence of the fluid property values must be taken into account if necessary. The material values of liquids, gases, and vapors are contained in Chap. D3 and their temperature dependence is described in Chap. D1. The material values of the mixture can be obtained from the material values of the vapor and of the inert gas. The thermal capacity may be simply calculated additively according to mole or mass fractions:

$$\tilde{c}_{pG} = \tilde{y}_1 \tilde{c}_{pG1} + \tilde{y}_2 \tilde{c}_{pG2} \tag{37a}$$

or

$$c_{pG} = y_1 c_{pG1} + y_2 c_{pG2}. \tag{37b}$$

For the calculation of the thermal conductivity λ_G and the viscosity η_G of the mixture, a simple addition of the values of the pure substances can lead to major errors. Special theorems are therefore necessary in these cases (Chap. D1). For the calculation of the mass transfer coefficient β_G or the Le number, the diffusion coefficient δ_G can be determined as described in Sect. 10.1 from Chap. D1.

3.2.5 Heat and Mass Transfer Coefficients

Reference is made to the equations for calculation of the transport coefficients α_K, α_F, α_G, and β_G in Sect. 2.3.

In many cases, as the controlling resistances are generally in the gas phase or in the coolant, a heat transfer coefficient of the condensate film α_F averaged over the condensation line and a constant heat transfer coefficient k' between condensate film and coolant may be assumed. For an estimate of α_F, in order to simplify the calculation, the influence of the vapor shear stress ($\tau^*_{DK} = 0$ in Chap. J1) can often be ignored.

Because of the decrease in the temperature and in the mass flow of the gas–vapor mixture along the condensation line, the heat and the mass transfer coefficient in the gas phase α_G and β_G must be calculated with the local fluid property values and the local Re numbers. It should be noted that a change in the cross-sectional area (e.g., as a result of pipe division in a pipe bundle system) also influences the gas velocity and thus the heat and mass transfer coefficients.

3.3 Distribution of Resistances Among the Gas Phase, the Condensate Film, and the Coolant

The individual resistances which are controlling the condensation are shown in Fig. 5. The heat transport here is from the inside (vapor space) outwards, i.e., from right to left (Fig. 1). The parallel heat and mass transfer resistances $1/\alpha_G$ and $1/\beta_G$ in the gas phase and the heat transfer resistances in the film $1/\alpha_F$, in the pipe wall s/λ_R and in the coolant $1/\alpha_K$ are arranged in series.

A simplified circuit diagram is obtained by introducing the heat transfer coefficients k and k' and the hypothetical heat transfer coefficients for the gas–vapor mixture α_{GD} (see Fig. 5). After calculation of the condensate film temperature T_F (Eq. (31)), using

$$\dot{q} = k(T_T - T_K) = k'(T_F - T_K) = \alpha_{GD}(T_T - \tilde{y}_{1B} - T_F) \tag{38}$$

the ratios of the resistances can be determined. The condensate film temperature must be above the coolant and below the dewpoint temperature ($T_K < T_F < T_T$). The resistance in the gas phase is controlling, if the relationship

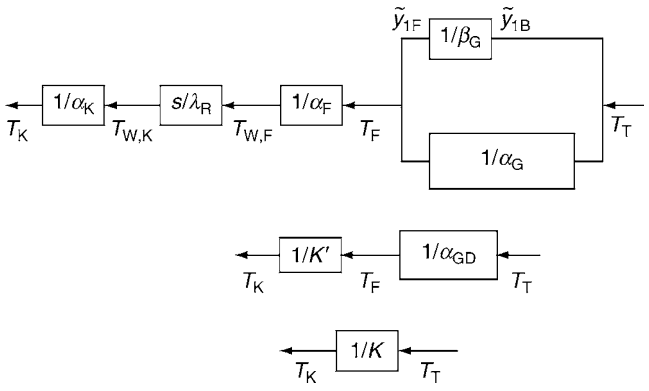
$$\frac{k'}{\alpha_{GD}} = \frac{T_T - \tilde{y}_{1B} - T_F}{T_F - T_K} \tag{38a}$$

is large ($k' >> \alpha_{GD}$, $k \approx \alpha_{GD}$, $T_F \approx T_K$).

Correspondingly, the total resistance $1/k$ is on the coolant-side ($k \approx k'$), if the relationship k'/α_{GD} is small ($k' << \alpha_{GD}$, $T_F \approx T_T$).

3.3.1 Estimation of the Individual Resistances

If there is no excessive superheating of the gas–vapor mixture, the heat flow $\dot{q}_G$ can generally be ignored in the comparison with



J2. Fig. 5. Heat and mass transfer resistances in the gas phase, in the condensate film and in the coolant. The second line summarizes the first line; the third row summarizes the second.

the enthalpy flow $\dot{n}_1 \Delta\tilde{h}_{v1}$ (Example 1, Part B). The calculation of the condensate film temperature can then be simplified to

$$T_F - T_K = C_T \ln\left(\frac{\tilde{y}_{2F}(T_F)}{\tilde{y}_{2B}}\right), \tag{39}$$

with

$$C_T = \frac{n_G \beta_G \Delta\tilde{h}_{v1}}{k'} \cong \frac{\alpha_G \Delta\tilde{h}_{v1}}{k' \tilde{c}_{pG} Le^{0.6}}. \tag{39a}$$

At high values of C_T and low inert gas contents $\tilde{y}_{2B}$, the condensation is heat transfer controlled.

At low values of C_T and high inert gas content, the resistance on the gas side is controlling; the condensation is mass transfer controlled. As the temperature difference $T_T - T_K$ increases, the resistance on the gas side increases in comparison with the resistance on the coolant side (Example 1, Part B).

The influence of the coolant temperature T_K and thus the condensate film temperature T_F on the locally condensing mass flow $\dot{n}_1$ is small in this case, as the driving concentration gradient is hardly changed. For the vapor pressure $p_1^* = 0$, the driving concentration gradient and the locally condensing mass flow is at its maximum (Example 1, Part B). The condenser performance is therefore primarily determined by the inert gas content. So, a marked increase in the condenser performance with high inert gas content cannot be achieved by a decrease in the coolant temperature T_K, but only by an improvement of mass transfer, i.e., in general, by an increase in the flow velocity of the gas–vapor mixture.

3.4 Simplified Methods for Determination of the Transfer Area

The level of the condensate film temperature T_F between the gas temperature T_G and the coolant temperature T_K depends on the distribution of the heat and mass transfer resistances among the gas phase, the condensate film, and the coolant. The distribution of these resistances changes in the course of the condensation, as the inert gas in the gas–vapor mixture is enriched. In many cases, by calculation of the condensate film temperature at the inlet T_{FE} and at the outlet T_{FA} of the condenser, it is possible to state whether the whole condensation process is controlled by heat or mass transfer. In these cases, simplified methods can be derived for determination of the transfer area [6].

3.4.1 Heat Transfer Controlled Condensation

As the smallest fraction of residual vapor, or the largest fraction of inert gas, is present at the gas outlet of the condenser, it must be determined whether the heat transfer resistance at the outlet is dominant. As a rule of thumb, it can be said that the whole condensation process is heat transfer controlled if the relationship

$$\left(\frac{k'}{\alpha_{GD}}\right)_A < 0.5$$

is true at the outlet. This condition is fulfilled in the case of low inert gas contents and high C_T values, i.e., at high α_G and β_G values or high gas velocities. The transfer area A of the condenser can then be determined according to the equation

$$A = \frac{\dot{Q}}{k' \Delta T_m}. \tag{40}$$

The mean driving temperature difference ΔT_m is calculated, according to the flow arrangement (Chap. C1), from the inlet and outlet temperatures of the condensate film T_{FE} or T_{FA} and the coolant T_{KE} or T_{KA}.

The total heat flow to be removed $\dot{Q}$ is calculated from the integral energy balance according to Eq. (8). If the gas outlet temperature is not known, it may be assumed as a first approximation that it is equal to the dewpoint temperature at the outlet:

$$T_{GA} = T_{TA}(\tilde{y}_{1B,A}).$$

It then follows from Eq. (8)

$$\begin{aligned}\dot{Q} &= \dot{N}_{FA}(\Delta\tilde{h}_{v1}(T_{TA}) + \tilde{c}_{pF}(T_{TA} - T_{FA})) \\ &\quad + \dot{N}_{GE}\tilde{c}_{pG}(T_{GE} - T_{TA}),\end{aligned} \tag{41}$$

with the condensate volume flow

$$\dot{N}_{FA} = \dot{N}_{GE} - \dot{N}_{GA} = \dot{N}_{GE}\left(1 - \frac{\tilde{y}_{2B,E}}{\tilde{y}_{2B,A}}\right). \tag{41a}$$

3.4.2 Mass Transfer Controlled Condensation

As the inert gas is enriched in the course of the condensation, the mass transfer resistance increases. Therefore, it must first be determined whether the mass transfer resistance is already dominant at the inlet of the condenser. With the condensate film temperature T_{FE} at the inlet, the ratio of the resistances $(k'/\alpha_{GD})_E$ can be calculated according to Eq. (38a). For the case

$$\left(\frac{k'}{\alpha_{GD}}\right)_E > 2,$$

the calculation procedure described below can be used. This condition is generally fulfilled at high inert gas contents or low C_T values (Eq. (39a)).

3.4.3 Condensation at Constant Condensate Film Temperature

With a knowledge of the condensate film temperature T_F, the locally condensing mole flux $\dot{n}_1$ and the resulting decrease in the gas volume flow $\dot{N}_G$ can be calculated. It is seen that, with the assumption of constant condensate film temperature T_F and thus constant inert gas content at the film surface $\tilde{y}_{2F}$, the differential mass balance can be obtained by integration. From the differential component balance equations

$$d\dot{N}_G = -\dot{n}_1 \, dA, \tag{13}$$

$$\dot{N}_{G2} = N_G \tilde{y}_{2B} \tag{34}$$

and the theorem for the mass transfer

$$\dot{n}_1 = n_G \beta_G \ln\frac{\tilde{y}_{2F}}{\tilde{y}_{2B}}, \tag{28}$$

it follows for the nondimensional transfer area, assuming constant gas density and constant mass transfer coefficient for simplification, that

$$\frac{n_G \beta_G A}{\dot{N}_{G2}} = -\frac{1}{\tilde{y}_{2F}} \int_{x_E}^{x_A} \frac{dx}{\ln x}, \tag{42}$$

with

$$x = \frac{\tilde{y}_{2F}}{\tilde{y}_{2B}}. \tag{42a}$$

With the parameter giving the number of transfer units

$$NTU_{G2} \equiv \frac{n_G \beta_G A}{\dot{N}_{G2}} \tag{42b}$$

and the integral logarithm

$$Li(x) = \int \frac{dx}{\ln x} = \ln(\ln x) + \ln x + \frac{(\ln x)^2}{2 \cdot 2!} + \frac{(\ln x)^3}{3 \cdot 3!} + \cdots \tag{42c}$$

this then gives

$$NTU_{G2} = \frac{1}{\tilde{y}_{2F}} [Li(x_E) - Li(x_A)]. \tag{43}$$

The series already converges, in the region of interest here ($x < 5$), after four or five series elements.

3.4.4 The Minimum Required Transfer Area

From Eq. (43), with the given gas contents at inlet and outlet, the minimum required transfer area can be calculated. As the temperature of the coolant medium falls, the vapor pressure $p_1^*(T_F)$ and thus the vapor content $\tilde{y}_{1F}$ at the condensate surface also falls. In the limit case, we have $\tilde{y}_{1F} = 0$ or $\tilde{y}_{2F} = 1$. The driving concentration gradient and thus the condensing mass flow is then at a maximum. The minimum required transfer area is then given by

$$A_{min} = \frac{\dot{N}_{G2}}{n_G \beta_G} \left[Li\left(\frac{1}{\tilde{y}_{2B,E}}\right) - Li\left(\frac{1}{\tilde{y}_{2B,A}}\right) \right], \tag{44}$$

with $\tilde{y}_{2B,E}$ and $\tilde{y}_{2B,A}$ as the inert gas contents of the gas–vapor mixture at the inlet and the outlet of the condenser.

3.4.5 Determination of the Transfer Area When the Film Temperature is not Constant

A more accurate value for the transfer area is obtained with the expedient selection of a suitable mean value for the inert gas content at the condensate surface $\bar{\tilde{y}}_{2F}$. An average value $\bar{\tilde{y}}_{2F}$ obtained from the inlet and outlet concentrations can lead to negative concentration gradients $\bar{\tilde{y}} - \bar{\tilde{y}}_{2B,A}$. It is therefore recommended to calculate an integral logarithm, to apply the inert gas content $\tilde{y}_{2F,A}$ at the outlet and the arithmetical mean of inlet and outlet concentrations in the prefactor. The transfer area is then given by

$$A = \frac{\dot{N}_{G2}}{n_G \beta_G} \frac{1}{\bar{\tilde{y}}_{2F}} \left[Li\left(\frac{\tilde{y}_{2F,A}}{\tilde{y}_{2B,E}}\right) - Li\left(\frac{\tilde{y}_{2F,A}}{\tilde{y}_{2B,A}}\right) \right], \tag{45}$$

with

$$\bar{\tilde{y}}_{2F} = \frac{1}{2}(\tilde{y}_{2F,E} + \tilde{y}_{2F,A}). \tag{45a}$$

By the use of $\tilde{y}_{2F,A}$, a locally greater driving gradient than that actually present is assumed and, therefore, the transfer area calculated is too small.

In the case of mass transfer controlled condensation, however, the influence on the condensing mass flow and the transfer area is small (Example 1, Part B).

If low residual vapor fractions $\tilde{y}_{1B,A}$ are required, the driving concentration gradient at the outlet becomes very small, so the transfer area becomes very large. In this case, it makes little difference whether the condensation at the inlet is already mass transfer controlled or even heat transfer controlled, as the transfer area is then determined by the low mass flows at low concentration gradients (Li (1,1) = −2.25; Li (1.01) = −4.60).

By linearization of the theorem for the mass transfer

$$\dot{n} = n_G \beta_G \frac{\tilde{y}_{1B} - \tilde{y}_{1F}}{1 - \tilde{y}_{1F}} \tag{46}$$

we obtain a simpler equation for calculation of the transfer area:

$$A = \frac{\dot{N}_{G2}}{n_G \beta_G \bar{\tilde{y}}_{2F}} \left[\frac{\tilde{y}_{2F,A}}{\tilde{y}_{2B,E}} - \frac{\tilde{y}_{2F,A}}{\tilde{y}_{2B,A}} + \ln \frac{\frac{\tilde{y}_{2F,A}}{\tilde{y}_{2B,E}} - 1}{\frac{\tilde{y}_{2F,A}}{\tilde{y}_{2B,A}} - 1} \right]. \tag{47}$$

As the linearized theorem gives lower mass flows, Eq. (47) results in larger transfer areas than Eq. (45). In many cases, this even cancels out the approximation error of Eq. (45) and leads to better results.

For determination of the transfer area, the mass transfer coefficient β_G can be expressed with the help of the Lewis relationship (Eq. (24)) by the heat transfer coefficient α_G:

$$A = \frac{\dot{N}_{GE} \tilde{c}_{pG} Le^{0.6}}{\alpha_G} \tilde{y}_{2B,E} NTU_{G2}. \tag{48}$$

For the transport coefficients α_G, β_G and the mass values, values averaged over the transfer area should be used.

3.4.6 Determination of the Transfer Area

In the first step, an assessment is made of whether the whole condensation process is heat or mass transfer controlled, by calculation of the condensate film temperatures at the inlet T_{FE} and at the outlet T_{FA} of the condenser according to Eq. (31). For this purpose, knowledge of the coolant and gas temperatures at the inlet and the outlet is required. The gas outlet temperature can in most cases be set equal to the dew-point temperature: $T_{GA} = T_{TA}(\tilde{y}_{1B,A})$. When coolant water is used, its heating-up is determined with the help of the integral energy balance (Eqs. (9) and (41)). Then, using Eq. (38), the ratio of the resistances at the inlet $(k'/\alpha_{GD})_E$ and at the outlet $(k'/\alpha_{GD})_A$ is determined. As the inert gas is enriched in the course of the condensation, the mass transfer resistance increases: $(k'/\alpha_{GD})_E < (k'/\alpha_{GD})_A$. Therefore, the condensation process for $(k'/\alpha_{GD})_A < 0.5$ may be regarded as heat transfer controlled and the transfer area calculated according to Eq. (40).

For $(k'/\alpha_{GD})_E > 2$, the whole process is mass transfer controlled, and the transfer area is given by Eq. (45) or (47).

Example 2 illustrates the procedure for the calculation of the transfer area in the case of heat transfer controlled (Part A) and mass transfer controlled condensation (Part B).

In some cases, the condensation at the inlet of the condenser is heat transfer controlled and, at the outlet, mass transfer controlled. As the calculation according to Eq. (40) generally leads to too high values and the calculation according to Eq. (45) (or Eq. (47)) to too low values for the transfer area, the transfer area can often be determined very satisfactorily by the application of both methods and averaging the results. The step-by-step calculation method naturally gives more reliable values, but it is also considerably more complicated.

3.4.7 Superheating of the Gas–Vapor Mixture

In a comparison of the condensation of a saturated gas–vapor mixture, more heat has to be removed in the case of superheating of the mixture. The condensate film temperature T_F is higher and the condensing mass flow is smaller (Example 1, Part B). Therefore, a larger transfer area is required.

It is frequently suggested that the transfer area is to be calculated in two steps in the case of condensation of a superheated mixture: In the first step, a fraction of the area is determined for cooling down to the dewpoint temperature and, in the second step, a further fraction of the area for the condensation of the saturated mixture. One part of the condenser is thus regarded as a simple gas cooler and designed accordingly. As the heat transfer coefficient α_G of a gas flow is generally very small, the area calculated for gas cooling may greatly exceed that required for condensation.

It is therefore advisable to check whether the condenser is actually working as a gas cooler or whether condensation is already taking place at the entry of the gas–vapor mixture. The condition for this is that the temperature of the cooling area (e.g., of the pipe wall) at the inlet of the condenser is below the dewpoint temperature:

$$T_{WE} < T_{TE}(y_{1B,A}). \tag{49}$$

The temperature is calculated from the energy balance equation

$$k''(T_{WE} - T_{KE}) = \alpha_G(T_{GE} - T_{WE}), \tag{50}$$

with

$$\frac{1}{k''} = \frac{s}{\lambda_R} + \frac{1}{\alpha_K} \tag{50a}$$

for flat walls or thin-walled pipes.

This results in the condition

$$\frac{T_{KE} + \frac{\alpha_G}{k''} T_{GE}}{1 + \frac{\alpha_G}{k''}} < T_{TE}(y_{1B,E}). \tag{51}$$

In practice, as the heat transfer in the gas is significantly poorer than the heat transfer to the coolant ($\alpha_G \ll k''$), condensation already occurs at the inlet. If not, the coolant temperature T_K and/or the heat transfer coefficient k'' should be adjusted accordingly.

As the heat to be dissipated from the superheating is generally much smaller than the condensation heat, superheating of the gas has little effect on condenser performance. The influence of the superheating of the gas is taken into account in the calculation of the condensate film temperature T_F and the total heat flow to be dissipated $\dot{Q}$. The simplified method for the determination of the transfer area according to Eq. (40) or (45) can therefore also be used for superheated gas–vapor mixtures. It is therefore clearly inadvisable to design a part of the condenser as a gas cooler. This can lead, in many cases, to the calculation of much too large transfer areas.

Example 2

The transfer area for the condensation of water vapor from a water vapor–air mixture in a condenser tube ($d = 0.03$ m) is to be determined. The coolant temperature is constant at $T_K = 20°C$; the overall heat transfer coefficient of coolant and pipe wall is $k'' = 1{,}000$ W/m^2 K.

Part A

From a gas–vapor flow of $M_{GE} = 10^{-2}$ kg/s with an entry temperature of $T_{GE} = 100°C$, an inert gas content on entry $y_{2B,E} = 0.152$ and at pressure $p = 1$ bar, 75% of the water vapor is to be condensed.

The conversion to molar values gives $\dot{N}_{GE} = 0.524$ mol/s, $\tilde{y}_{2B,E} = 0.10$, and $\dot{N}_{G2} = 0.0524$ mol/s; in addition, $T_{TE} = 96.7°C$.

The mass flow at the outlet is calculated from

$$\tilde{y}_{2B,A} = \frac{\dot{N}_{G2}}{\dot{N}_{G2} + 0.25\dot{N}_{G1,E}} = 0.308,$$

$\dot{N}_{GA} = 0.170$ mol/s.

Temperature T_{TA} is 90°C.

Calculation of the heat transfer coefficient gives

$$\mathrm{Re}_G = \frac{4\dot{M}_G}{\pi d\,\eta_G}, \quad \mathrm{Re}_{GE} = 3.2 \cdot 10^4, \quad \mathrm{Re}_{GA} = 1.0 \cdot 10^4.$$

Sect. 4 from Chap. G1 gives the pressure loss coefficient ξ, with Pr = 1, the Nu number and the heat transfer coefficient α_G:

$$\xi_E = 0.0232, \quad \mathrm{Nu}_E = 90, \quad \alpha_{GE} = 78.5\,\mathrm{W/m^2K};$$
$$\xi_A = 0.0315, \quad \mathrm{Nu}_A = 35, \quad \alpha_{GA} = 32.5\,\mathrm{W/m^2K};$$

$k'_E = k'' = 1{,}000$ W/m^2 K. It follows from Chap. J1, ignoring the vapor shear stress, $\alpha_{FA} = 4{,}000$ W/m^2 K and thus $k'_A = 800$ W/m^2 K.

Determination of the resistance distribution at inlet and outlet: With the help of Eq. (31), the values for the condensate film temperature can be calculated iteratively: $T_{FE} = 94.2°C$, $T_{FA} = 72.0°C$.

It follows from Eq. (38) that $(k'/\alpha_{GD})_E = 0.03$ and $(k'/\alpha_{GD})_A = 0.34$. The condensation process is thus heat transfer controlled.

Determination of the transfer area: Eq. (8) and/or Eq. (14) gives the total heat flow to be removed $\dot{Q} = 15.8$ kW.

The mean driving temperature difference in the case of parallel flow is

$$\Delta T_m = \frac{T_{FE} - T_{FA}}{\ln\left(\frac{T_{FE} - T_K}{T_{FA} - T_K}\right)} = 62.44\,\mathrm{K}.$$

With $\bar{k}' = 900\ \mathrm{W/m^2\,K}$, it follows from Eq. (40) that

$$L = \frac{Q}{\bar{k}'\Delta T_m \pi d} = 3.0\ \mathrm{m}.$$

The calculation of the tube length required according to Eq. (45) (mass transfer controlled) gives $L = 2.2$ m and, by the step-by-step calculation method, $L = 2.8$ m.

Part B

From a gas–vapor flow of $\dot{M}_{GE} = 2 \cdot 10^{-3}$ kg/s at an inlet temperature of $T_{GE} = 100°C$ and an inert gas content at the inlet of $y_{2B,E} = 0.617$, at pressure $p = 1$ bar, 75% of the water vapor is to be condensed.

Calculations corresponding to Part A

$$\dot{N}_{GE} = 0.085\ \mathrm{mol/s}, \quad \tilde{y}_{2B,E} = 0.5, \quad \dot{N}_{G2} = 0.0425\ \mathrm{mol/s},$$
$$T_{TE} = 81.4°C,$$
$$\dot{N}_{GA} = 0.053\ \mathrm{mol/s}, \quad \tilde{y}_{2B,A} = 0.8, \quad T_{TA} = 60.1°C,$$
$$\alpha_{GE} = 17\ \mathrm{W/m^2\,K}, \quad \alpha_{GA} = 10.5\ \mathrm{W/m^2\,K},$$
$$k'_E = 1,000\ \mathrm{W/m^2K}, \quad k'_A = 800\ \mathrm{W/m^2\,K},$$
$$T_{FE} = 38.6°C, \quad (k'/\alpha_{GD})_E = 2.3,$$
$$T_{FE} = 25.4°C, \quad (k'/\alpha_{GD})_A = 6.4.$$

The condensation process is thus mass transfer controlled.

Determination of the transfer area: With $\tilde{y}_{2F,A} = 0.968$ and $\bar{\tilde{y}}_{2F} = 0.95$, it follows according to Eq. (45) that

$$\mathrm{Li}(\tilde{y}_{2F,A}/\tilde{y}_{2B,E}) = 0.37,$$
$$\mathrm{Li}(\tilde{y}_{2F,A}/\tilde{y}_{2B,E}) = -1.46, \quad \mathrm{NTU}_{G2} = 1.93.$$

with $\bar{\alpha}_G = 14\ \mathrm{W/m^2K}$, $\bar{\tilde{c}}_{pG} = 32\ \mathrm{J/mol\,K}$ and $\mathrm{Le}^{0.6} = 0.84$

which gives the required tube length as

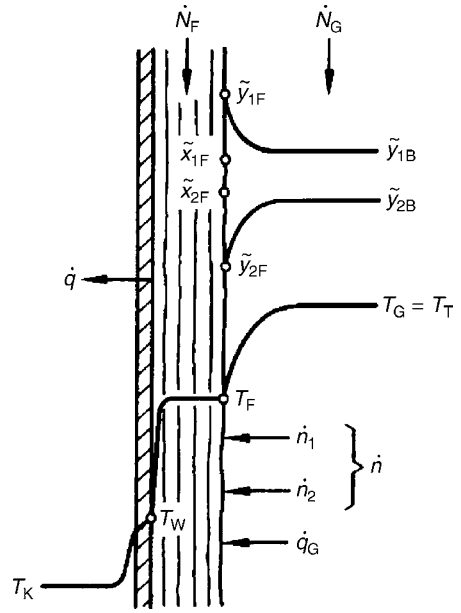
$$L = \frac{\dot{N}_{G2}\bar{\tilde{c}}_{pG}\mathrm{Le}^{0.6}}{\bar{\alpha}_G \pi d}\mathrm{NTU}_{G2} = 1.67\ \mathrm{m}.$$

According to Eq. (47), $\mathrm{NTU}_{G2} = 2.22$ or $L = 2.03$ m. A calculation of the tube length required with a step-by-step method gives the value $L = 1.85$ m.

4 Condensation of a Binary Vapor Mixture

In the condensation of a binary vapor mixture, the less volatile and therefore preferentially condensing component in the vapor phase is reduced, while the more volatile is enriched. As a result of mass and heat transfer resistances in the vapor phase, the composition of the vapor and the vapor temperature in the core (bulk) of the vapor flow and at the condensate film surface are not equal, as seen in Fig. 6. The mass and heat transfer resistances in the vapor phase, together with the heat transfer resistances in the condensate film and in the coolant, determine the performance of the condenser.

The general procedure for the determination of the transfer area of the condenser is the same as that for the condensation of a pure vapor in the presence of an inert gas. The local condensate film temperature T_F must also be determined iteratively in order to find the local mass flow $\dot{n}$ and the local heat flow $\dot{q}$.



J2. Fig. 6. Concentration and temperature profiles in the condensation film of a binary vapor mixture. 1 – more readily boiling component. 2 – less readily boiling component.

The change in the vapor mass flow $\dot{N}_G$ and the vapor composition $\tilde{y}_{jB}$ and the vapor temperature T_G in the course of the condensation are then calculated by a step-by-step method. A description of the general procedure can therefore be restricted to the differences which occur in the condensation of a binary vapor mixture as opposed to the condensation of pure vapor in the presence of an inert gas.

An examination of the distribution of the resistances in the coolant, in the condensate film, and in the gas phase shows that, at high temperature differences, the condensation is heat transfer controlled. The vapor mixture then condenses almost like pure vapor. In this case, the required transfer area is easy to determine.

If selective condensation, i.e., a separation of the vapor mixture, is desired, small temperature differences and, thus, large transfer areas are necessary. In this case, the calculation of such an area (e.g., that of a dephlegmator) can be carried out by a step-by-step calculation method.

4.1 General Method for Determination of the Transfer Area

If, also in this case, the cooling of the condensate film is at first ignored, it follows according to Eq. (30) that

$$\dot{q} = k'(T_F - T_K) = \dot{n}\Delta\tilde{h}_v(T_F) + \alpha_G E_T(T_G - T_F). \qquad (52)$$

The kinetic theorem for the mass transfer in the gas phase is

$$\dot{n} = \dot{n}_1 + \dot{n}_2 = n_G\beta_G \ln\left(\frac{\dot{r}_1 - \tilde{y}_{1F}}{\dot{r}_1 - \tilde{y}_{1B}}\right). \qquad (23)$$

The mass transfer in the liquid phase can be described as in the gas phase. In general, however, it is assumed for simplicity that

the local composition of the liquid at the condensate surface is determined by the local mass flux [8]:

$$\tilde{x}_{1F} = \dot{r}_1. \tag{53}$$

This hypothesis presupposes a stratified, unmixed condensate film. In the opposite case, i.e., a completely mixed condensate film, the condensate film concentration can be determined from the condensate mass flux:

$$\tilde{x}_{1F} = \frac{\dot{N}_{F1}}{\dot{N}_F}. \tag{54}$$

This limiting case, however, is not usually taken as a basis, as condensate films mostly have a laminar flow and diffusion in the liquid alone does not generally lead to significant mixing.

It is also assumed that the liquid and vapor mixture at the condensate film surface is in thermodynamic equilibrium. Then (Sect. 2.3 from ◉ Subchap. D5.1)

$$\tilde{y}_{1F} = \gamma_1 (\tilde{x}_{1F}) \tilde{x}_{1F} \frac{p_1^*(T_F)}{p} \text{ is true.} \tag{55}$$

The parameters for the calculation of the vapor pressure curves $p_1^*(T_F)$ (Eq. (29)) and the activity coefficients $\gamma_1(\tilde{x}_{1F})$ (◉ Subchap. D5.1) can be found in the literature [3, 4].

4.1.1 Iterative Determination of the Condensate Film Temperature

Equations (23), (52), and (53) are combined to give the equation for the determination of the condensate film temperature T_F:

$$k'(T_F - T_K) = \alpha_G \phi_T \left(\frac{\Delta \tilde{h}_v}{c_{pG}} + \frac{T_G - T_F}{1 - \exp(-\phi_T)} \right), \tag{56}$$

with

$$\phi_T = \frac{\dot{n} \tilde{c}_{pG}}{\alpha_G} = \frac{n_G \beta_G \tilde{c}_{pG}}{\alpha_G} \ln \left(\frac{\tilde{x}_{1F} - \tilde{y}_{1F}}{\tilde{x}_{1F} - \tilde{y}_{1B}} \right). \tag{56a}$$

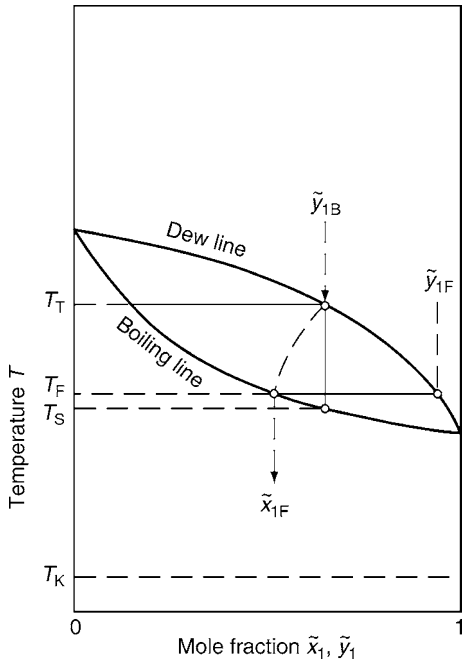
Using the Lewis relationship (Eq. (24)), it follows that

$$\phi_T = \mathrm{Le}^{-0.6} \ln \left(\frac{\tilde{x}_{1F} - \tilde{y}_{1F}}{\tilde{x}_{1F} - \tilde{y}_{1B}} \right). \tag{56b}$$

The iteration in to Eq. (56) is more complicated than that in to Eq. (31), as in this case, a value triplet must be determined for $\tilde{x}_{1F}, \tilde{y}_{1F}$, and T_F, fulfilled by Eq. (56). It is convenient to set the liquid composition $\tilde{x}_{1F}$ and to calculate the associated boiling temperature and vapor composition according to Example 6, ◉ Subchap. D5.1. The equilibrium diagram in Fig. 7 shows such a value triplet.

4.1.2 Determination of the Transfer Area

The determination of the transfer area is carried out according to the calculation scheme (Fig. 4) described in Sect. 3.2. With the help of the condensate film temperature T_F calculated according to Eq. (56), the local mass flow $\dot{n}$ and the local heat flow $\dot{q}$ and thus the decrease in the vapor volume flow (Eq. (32)) and the



J2. Fig. 7. Boiling equilibrium of a binary mixture.

vapor temperature (Eq. (35)) along the condensation line can be calculated. The change in vapor composition between two consecutive sampling points i and $i+1$ follows from the component balance equation for component 1 (Eqs. (13) and (14)):

$$\tilde{y}_{1B,i+1} = \tilde{y}_{1B,i} + (\tilde{y}_{1B,i} - \tilde{x}_{1F,i}) \frac{\dot{n}_i}{\dot{N}_{Gi}} \Delta A. \tag{57}$$

4.2 Limiting Cases in the Condensation of Binary Vapor Mixtures

The level of the condensate film temperature T_F determines the distribution of resistances between the condensate film and the gas phase:

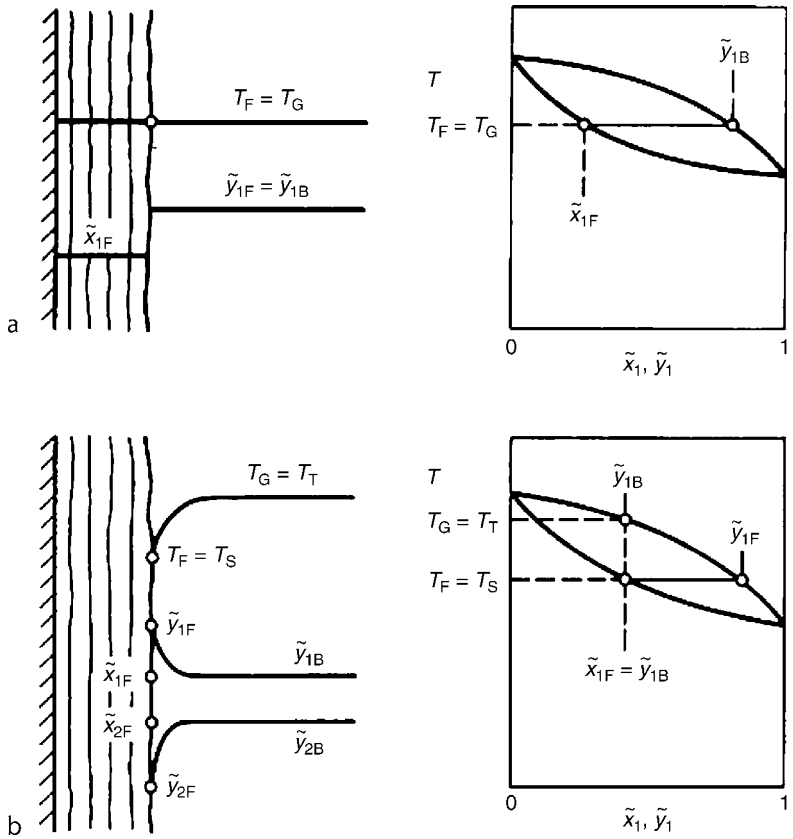
$$\dot{q} = k(T_T - T_K) = k'(T_F - T_K) = \alpha_{GD}(T_T - T_F). \tag{38}$$

It can be seen from the level of the boiling and dew lines in Fig. 7 that the condensate film temperature T_F must be between the dewpoint and boiling point of the mixture at vapor concentration $\tilde{y}_{1B}$:

$$T_S < T_F < T_T.$$

From this fact, two limiting cases for the condensation of binary vapor mixtures can be derived [9].

- Condensation in equilibrium ($T_F = T_T$)
  In the case of vanishingly small mass flows ($\dot{n} \to 0$) and temperature differences ($T_T - T_K \to 0$), the temperature and concentration profile in the gas phase is compensated. Only in this limiting case is it true that the liquid and the vapor compositions in the core are in equilibrium with each other as in Fig. 8. The difference between the liquid and the vapor composition – the selectivity – is then at a maximum.
- Local total condensation ($T_F = T_S$).



J2. Fig. 8. Limiting cases in the condensation of binary vapor mixtures: (a) condensation in equilibrium and (b) total condensation.

For very large mass flows ($\dot{m} \to \infty$) and temperature differences ($T_F - T_K \to \infty$), the vapor composition in the bulk is the same as the liquid composition, as shown in Fig. 8b, i.e.,

$$\tilde{x}_{1F} = \tilde{y}_{1B}, \tag{58}$$

and the condensate film temperature is the same as the associated boiling temperature:

$$T_F = T_S(\tilde{x}_{1F} = \tilde{y}_{1B}). \tag{59}$$

The vapor mixture condenses without a change in composition; a local total condensation takes place. From

$$\frac{k}{k'} = 1 - \frac{T_T - T_S}{T_T - T_K} \tag{60}$$

it follows that, in the limiting case $(T_T - T_K) \to \infty$, the total resistance of the condensation equals the sum of the heat transfer resistances in the condensate film and in the coolant: $k = k'$. The vapor mixture then condenses like pure vapor.

4.3 Simplified Methods for Determination of the Transfer Area

If – for example, in a dephlegmator – selective condensation, i.e., a separation of the vapor mixture, is desired, small temperature differences and thus large transfer areas are required. The limiting case of condensation in equilibrium can then be almost fulfilled. In this case, use of the step-by-step calculation method described in Sects. 3.1 and 4.1 is recommended.

If condensation without separation is required, high temperature differences $T_T - T_K$ are permissible. As the condensate film temperature must be above the boiling temperature of the vapor mixture ($T_F > T_S$), the influence of the mass transfer resistance in the gas phase is limited. If the temperature difference $T_T - T_K$ is significantly greater than the difference between dewpoint and boiling point ($T_T - T_S$), as in Fig. 6, the limiting case of local total condensation exists in practice. The condensation process is then heat transfer controlled ($k' << \alpha_{GD}$), the vapor mixture condenses almost like pure vapor, but not at the dewpoint temperature $T_T(\tilde{y}_{1B})$, but at boiling point $T_S(\tilde{y}_{1F} = \tilde{y}_{1B})$.

As a rough rule of thumb, it can be said that the condensation is heat transfer controlled, if

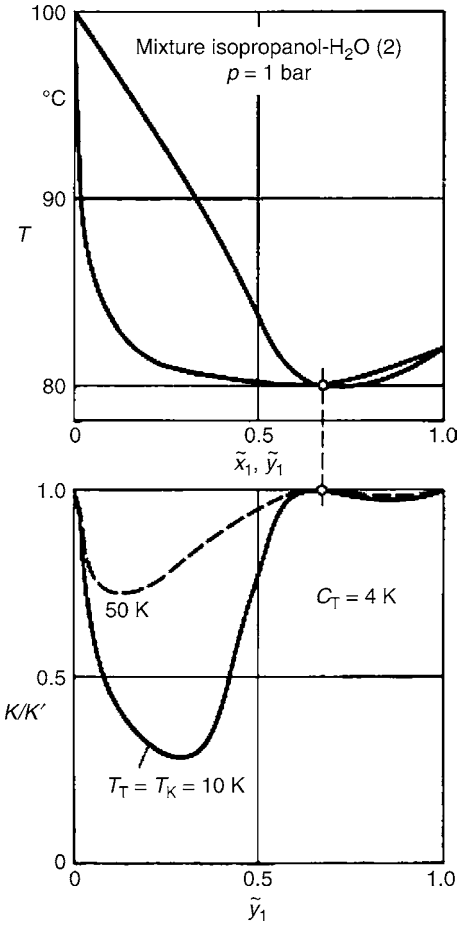
$$(T_T - T_K) > (T_T - T_S). \tag{61}$$

The transfer area is determined in this case as described in Chap. J1.

Presupposing an almost constant or averaged heat transfer coefficient k', the transfer area is given by

$$A = \frac{\dot{Q}}{k' \Delta T_m}. \tag{40}$$

The mean driving temperature difference ΔT_m is calculated according to flow routing (Chap. C1) from the inlet and outlet temperatures of the coolant medium T_{KE} or T_{KA} and the constant boiling temperature of the vapor mixture $T_S(\tilde{x}_{1F} = \tilde{y}_{1B})$. If the temperature of the coolant is constant or its heating is negligible,



J2. Fig. 9. Boiling equilibrium and resistance distribution in the condensation of isopropanol–water vapor mixtures.

$$\Delta T_m = T_S - T_K. \tag{62}$$

The heat flow $\dot{Q}$ is given by the integral energy balance (Eq. (8)).

Taking as an example the condensation of an isopropanol (1)–water vapor(2) mixture, the influences of the phase equilibrium, the mass transfer, and the applied temperature difference $T_T - T_K$ can be illustrated [9]. Figure 9 shows the phase equilibrium of the mixture with the azeotropic point at $\tilde{x}_1 = \tilde{y}_1 = 0.68$ and the ratio of the total resistance to the heat transfer resistance on the coolant side k/k'. For this purpose, the condensate film temperature is calculated according to Eq. (56) and the resistance distribution according to Eq. (38). The parameter C_T (Eq. (39a)) has been set as

$$C_T = \frac{n_G \beta_G \Delta \tilde{h}_v}{k'} = 4 \text{ K}.$$

It can be seen that it is not the absolute temperature difference $T_T - T_K$, but the ratio to the difference between dewpoint and boiling point $T_T - T_S$ (Eq. (60)) which determines the distribution of the resistances.

An azeotropic vapor mixture always condenses like pure vapor ($k = k'$). But close-boiling mixtures, for example, those in the range $0.6 < \tilde{y}_1 < 1$, condense, practically regardless of the applied temperature difference $T_T - T_K$, almost like pure vapor. In the range $\tilde{y}_1 < 0.5$, the influence of the temperature difference on the distribution of resistances is clear. Thus, for example, for $\tilde{y}_1 = 0.2$, the values $k/k' = 0.33$ at $T_T - T_K = 10$ K and $k/k' = 0.75$ at $T_T - T_K = 50$ K; the difference between dewpoint and boiling point temperature at this point is $T_T - T_S = 12.4$ K. The determination of the transfer area according to Eq. (40) thus leads to good results in the case of a small temperature difference of $T_T - T_K = 10$ K in the range $\tilde{y}_1 > 0.5$, but can naturally not be applied, for example, for $\tilde{y} = 0.2 (T_K > T_S)$. Assuming a normal coolant water temperature of approx. 20°C, the applied temperature difference $T_T - T_K$ is greater than 50 K. For the temperature difference $T_T - T_K = 50$ K, Eq. (40) already supplies exact values for the required transfer area, as the ratio of the temperature differences in the whole concentration range

$$\frac{T_S - T_K}{T_F - T_K} > 0.99.$$

The condensate film temperature T_F is thus practically equal to the boiling point T_S ($\tilde{y}_{1F} = \tilde{y}_{1B}$). The limiting case of local total condensation on which Eq. (40) is based is nearly fulfilled.

5 Symbols

A	transfer area (m^2)
A, B, C	constants of the Antoine equation (Eq. (29)) (−)
C_T	constant (Eq. (39a)) (−)
$\tilde{c}_p$	molar heat capacity (J/mol K)
E_T	Ackermann correction (Eq. (22a)) (−)
$\tilde{h}$	molar enthalpy (J/mol)
$\Delta \tilde{h}_v$	molar evaporation enthalpy (J/mol)
k, k', k''	heat transfer coefficients (W/m^2 K)
Le	Lewis number (Eq. (25)) (−)
$\dot{M}$	mass flow (kg/s)
$\dot{m}$	locally condensing mass flow (kg/m^2 s)
$\dot{N}$	molar flow (mol/s)
$\dot{n}$	locally condensing molar flow (mol/m^2 s)
n	molar density (mol/m^3)
NTU	nondimensional transfer area (Eq. (42b)) (−)

J3 Dropwise Condensation

Alfred Leipertz
Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany

1 Introduction

Pure vapor condenses when it contacts a solid surface whose temperature is below the saturation temperature of the vapor T_s. Dropwise, filmwise and mixed forms of condensation with distinctly differing heat transfer performances can be observed, for example, the heat transfer coefficients for ideal dropwise condensation can be up to one order of magnitude that is larger than those for the filmwise mode. In this contribution, dropwise condensation is analyzed from a phenomenological point of view, and concerns heat transfer characteristics important for apparatus design.

2 Prerequisites and Appearance

The condensation form that appears mainly depends on the wettability of the surface which results from the free surface energy of the wall material and the surface tension of the condensing fluid. The wettability can be expressed in terms of the equilibrium contact angle γ_{eq} which is formed between a surface and a droplet lying on it. For ideal surfaces, a balance of the interfacial tensions σ between solid (S), liquid (L), and vapor (V) at the three phase contact line yields Young's Law [1]

$$\cos\gamma_{eq} = \frac{\sigma_{SV} - \sigma_{SL}}{\sigma_{LV}}. \quad (1)$$

Incomplete wettability, which mostly results in dropwise condensation, is given for contact angles of more than 90° [2]. However, contact angles of 60° and larger can also lead to dropwise condensation phenomena, which tend to pass into mixed condensation forms with increasing surface subcooling [3].

With decreasing surface tension σ_{LV} of the condensing fluid, the contact angles also become smaller. In comparison with other fluids of technical interest like organics (<50 mN·m^{-1}) or refrigerants (<10 mN·m^{-1}), water has a large surface tension of about 60 mN·m^{-1} at 100°C. Thus, the largest contact angles and the strongest tendency to dropwise condensation can be expected in steam systems.

On wall materials with good wettability, e.g., pure metallic surfaces with σ_{SG} values of 0.5 up to 5 N·m^{-1}, dropwise condensation can still be achieved by

(a) Adding to the vapor a non-wetting substance which is adsorbed on the condenser surface
(b) Applying hydrophobic materials like fatty acids or waxes to the surface
(c) Coating the surface with materials possessing low free surface energy, e.g., polymers or amorphous layers of hydrogenated carbon
(d) Direct modification of the metal surface in order to reduce its surface energy, e.g., by ion irradiation

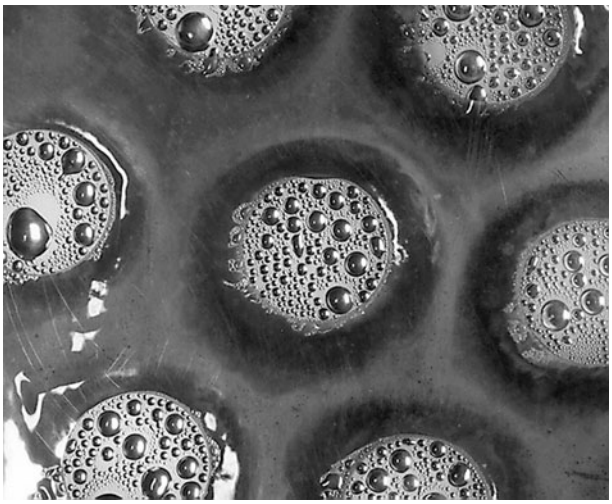
The methods (a) and (b) can only be used for short-term applications. Both of the other methods have the potential for realization in industrial scales in case the coating according to method (c) satisfies a broad requirement profile [3] and the ion irradiation process mentioned in method (d) is adequately applied. Intensive research concerning heat transfer characteristics and long-term stability of these types of surface modification is done at present. Since the year 1989, a power plant condenser consisting of ion irradiated brass tubes is applied in China, achieving mean heat transfer coefficients of more than 6,000 W·m^{-2}·K^{-1} [4].

Figure 1 exemplarily shows a partially coated copper disk, on which dropwise condensation is induced by a promoter with a contact angle of 90° and pure filmwise condensation takes place on the untreated metal surface [5].

Mixed condensation can be observed when the wettability is not sufficiently reduced by the promoter, see, e.g., Fig. 2, with a contact angle of 74° and a surface subcooling of about 15 K [3]. When coatings are used to promote dropwise condensation, their additional heat transfer resistance has to be taken into account. For the hard coating used on the sample shown in Fig. 1, a thermal conductivity of 0.2 W·m^{-1}·K^{-1} was measured [5].

Although gold and silver with large free surface energies inhering good wettability are expected to show filmwise condensation, Westwater and coworkers [6, 7] observed dropwise condensation on these noble metals. This phenomenon was explained by the adsorption of organic substances with

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_38,



J3. Fig. 1. Dropwise and filmwise condensation on a partially coated copper disk; dropwise condensation only on the hard coated surface, filmwise condensation on the uncoated parts (diameter of the coated areas: 10 mm, layer thickness: 1.1 μm).

hydrophobic characteristics on the surface, promoting dropwise condensation. In experiments under high cleanliness conditions, the expected good wettability and filmwise condensation were verified [8].

3 Dropwise Condensation Process and Models

In spite of the large number of studies on dropwise condensation carried out in the past decades, differing models are still discussed, partially associated with different dependencies in experimentally and theoretically acquired results, e.g., for the dependency of the heat transfer coefficient from the wall subcooling. During the last years, several review articles concerning dropwise condensation have been published [4, 9–11].

The transient process of droplet formation, growth, and drainage on the whole surface is a characteristic of the

J3. Fig. 3. Transient process of dropwise condensation on a hard coated copper disk showing a contact angle of 90° [3].

appearance of dropwise condensation, see Fig. 3. At first, small droplets are formed on locations with local minima of free surface energy. Due to condensation, these droplets grow and coalesce with neighboring droplets. When a certain size is reached, the gravitational force of the droplet and/or shear forces exerted by the vapor flow exceed the adhesive force between the droplet and the condensation surface. Thus, the droplet begins to roll along the surface and wipes other droplets off, which results in new "clean" surface areas, where smaller droplets can be formed again. This process of wiping and formation of new small droplets exhibiting low heat transfer resistance is considered to be the reason for the large heat transfer coefficients observed for dropwise condensation.

Concerning the mechanism of dropwise condensation, three different models are discussed:

(a) The vapor condenses between the droplets in almost droplet-free areas. The condensate is transported to the droplets by surface diffusion within an adsorbed film. Here, the boundary layer's thickness associated with heat conduction resistances can be neglected, which is the reason for the very large heat transfer coefficients [12]. According to this model, heat transfer takes place both at an extremely thin liquid film and at the droplets. Optical dynamic measurements of the film thickness [13] confirm this model with respect to the existence of a thin film between the droplets, but also model (b) is corroborated.

(b) According to this model, the vapor condenses as a thin film between the droplets as well, which can be regarded as filmwise condensation at first. When the film reaches a critical thickness, it breaks up and small droplets are formed. The major part of the heat transfer takes place at the very thin condensate film, while the droplets mainly act as liquid collectors [14, 15]. The models (a) and (b) are often combined to one model due to their strong similarities.

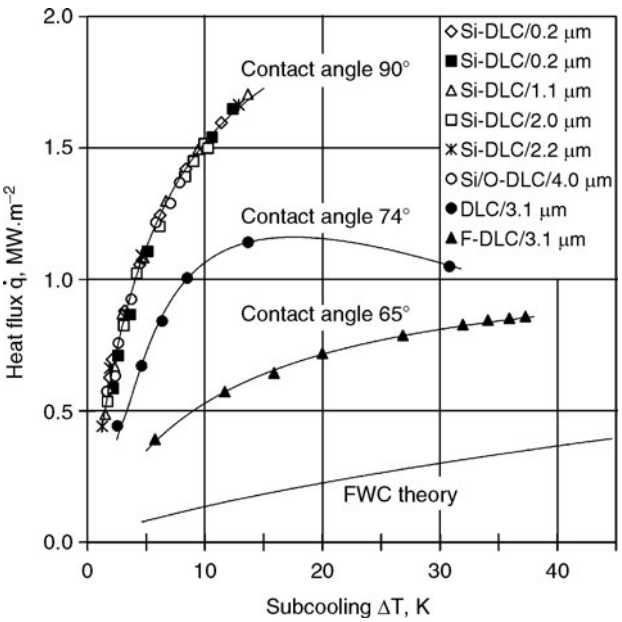
(c) The droplets are formed at individual nucleation sites, while the area between the droplets is regarded to be inactive with respect to condensation. The heat transfer occurs only through the droplets and is limited by their heat conduction resistance [16, 17]. In contrast to the works of Song et al. [13], optical investigations by Umur and Griffith [18] as well as studies on magnesium surfaces by Liu et al. [19] show that the area between the droplets is dry.

4 Heat Transfer Measurement and Calculation

The heat transfer measurement as a function of the wall subcooling $T_s - T_w$ is difficult due to temporally and locally fluctuating surface temperature of the condenser wall. In practice, only a mean surface temperature can be gained by extrapolation of the temperature profile inside the wall as far as one-dimensional thermal conduction can be proved by conformance of several heat balances [12, 20]. When additional promoter layers are present on the condenser surface, this procedure becomes more complex.

In addition, the influence of inert gases in the vapor is distinctly stronger for dropwise than for filmwise condensation. Beside problems with the stability of applied promoters, this phenomenon may be one of the main reasons for the wide variety of research results published. Especially concerning the dependence of the heat transfer coefficient on the wall subcooling, the diversity of statements is astonishing. Tanner et al. [21] and Rose and coworkers [20, 22, 23] found an increase in the heat transfer coefficient with increasing subcooling, and confirmed their theoretical predictions [4, 24]. In contrast, Shea and Krase [25], Welch and Westwater [15], Takeyama and Shimizu [26] as well as Koch et al. [3] and Rausch et al. [27] in later works showed a decreasing course similar to filmwise condensation. These results correspond to a Nu-correlation for a defined condensation system set up by Peterson and Westwater [28].

The diagram in Fig. 4 exemplarily compares heat transfer coefficients for filmwise condensation with measurement data acquired during dropwise condensation of steam at atmospheric pressure on vertically oriented condenser walls. The applied copper samples were coated with diverse hard coatings showing different contact angles [3, 12]. For small subcoolings, the measured heat flux values for dropwise condensation are up to 14 times larger than those for filmwise condensation.



J3. Fig. 4. Measured heat flux as a function of the wall subcooling $\Delta T = T_s - T_w$ for various hard coatings on copper disks showing different contact angles (T_s = 373 K) [3, 12]. Choosing an appropriate coating (Si-DLC, 90°), the additional heat transfer resistance caused by the layer obviously has negligible effects on the achievable heat flux.

The heat transfer calculation depends on the applied model and is governed by the existing heat transfer resistances caused in the single steps of the heat transfer [9], namely phase transition and thermal conduction through the droplet or a film between the droplets. A constriction resistance originating from the heat flow around the thermally inactive surface underneath the big droplets has also to be taken into account. Furthermore, the additional thermal conduction resistance of the promoter layer and the thermal conductivity of the wall material need consideration. In case of a vapor consisting of different components, another resistance associated with the mass transport of the condensing component to the surface occurs. In this contribution, apart from some special remarks, only pure vapor is considered.

Detailed modeling based on droplet formation due to a heterogeneous nucleation process corresponding to model (c) or in a modified form in model (a) to obtain heat transfer equations was done by various research groups. For this, the droplet size distribution must be known, which is not easily available for most of the interesting systems. For pure steam with an empirically acquired droplet size distribution, Rose [4, 29] obtained results for the heat flux and the heat transfer coefficient using quite complicated calculation methods. One example is shown in Fig. 5, where the heat flux is given in dependence on the subcooling for several saturation temperatures on a vertical copper wall. Compared with the experimentally obtained values for fully developed dropwise condensation at a contact angle of 90° given in Fig. 4, it can be seen that the calculated values correspond very well in spite of the mentioned measuring problems and the assumptions made for the calculations.

In contrast, the values for the heat transfer coefficient do not correspond. While for the measurements [3, 12] in Fig. 4 for fully developed dropwise condensation (90°)

$$\alpha = \frac{\dot{q}}{T_s - T_w} \tag{2}$$

yields a decreasing heat transfer coefficient with increasing subcooling corresponding to

$$\alpha = -98.7 \ln(T_s - T_w) + 381 \text{ in } \mathrm{kW \cdot m^{-2} \cdot K^{-1}}, \tag{3}$$

the results in Fig. 5 show an inverse tendency represented by

$$\alpha = \vartheta^{0,8}[5 + 0.5(T_s - T_w)] \text{ in } \mathrm{kW \cdot m^{-2} \cdot K^{-1}}, \tag{4}$$

in a form which is dimensionless for the temperatures given by Rose [10]. For steam in the range of ϑ = 40...100°C for the actual fluid core temperature and for $\Delta T = T_s - T_w$ up to 8 K, a modified form with the factor 0.3 (instead of 0.5) in the brackets was introduced [4].

Several correlations for the heat transfer coefficient were suggested [14, 28], e.g., for steam and ethylene glycol on a hydrophobic coating in the form [28]

$$\mathrm{Nu} = 1.46 \cdot 10^{-6} \mathrm{Re}^{*-1.63} \pi_k^{1.16} \mathrm{Pr}_L^{0.5} \tag{5}$$

with

$$\mathrm{Nu} = \frac{2\alpha\sigma_{LV}\, T_s}{\rho_L \Delta h_v \lambda_L (T_s - T_w)}, \tag{6}$$

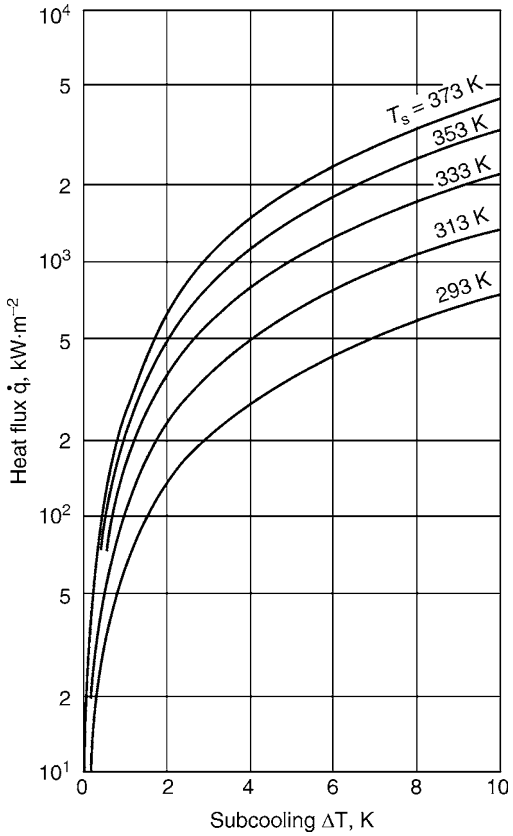
$$\mathrm{Re}^* = \frac{\lambda_L (T_s - T_w)}{\eta_L \Delta h_v}, \tag{7}$$

$$\pi_k = \frac{2\sigma_{LV}\, T_s}{\eta_L^2 \Delta h_v} \left(\frac{d\sigma_{LV}}{dT} \right), \tag{8}$$

and the Prandtl number of the liquid phase (Δh_v is the heat of vaporization in J·kg^{-1}). This correlation is recommended for $1.75 \leq \mathrm{Pr}_L \leq 23.6$; $7.8 \cdot 10^{-4} \leq \pi_k \leq 2.65 \cdot 10^{-2}$, and $2 \cdot 10^{-4} \leq \mathrm{Re}^* \leq 3 \cdot 10^{-2}$ [9] and is approximately valid outside these intervals as well. It must be kept in mind that such correlations were set up for defined condensation systems and their transferability to other systems is doubtable [9]. A discussion of heat transfer correlations for condensation can be found in a review article by Merte [30].

For the dependence of heat transfer coefficients on the subcooling, $\alpha \sim (T_s - T_w)^{-0.63}$ follows from Eq. (5). Corresponding to Eq. (3) and the measurement results in Fig. 4 and in contrast to Eq. (4), it gives a decreasing coefficient with increasing subcooling. As dropwise condensation is still in a testing phase, it is too early to decide which tendency is correct. However, it is recommended to apply Eq. (3), especially for subcoolings larger than 3 K, as Eq. (4) delivers too large and Eq. (5) yields distinctly too small heat transfer coefficients. In a calculation example given in Sect. 6, this is demonstrated in form of the obtained results.

For a technical application and its demands concerning long-term stability, the attainable heat transfer performance after a possible damage of the non-wetted coating is very important. Investigations with partially coated surfaces as given in Fig. 1 showed that for base materials with a large thermal conductivity only 20% of the surface have to be modified in order to obtain integral heat flows which make up about 80% of those for completely coated surfaces [5, 12]. Due to the high heat transfer performance on areas with fully developed dropwise condensation, the inactive part of the surface does not play an important role, even when it makes up more than half of the complete surface area. So damage to the promoter layer obviously has no decisive effect on the attainable heat transfer performance.



J3. Fig. 5. Calculated heat flux in dependence on the subcooling for various vapor saturation temperatures corresponding to [29].

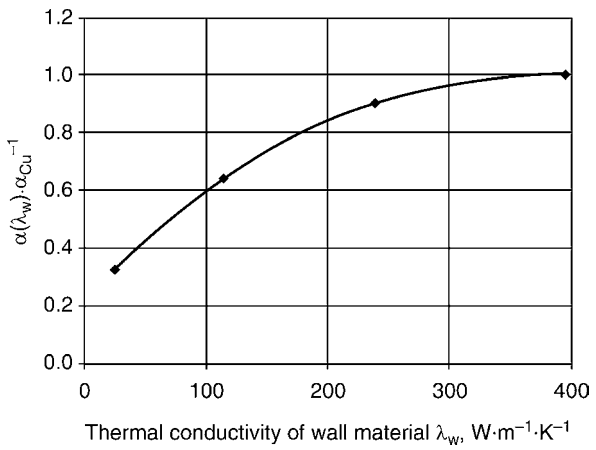
5 Influence of Base Material, Inert Gas Concentration, and Wall Inclination

When instead of copper a different base material with a smaller thermal conductivity λ_w is used as condensation wall, the achievable heat transfer coefficients decrease. In Fig. 6, this dependency on the thermal conductivity of the base material is shown for aluminum, brass, and steel by mean values taken from several published results [31–33]. These mean values can be represented by the empirical equation

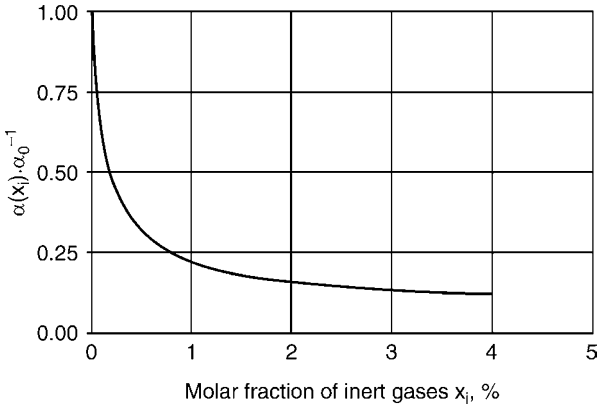
$$\alpha(\lambda_w) = f(\lambda_w) \cdot \alpha_{copper}. \tag{9}$$

In the range of 24 W·m^{-1}·K^{-1} $\leq \lambda_w \leq$ 400 W·m^{-1}·K^{-1}, $f(\lambda_w)$ can be described with

$$f(\lambda_w) = 3.75 \cdot 10^{-9} \lambda_w^3 - 8.11 \cdot 10^{-6} \lambda_w^2 + 4.61 \cdot 10^{-3} \lambda_w + 0.212 \tag{10}$$



J3. Fig. 6. Empirical function of the dependence of the heat transfer coefficient $\alpha(\lambda_w)$ on the thermal conductivity of the condenser wall material λ_w in comparison with the heat transfer coefficient with copper α_{copper}.



J3. Fig. 7. Reduction of the heat transfer coefficient in dependence on the molar fraction of inert gases x_i in % corresponding to [35].

in a good approximation. In a simpler form compared to other published results, this dependence can be expressed by

$$\frac{\alpha(\lambda_w)}{\alpha_{copper}} = \left(\frac{\lambda_w}{\lambda_{copper}}\right)^{0.42} \quad (11)$$

The exponent 0.42 is between previously published values of 0.5 [32, 34] and 0.33 [10].

In the presence of non-condensing gas components, the heat transfer coefficient decreases in dependence on the molar inert gas fraction x_i as shown by the measurements of Abdul-Hadi [35] in Fig. 7.

Maximum heat transfer coefficients are obtained for vertically oriented condenser wall surfaces. When the wall is inclined, the coefficient changes differently for forward (hanging droplets) and backward (lying droplets) inclinations. With the inclination angle β (horizontal surface: 0° for condensation on top and 180° for condensation on the undersurface), an empirical function in the form [5]

$$\frac{\alpha(\beta)}{\alpha(90°)} = (\sin\beta)^n. \quad (12)$$

with n = 0.270 for $0° \le \beta \le 90°$ and n = 0.176 for $90° \le \beta \le 180°$ was found.

The transferability of measured heat transfer coefficients in the case of dropwise condensation outside the horizontal tubes is of great interest for technical applications, e.g., tube bundle heat exchangers. Integration of the measurement results for the wall inclination range from 0° to 90° gives heat transfer coefficients on the horizontal tube of 87.6% compared with the values obtained on vertical walls for equal heat flux densities. For laminar filmwise condensation, the corresponding value is 86.4% [36].

6 Calculation Example

Steam condenses at a pressure of $p = 1.01325$ bar on the outside of a horizontal brass tube with hydrophobic coating. The outside wall temperature is 92°C. At a molar inert gas fraction of 1%, the heat transfer coefficient α is to be determined using the equation by Koch et al. [3].

From Eq. (3) by Koch with the subcooling $\Delta T = 8$ K follows

$$\alpha_{copper} = 175.8\,kW \cdot m^{-2} \cdot K^{-1}.$$

Consideration of the wall material brass with $\lambda_{brass} = 113$ $W \cdot m^{-1} \cdot K^{-1}$ using Eqs. (9) and (10) gives

$$\alpha_{brass} = 111.1\,kW \cdot m^{-2} \cdot K^{-1}.$$

For the influence of the molar inert gas fraction of 1%, Fig. 7 delivers $\alpha_i \cdot \alpha_0^{-1} = 0.225$ and thus

$$\alpha = 24.7\,kW \cdot m^{-2} \cdot K^{-1}.$$

The geometrical conversion from a vertical plain wall to a horizontal tube is taken into account by the factor 0.876 and gives the demanded value

$$\alpha_{tube} = 21.655\,kW \cdot m^{-2} \cdot K^{-1}.$$

Using the calculation equation by Rose, Eq. (4), instead of the equation by Koch,

$$\alpha_{tube} = 44.147\,kW \cdot m^{-2} \cdot K^{-1}.$$

would have been the result. Application of the correlation equation by Peterson and Westwater, Eq. (5), would have delivered a distinctly smaller value of

$$\alpha_{tube} = 2.071\,kW \cdot m^{-2} \cdot K^{-1}.$$

J4 Mixing and Spray Condensation

Ulrich Hochberg
Hochschule Offenburg, University of Applied Sciences, Offenburg, Germany

1 Introduction

Spray condensers are condensers in which the steam to be condensed is immediately brought into contact with the cooling medium [1].

Compared to surface condensers, mixing condensers offer a number of advantages:

- low investment costs,
- large specific heat transfer surface,
- low fouling,
- easy maintenance,
- high operational reliability,
- low cooling water requirement,
- can be designed in materials that are not suitable for surface condensers.

The most important disadvantage of a spray condenser is the fact that the applications are limited because in many cases the contact of the condensate with the cooling medium is not allowed.

Mixing condensers are primarily used [2–9]:

- in connection with steam jet vacuum pumps,
- in demineralization systems,
- in connection with evaporation plants, in particular in the sugar and potash industry,
- in steam jet cooling systems,
- as water heaters,
- to condense the turbine steam in power stations, in connection with dry cooling towers.

When using alternative energy sources (geothermal, ocean thermal energy conversion) the use of mixing condensers is favorable [10, 11], since here only small temperature differences are obtained.

In special cases, it is reasonable to cool the heated mixture of cooling medium and condensate that is discharged from the mixing condenser in a liquid–liquid heat exchanger and to reuse it as cooling medium [12].

In mixing condensers operated in industrial, large-scale applications, the heat transfer resistance in the gaseous phase can normally be neglected when compared to the heat transfer resistance in the liquid phase. To dimension the mixing condensers, it can be restricted to the consideration of the heat transfer in the liquid. The temperature on the phase boundary can be calculated as saturation temperature corresponding to the partial pressure of the condensing liquid.

Gas coolers (quenches) as frequently used in technical applications are not discussed in this chapter. In these gas coolers, mostly a part of the cooling liquid evaporates, and here, the heat transfer resistance in the gaseous phase must not be neglected. The possible simplifications for the calculation of these units essentially differ from possible simplifications for the calculation of mixing condensers [13].

Different mixing condenser designs are described in [14].

For the preliminary calculation of mixing condensers a certain experience is required because there are many influences and condenser constructions; only if there are sufficient measured values for special condenser types, a reliable design will be possible. Therefore, the following equations can only be used for a first assessment.

The energy balance of a mixing condenser will be as follows, if the heat transfer to the environment is neglected:

$$\frac{\mathrm{d}U}{\mathrm{d}t} = (\dot{H}_{\mathrm{l,In}} + \dot{H}_{\mathrm{g,In}}) - (\dot{H}_{\mathrm{l,Out}} + \dot{H}_{\mathrm{g,Out}}). \qquad (1)$$

The following shall apply: $\dot{H}_{\mathrm{l,In}}$ and $\dot{H}_{\mathrm{l,Out}}$ are the enthalpy flows of feed and discharge of cooling medium and $\dot{H}_{\mathrm{g,In}}$ and $\dot{H}_{\mathrm{g,Out}}$ are the enthalpy flow of the feed and discharge of steam and inert gases, respectively.

The enthalpy flow of the discharged steam and gases $\dot{H}_{\mathrm{g,Out}}$ must not be neglected for many mixing condensers, because it is essential to discharge steam and gases from the condenser ("ventilation steam") in order to avoid excessive inert gas concentrations. The mass flow of the gas to be discharged strongly depends on the type of mixing condenser; it can be assessed, for example, according to [2].

The timely change of the internal energy $\mathrm{d}U/\mathrm{d}t$ of the mixing condenser and its contents only has to be taken into consideration for the simulation of transient conditions.

In the stationary case, the following shall apply, neglecting steam superheating and condensate subcooling, and for constant properties of the cooling medium

$$\dot{Q} = \dot{m}_{\mathrm{l}} c_{\mathrm{pl}} (T_{\mathrm{Out}} - T_{\mathrm{In}}) \qquad (2)$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_39,

and for a given condenser pressure for the max. transferable heat flow

$$\dot{Q}_m = \dot{m}_l c_{pl}(T_S - T_{In}). \quad (3)$$

In order to simplify the calculation, the dimensionless discharge temperature of the condensate-cooling medium mixture is introduced as quotient of these temperatures:

$$\bar{\theta} = \frac{T_{Out} - T_{In}}{T_S - T_{In}}. \quad (4)$$

2 Condensation on Freely Falling Plane or Round Liquid Jets

If there is no inert gas, the heat transfer coefficient between steam and liquid is very high; therefore, the condensation of freely falling liquid jets is determined by the heat transfer in the liquid. The characteristic key figure to calculate the heat transfer is the Stanton figure:

$$St = \frac{\alpha}{\rho c_{pl} w}. \quad (5)$$

α is a fictional heat transfer coefficient to the liquid, related to the fictional surface F that is formed by the wetted circumference of the liquid discharge and the jet length L, ρ is the density and c_{pl} is the specific heat capacity of the liquid, and w is the speed in the discharge cross section A.

The dimensionless discharge temperature θ can be calculated according to the following formula if the Stanton figure is known:

$$\bar{\theta} = 1 - \exp\left(-\frac{F}{A}St\right). \quad (6)$$

The following shall apply to the round liquid jet:

$$\frac{F}{A} = 4\frac{L}{d}. \quad (7)$$

The following shall apply to the plain liquid jet with very large gaps:

$$\frac{F}{A} = 2\frac{L}{d}, \quad (8)$$

if d is the discharge diameter or the width of the discharge gap.

After a certain decomposition length, the liquid jet is dissolved into individual droplets [15–18]; this process has to be taken into consideration for the calculation of the Stanton figure.

The following shall apply to the Stanton number in general:

St = f (Ph, Pr, We, Fr, Re, geometry, flow arrangement).

The dimensionless parameters are explained in Chap. A2.

Numerous equations were published [10, 18–25] regarding the mathematical formulation of the dependence of the Stanton figure on its influencing variables.

Sometimes, these equations reflect the influence of the parameters on the Stanton figure in a qualitatively different way. As long as the number of measured values is not sufficient to be able to determine the influence of the parameters by means of equations, measured values of the design of mixing condensers shall be directly taken as a basis.

A first assessment of the Stanton figure is possible with the equation by Theofanous [10]:

$$St = 0.02\left(\frac{L}{d}\right)^{-0.5}. \quad (9)$$

The heat transfer on the liquid jet can be considerably increased by means of periodic transient liquid feed [26].

3 Heat Transfer on the Individual Drop

The highest volume-related heat flow densities can be achieved if the condensation takes place on individual drops as in this case the surface of the cooling medium is very large. The most important application is the condensation of water steam on liquid water. The growth of the drops due to condensation can be neglected in this case if the difference between cooling water inlet temperature and saturation temperature of the steam is smaller than 100 K. The most popular theories assume that the radius of the drops is constant and that the heat transfer resistance in the resulting condensate layer can be neglected [27–29].

If the cooling medium is a fluid, which has a miscibility gap with the cooling medium, the thermal conduction of the resulting condensate layer has to be taken into consideration as well [29]. The preliminary calculation of such condensers, however, is very inaccurate; there are studies showing that the accommodation coefficient is then unequal to 1 [30] (and the assumption of a thermodynamic equilibrium at the phase boundary is not justified).

In the following, it is assumed that the cooling medium is the same substance as the condensing vapor, the drop growth can be neglected, and there will be a thermodynamic equilibrium ($T_{ph} = T_s(p)$) on the phase boundary, i.e., the heat transfer coefficient of the steam is very high.

The introduction of the dimensionless temperature

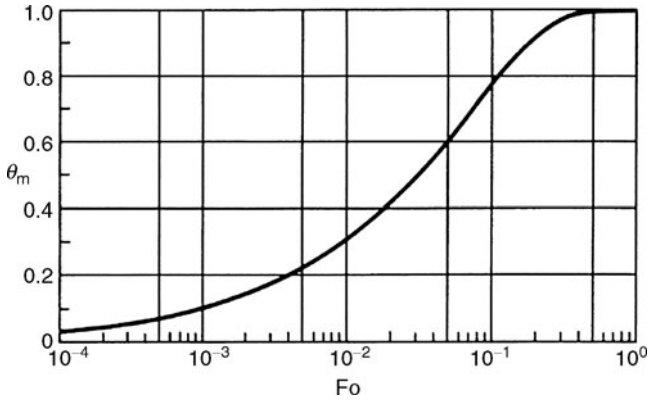
$$\bar{\theta} = \frac{T - T_{In}}{T_S - T_{In}} \quad (10)$$

facilitates the calculation of the heat transfer.

When determining the heat transfer on the basis of the sprayed drops, it is assumed that the drops do not influence each other [27, 28, 31]. The heat transfer in drops is calculated in the same way as the thermal conduction in a rigid ball. The temperature of the ball is constant for time $t < 0$, and the surface temperature of the ball equals T_S for $t > 0$.

In case of a high relative speed between drop and steam, the measured heat transfer is higher than the heat transfer calculated for a rigid ball from mere thermal conduction. The increased heat transfer can be explained by the flow inside the drop [32–34] and by the oscillation of the drop [35].

If the thermal conductance in the individual drop is calculated in the same way as the thermal conductance in a rigid ball, and assuming a thermodynamic equilibrium on the ball surface,



J4. Fig. 1. Standardized average temperature of a drop depending on the Fourier number.

the dimensionless mean temperature θ_m of the drop will result [36] as

$$\theta_m = 1 - \frac{6}{\pi^2}\sum_{n=1}^{\infty}\frac{1}{n^2}e^{-n^2\pi^2 Fo}, \tag{11}$$

with the Fourier number

$$Fo = \frac{\lambda t}{\rho c_{pl} r^2}. \tag{12}$$

The solution of Eq. (11) is shown in Fig. 1.

Although the sum in Eq. (11) converges rapidly, it is easier for practical application to determine the average temperatures via the proximity equation [37]

$$\theta_m = \sqrt{1 - e^{-\pi^2 Fo}}. \tag{13}$$

The proximity equation deviates from the exact solution according to Eq. (11) by less than 0.02.

Celata and others performed measurements of individual drops in technically interesting ranges from $r = 0.16$ mm to $r = 1.4$ mm [38]. It turned out that faults due to neglect of flow inside the drop and due to the oscillation of the drop are much more important than that assumed up to now. The measurements are limited to drop path lengths of less than 0.1 m. Velata and others propose to use the empiric correlation

$$Fo \cdot 0.21 \cdot \left(r \cdot \left|\vec{v}_g - \vec{v}_e\right| \cdot \frac{\rho c_{pl}}{\lambda} \cdot \frac{\eta_g}{\eta_e + \eta_g} \right)^{0.454} \tag{14}$$

in Eqs. (11–13) instead of the Fourier figure. For large mixing condensers, however, Eqs. (11–13) result in excessive values for the average temperature.

The Fourier number ("dimensionless residence time") (Eq. (12)) depends not only on the drop radius r, but also on the residence time t of a drop in the mixing condenser. In order to calculate the residence time, the equation of motion of the drop has to be solved.

On the assumption that the condensation does not essentially influence the trajectory of the drop and neglecting the buoyant force, Ref. [39] shall apply

$$\frac{d\vec{v}_l}{dt} = \frac{9}{2}\frac{\eta}{\rho_l r^2}\frac{c_d Re}{24}(\vec{v}_g - \vec{v}_l) + \vec{g}, \tag{15}$$

with

$$\frac{c_d\ Re}{24} = 1 + 0.197\ Re^{0.63} + 2.6 \cdot 10^{-4}\ Re^{1.38} \tag{16}$$

and

$$Re = \frac{2\left|\vec{v}_g - \vec{v}_l\right| r \rho_g}{\eta_g}. \tag{17}$$

Because of

$$\frac{d\vec{x}}{dt} = \vec{v}_l \tag{18}$$

this is a system of ordinary, nonlinear differential equations that can be solved with differential solvers, which are available in most of the standard program libraries. With the initial and boundary conditions given by the units (condenser geometry, initial drop speed according to the speed of the liquid in the tightest cross section), the result is the residence time of the drops in the mixing condenser.

The temperature of the liquid in the condenser discharge is the average temperature of all drops. Knowing the density of the volume distribution of the drops dv/dt, the temperature $\bar{\theta}$ can be calculated according to

$$\bar{\theta} = \sum_0^{\infty}\frac{dv}{dr}\theta_m(Fo)dr. \tag{19}$$

Manufacturers of spray nozzles frequently indicate the density of the drop size distribution $dN(r)/dr$. If atomization is done by means of hollow cone nozzles, the drop size distribution can be estimated according to [40]. These values can be taken as rough estimates, however, in case of high condensation rates, the jet geometry will change considerably, and this might result in the reduction of the heat transfer [41]. On the basis of the density of the drop size distribution, it is possible to calculate the volume distribution according to

$$\frac{dv}{dr} = \frac{r^3 dN(r)}{d} \Big/ M_3 \tag{20}$$

with the third moment of distribution [42]

$$M_3 = \int_0^{\infty} r^3 \frac{dN(r)}{dr} dr. \tag{21}$$

The equation by Mugele and Evans [43] proved itself [29, 31, 44] for the description of measured values of drops. It well represents the measured average diameter. The required constants are easy to adjust. Mugele and Evans assume that with a given flow field there is a maximum, stable drop radius r_m. With this maximum drop radius r_m and the adjustable parameter a the dimensionless function y of drop size r is formed:

$$y = \ln\frac{ar}{r_m - r}. \tag{22}$$

According to Mugele and Evans, y shall be distributed in a normal manner:

$$\frac{dv}{dy} = \frac{\delta}{\sqrt{\pi}}e^{-\delta^2 y^2}, \tag{23}$$

$$\frac{dv}{dr} = \frac{r_m}{(r_m - r)r} \cdot \frac{\delta}{\sqrt{\pi}}e^{\delta^2 y^2}, \tag{24}$$

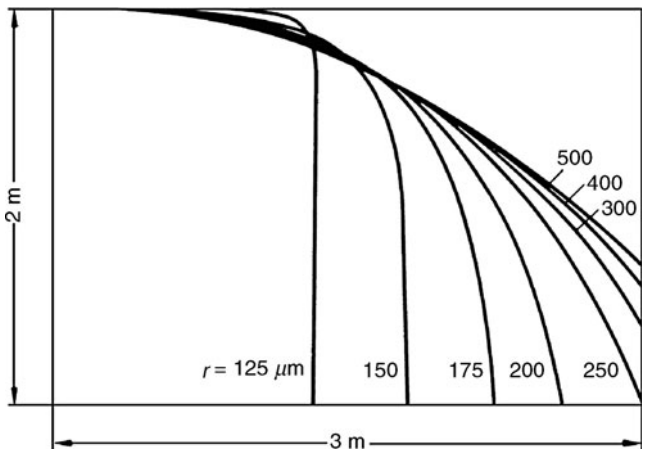
with δ as distribution parameter.

If the density of the volume distribution dv/dr is known, the dimensionless discharge temperature can be calculated by means of a numerical or graphical evaluation of Eq. (19).

Example

Given: We assume that there is a mixing condenser with a width of 3 m for water steam with a saturation temperature $T_S = 40°C$. The steam speed, vertically from the bottom to the top, amounts to 2 m/s. Drops from a flat jet nozzle flow horizontally into the steam chamber, with an initial speed of 6 m/s. The inert gas rate can be neglected. We assume that the distribution according to Mugele and Evans the drops are distributed with $r_m = 0.8$ mm, $a = 0.4$, and $\delta = 0.5$. What is the average standardized discharge temperature of the cooling water?

On solving Eq. (15), we get the flight path of the drops. Figure 2 shows the graphical representation of the flight paths of some drops with different radii. For the numerical evaluation, the substance data of water at 40°C were used. The residence time of the drops and the volume distribution density are shown above the radius in Fig. 3. The graphical or numerical evaluation of Eq. (19) results in $\bar{\theta} = 0.94$.



J4. Fig. 2. Example of the flight paths of drops of different radii.

4 Inert Gas Influence

The presence of inert gas reduces the capacity of the mixing condenser. In the literature, e.g., [45–50], this phenomenon is exclusively ascribed to the fact that the inert gas enriches on the phase boundary surface. Therefore, the partial pressure of the steam reduces on the phase boundary surface, and as a result, the condensation temperature that corresponds to the saturation temperature for this partial pressure decreases as well.

The decreasing capacity of a mixing condenser can be described in a first approximation by the fact that the reduction of the partial pressure on the phase boundary surface and thus, the reduction of the condensation temperature T_{Ph} are taken into consideration. (As already mentioned, other physical phenomena have to be taken into consideration in case of gas cooling by means of liquid injection.)

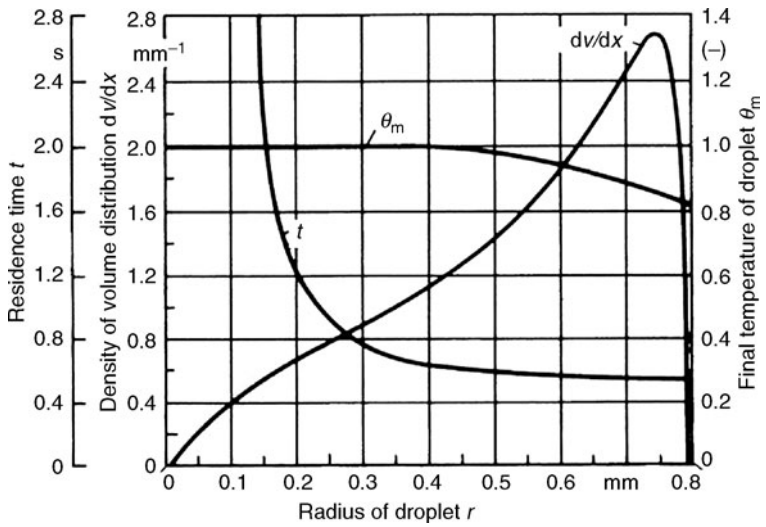
Taking into consideration the Clausius–Clapeyron equation, according to Schlünder [48] the saturation temperature T_{Ph} on the phase boundary surface under steady-state conditions can be calculated according to

$$0 = T_{In} - T_{Ph} + \Phi \frac{\Delta h_v}{c_{pg}} \cdot \ln \frac{\tilde{y}_I + \frac{\Delta h_v}{RT_{sv}^2}(T_{sv} - T_{Ph})}{\tilde{y}_I}, \qquad (25)$$

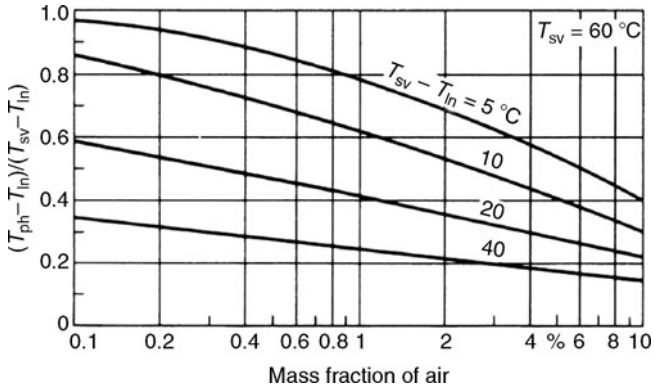
if the specific volume of the liquid and the real gas behavior of the steam are neglected. $T_{In} - T_{ph}$ is the driving temperature difference for the heat transfer through the condensate, Δh_v is the evaporation enthalpy, and c_{pg} is the specific heat of the steam. T_{sv} is the saturation temperature of the steam in the core flow, and R is the gas constant. It has to be observed that the temperatures in Eq. (25) have to be in kelvin. The mole fraction $\tilde{y}_I$ can be calculated on the basis of the weight fraction of the inert gas y_I according to

$$\tilde{y}_I = \frac{y_I}{y_I + (1 - y_I)M_I/M_g}, \qquad (26)$$

with molecule masses M_I and M_g of the inert gas and of the steam, respectively.



J4. Fig. 3. Final temperature, residence time, and volume distribution of the drops.



J4. Fig. 4. Influence of the air as inert gas to the condensation of water steam at $\Phi = 1.5 \cdot 10^{-3}$.

Φ is approximately the ratio of the heat transfer coefficient of the gas to that of the liquid.

Although the thermal conduction in the condensate is transient, Eq. (25) can even be applied if Φ is considered an adjustable constant. For many condensers and operating conditions, Φ ranges between 1 and $2 \cdot 10^{-3}$.

In the calculation of T_{Ph} according to Eq. (25) convergence problems might occur due to the stiffness of the problem with algorithms which converge with higher order. Simpler solvers avoid such problems.

Condensers for steam–inert gas mixtures can then be designed as condensers for pure steam, if T_S is the temperature on the phase boundary surface T_{Ph}. For a first assessment of the inert gas influence, Fig. 4 shows the relation of $(T_{Ph} - T_{In})/(T_{sv} - T_{In})$ over the inert gas concentration. The figure applies to water with $T_{sv} = 60°C$ and air as inert gas.

The important influence of the temperature difference $T_{sv} - T_{In}$ and thus, the heat flow density can be recognized. The higher the steam flow to the phase boundary surface, the higher the inert gas concentration on the phase boundary surface and thus, the reduction of the condensation temperature T_{Ph} on the phase boundary surface.

Equation (25) does not consider the compression of inert gas in the condenser and the heating of the cooling medium. In case of strong compression of the inert gas and (or) strong heating of the cooling medium, the condenser has to be calculated in steps [44].

5 Symbols

A	discharge surface of a liquid jet (m^2)
a	distribution parameter (–)
c_d	resistance coefficient (Eq. (14)) (–)
c_{pl}, c_{pg}	specific efficient heat capacity of the liquid or of the steam (J/kg K)
d	diameter or gap width (m)
F	fictional surface (see text) (m^2)
Fo	Fourier figure (Eq. (12)) (–)
$\vec{g}$	acceleration of gravity 9.81 m/s^2 (m/s^2)
Δh_v	evaporation enthalpy (J/kg)
$\dot{H}$	enthalpy flow (J/s)
L	jet length (m)
$\dot{m}_l$, $\dot{m}_g$	mass flow of the cooling medium or of the steam (kg/s)
M_I, M_g	molecular weight of the inert gas or of the steam (g/mol)
M_3	third moment of distribution of number (Eq. (21)) (–)
$N(r)$	distribution of total number (–)
$\dot{Q}$	heat flow (J/s)
$\dot{Q}_m$	max. transferable heat flow (J/s)
R	gas constant (J/kg K)
Re	Reynolds figure (Eq. (17)) (–)
r	drop radius (m)
r_m	max. drop radius (m)
St	Stanton value (Eq. (5)) (–)
T_{Out}	discharge temperature of the cooling medium (K)
T_{In}	inlet temperature of the cooling medium (K)
T_{sv}	saturation temperature of the steam in the core flow (K)
T_{Ph}	saturation temperature of the steam on the phase boundary (K)
T_S	saturation temperature of the steam for the condenserpressure (K)
t	time (s)
$\vec{v}\,(r)$	distribution of the volume total (–)
$\vec{v}$, $\vec{v}_g$	vector of the drop or gas speed (m/s)
w	speed of the cooling water (m/s)
$\vec{x}$	coordinate of a liquid drop (m/s)
y	dimensionless function of the drop size (–)
$\tilde{y}_I$, y_I	molecular or mass portion of the inert gas (–)
α	liquid-side heat transfer coefficient (W/m^2 K)
δ	distribution parameter (–)
η_g	gas viscosity (kg/m s)
θ	standardized temperature (Eq. (10)) (–)
$\bar{\theta}$	standardized caloric average temperature of the cooling medium (–)
θ_m	standardized caloric average temperature of a drop (–)
Φ	constant for the calculation of the inert gas influence (–)
ρ_g, ρ_l	density of gas or liquid (kg/m^3)

[2]Munich, Germany

1 Introduction

All substances, regardless of shape and consistency, emit and absorb radiation energy when their temperature is above absolute zero ($T > 0$ K). For nontransparent opaque bodies, the absorption and emission processes are confined to their surfaces. Thermal radiation energy can be regarded as electromagnetic waves carrying energy and entropy in the wavelength range between 0.1 µm and about 1000 µm (0.1 µm $< \lambda <$ 1000 µm). Because of these emission and absorption processes in all substances (solids, liquids, and gases) around there will be a net transfer of energy between those bodies which face each other and whose surfaces have different temperatures. This net thermal radiation energy is, from a thermodynamic view, a heat flux, as its only driving force is a temperature difference and as it carries entropy. In thermal equilibrium situations, the emission and absorption processes still exist, but the net radiation energy will be zero. The calculation of thermal radiation energy fluxes is derived in this chapter. These radiation fluxes typically appear in addition to convective heat fluxes and thus have to be worked out separately and added to give the overall heat flux. For more introductory literature, see [1–5].

1.1 The Black Body

The black body serves as a baseline for all calculations concerning thermal radiation, because only for this specific body an exact and simple physical description is known. A black body is a hypothetical radiating body, the surface of which absorbs *all* incoming radiation. No reflection or transmission occurs. Because of this the black body of a given temperature T will emit a maximum amount of radiation energy, no other body with the same temperature will emit more radiation in any wavelength interval. This black body radiation shows a characteristic spectral distribution which can be derived from quantum physics [2].

The spectral intensity M_λ^b, i.e., the radiation energy flux within an infinitely small wavelength interval dλ at a wavelength λ emitted from a small surface segment dA of a black body into the surrounding hemisphere is calculated by the formula first derived by Max Planck [6]:

$$M_\lambda^b(\lambda, T) = \frac{c_1}{\lambda^5[\exp(c_2/\lambda \cdot T) - 1]} \tag{1}$$

The constants c_1 and c_2 are not empirical numbers but products of basic nature constants. They result as

$$c_1 = 2\pi h c_0^2 = 3.74177107 \cdot 10^{-16}\,\mathrm{W\,m^2} \text{ and}$$
$$c_2 = h c_0 / k = 14387.75\,\mu\mathrm{m\,K}.$$

If the wavelength λ is introduced in µm, the second version of c_1 must be used and $M_\lambda{}^b$ results in $\mathrm{W{\cdot}m^{-2}{\cdot}\mu m^{-1}}$.

In Fig. 1, the spectral intensity $M_\lambda{}^b$ of a black body is shown as a function of wavelength λ for four different temperatures. The spectral intensity emitted by the surface of any real body having the same temperature T will be lower than the curves shown in Fig. 1.

Integration of Eq. (1) over all wavelengths gives the intensity of the black body

$$M^b = \int_0^\infty M_\lambda^b(\lambda, T)\mathrm{d}\lambda = \sigma \cdot T^4 \tag{2}$$

This equation is called the Stefan–Boltzmann equation, and σ is the Stefan–Boltzmann constant:

$$\sigma = \frac{2\pi^5 k^4}{15\, c_0\, h^3} = 5.67040 \times 10^{-8}(\mathrm{W/m^2\,K^4}).$$

The temperature T in Eqs. (1) and (2) is the thermodynamic temperature of the black body in the vicinity of the emitting body surface, given in Kelvin K with $T\,(\mathrm{K}) = T\,(^\circ\mathrm{C}) + 273.15$ K. For a quick lookup, Table 1 gives values of the intensity of black body radiation as a function of temperature as calculated by Eq. (2).

1.2 Radiation Intensity of Real Bodies

ΔE is the radiation energy flux within the wavelength gap λ and $\lambda + \Delta\lambda$ emitted into the solid angle element $\Delta\Omega$ of an arbitrary body at temperature T as shown in Fig. 2. This radiation flux is composed of radiation of all wavelengths heading in all directions into the hemisphere above the emitting piece of area ΔA. The direction of a ray is represented by an element of solid angle $\Delta\Omega$ given in steradiant (sr), which is calculated from the polar angle β and the azimuth angle φ as $\Delta\Omega = \sin\beta{\cdot}\Delta\beta{\cdot}\Delta\varphi$, see Fig. 2. Thus, for an exact calculation of the radiation flux emitted by the surface area element ΔA of a real body all rays have to be integrated over all wavelengths and solid angles. The energy of one single basic ray is given as a spectral directional intensity L_λ

$$L_\lambda = \frac{\Delta^3 E}{\cos\beta\Delta A\Delta\Omega\Delta\lambda} \tag{3}$$

ΔE is the radiation energy flux within the wavelength gap λ and $\lambda + \Delta\lambda$ emitted into the solid angle element $\Delta\Omega$ per projected area element $\cos\beta{\cdot}\Delta A$. L_λ is typically given in W m^{-2} µm^{-1} sr^{-1}.

Integration of the spectral directional intensity L_λ over all directions of the hemisphere ($0 \le \beta \le 90°$; $0 \le \varphi \le 360°$) as described by the solid angle $\Omega = 2\pi$ results in the spectral intensity $M_\lambda(\lambda, T)$

$$M_\lambda(\lambda, T) = \int_{\Omega} L_\lambda(\lambda, T, \beta, \varphi)\cos\beta \mathrm{d}\Omega \tag{4}$$

One more integration summing up all possible wavelengths ($0 \le \lambda \le \infty$) gives the intensity M

$$M(T) = \int_0^\infty M_\lambda(\lambda, T)\mathrm{d}\lambda \tag{5}$$

If the temperature Tor radiation properties (optical properties) vary along the surface of a real body, each surface element ΔA has to be treated separately, and all surface elements have to be integrated to give the overall radiation emitted by the body under consideration.

When the spectral directional intensity L_λ is first integrated over all wavelengths ($0 \leq \lambda \leq \infty$) the directional intensity L independent of wavelength results

$$L(\beta, \varphi, T) = \int_0^\infty L_\lambda(\lambda, \beta, \varphi, T)\mathrm{d}\lambda \qquad (6)$$

which in turn will give the intensity $M\,(T)$ when integrated over the solid angle $\Omega\ (\beta, \varphi)$. $M\,(T)$ is the integral value giving the overall radiation energy flux emitted by a surface element of a real body in W/m^2. The spectral directional intensity L_λ will be conserved along its line of traveling as long as no scattering or absorption of molecules or particles takes place. Thus, an energy balance equation for radiation, the radiative transport Eq. (7), uses the spectral directional intensity L_λ as the base value. In technical radiative heat transfer calculations usually only spectral intensities M_λ or overall intensities M are considered, very few calculations take into account a directional dependence of radiation fluxes. This is allowed as most real bodies do not show a strong dependency of emitted radiation on the solid angle. Figure 3 gives the directional dependence of emissivity of some nonconducting materials as a function of the polar angle β. The emissivity ε is explained in Eq. (7). Electric conductors such as metals show a different behavior on behalf of solid angles as demonstrated in Fig. 4. They typically have a low emissivity for all polar angles except low polar angles close to the normal direction.

Surfaces which show no or negligible dependence of radiation intensities in a direction are called diffusive radiators or diffusive surfaces. For a diffusive surface, integration over the solid angle according to Eq. (4) gives

$$M_\lambda(\lambda, T) = \pi \cdot L_\lambda(\lambda, T)$$

for the spectral intensity, or

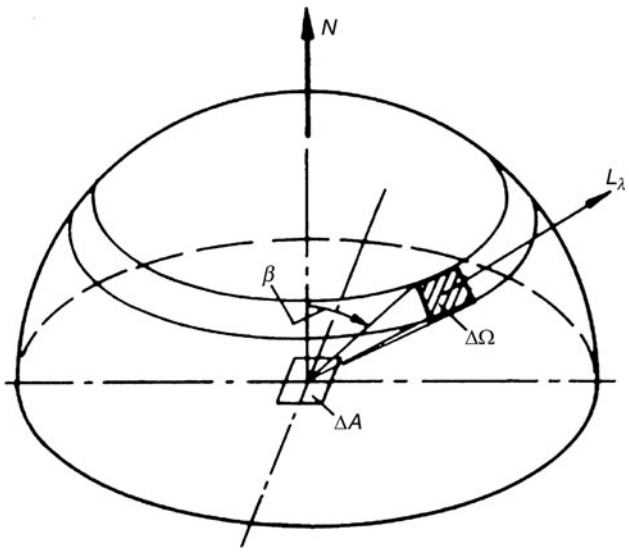
$$M(T) = \pi \cdot L(T)$$

for the overall intensity. The radiation energy flux emitted from a diffuse surface element $\Delta\Omega$ seen in a polar angle β reads

$$\Delta^2 E = L(T) \cdot \cos\beta \Delta A \Delta\Omega.$$

This relation is called the Lambert's cosine law, and it is used for the definition of a diffuse surface. The black body is a diffuse radiator.

The spectral distribution of radiation emitted by real bodies is complicated and cannot be cast into simple mathematical formulas. This spectral distribution depends on the atomic structure of the surface region of the body, it is something like a fingerprint of each individual substance, it can be calculated in principle on the basis of electromagnetic theory if the complex refractive index of the substance forming the uppermost molecular layer of the radiating body under consideration is known and if the exact topology of the surface is known [7, 8]. So the radiative emission of real bodies is tied to the emission of the black body by empirical correlations. The directional spectral degree of emission



K1. Fig. 2. Radiation of a surface element ΔA.

K1. Fig. 4. Directional emissivity of some metals with polished surfaces [3].

$$\varepsilon'_\lambda(\lambda, T, \beta, \varphi) := \frac{L_\lambda(\lambda, T, \beta, \varphi)}{L^b_\lambda(\lambda, T)} \tag{7}$$

gives the directional and spectral distribution of the radiation emitted by a real body as compared to the spectral intensity $L^b_\lambda = M^b_\lambda/\pi$ of a black body having exactly the same temperature as the real body. In the same manner

a hemispherical spectral degree of emission

$$\varepsilon_\lambda(\lambda, T) := \frac{M_\lambda(\lambda, T)}{M^b_\lambda(\lambda, T)} = \frac{1}{\pi}\int \varepsilon'_\lambda(\lambda, T, \beta, \varphi)\cos\beta \mathrm{d}\Omega$$

and a directional spectral degree of emission

$$\varepsilon'_\lambda(T, \beta, \varphi) := \frac{L(T, \beta, \varphi)}{L^b(T)} = \frac{\pi}{\sigma T^4}\cdot L(T, \beta, \varphi)$$

can be defined. All these degrees of emissivity have values between zero and one, $0 < \varepsilon_\lambda \leq 1$. As wavelength- and/or direction-dependent calculations are still too involved for most heat transfer calculations, the overall hemispherical degree of emission is defined as

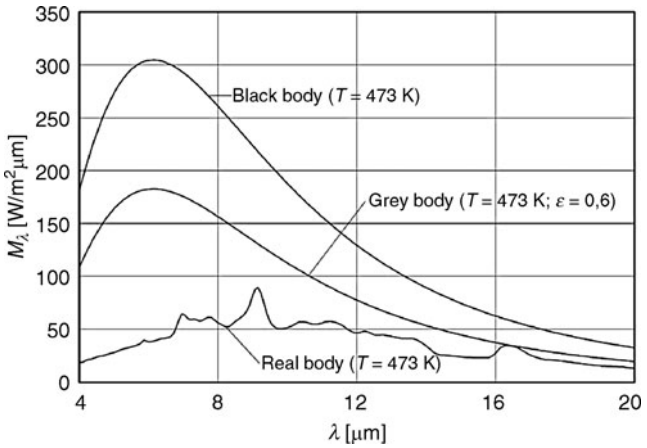
$$\varepsilon(T) := \frac{M(\lambda, T)}{M^b(\lambda, T)} = \frac{M(\lambda, T)}{\sigma \cdot T^4}, \tag{8}$$

which is the ratio of the intensity emitted by the real body at a temperature T and the intensity of the black body at the same temperature T. If the degree of emission ε for a real body at temperature T is known, the intensity of the radiation of this body is calculated by

$$M(T) = \varepsilon(T)\cdot M^b(T) = \varepsilon(T)\cdot\sigma\cdot T^4 = \int_0^\infty \varepsilon_\lambda(\lambda, T) M^b_\lambda(\lambda, T)\mathrm{d}\lambda. \tag{9}$$

Table 1 can be used here to find values for the black body intensity $M^b(T)$. A body which is not black but which has a constant spectral degree of emission $\varepsilon_\lambda = \text{const.} = \varepsilon \leq 1$ is called a gray body. Typically, the Lambert's cosine law is additionally assumed to be valid for gray bodies. Figure 5 shows the spectral intensity M_λ ($T = 473$ K) for a black, a gray, and a real body.

Table 2 gives the hemispherical degree of emission $\varepsilon(T)$ for different materials. In some cases, the directional degree of



K1. Fig. 5. The spectral intensity M_λ for a black body, a gray body $\varepsilon = 0.6$, and some arbitrary body, each at $T = 473$ K.

emission $\varepsilon_n = \varepsilon'$ ($\beta = 0°$) for a direction normal to the surface is given. The approximate conversion of ε_n into ε is shown in Fig. 6, which depicts the ratio of these two values for metals (curve b) and nonconducting materials (curve a). Note that emissivities are very sensitive to different surface finishings, so you may find for some materials values for ε which deviate from the values given in Table 2. More degrees of emissivity can be found in the literature [9–13].

Other parameters which characterize the optical properties of a material are the degree of absorption a, the degree of reflection r, and the degree of transmission τ. These parameters are *not* connected to the black body characteristics but are ratios based on the overall incoming radiation energy flux E. The overall incoming radiation flux E is the area-specific radiation impinging on a surface, integrated over all directions (i.e., the hemisphere) and all wavelengths. According to the hemispherical spectral intensity M_λ, we can introduce a spectral incoming radiation flux, also called radiosity, E_λ, so that

$$E = \int_0^\infty E_\lambda(\lambda)\mathrm{d}\lambda.$$

Contrary to black bodies, real bodies will not absorb all incoming radiation. Some radiation will be reflected, some may go

This table shows measured values. Most values have been measured in normal direction to the surface, so ε_n is given. This value can be converted to a hemispherical value ε by using Fig. 6. More values are given in [9–13]

through the body (transmission), and only the rest will be absorbed and converted into internal energy of the body.

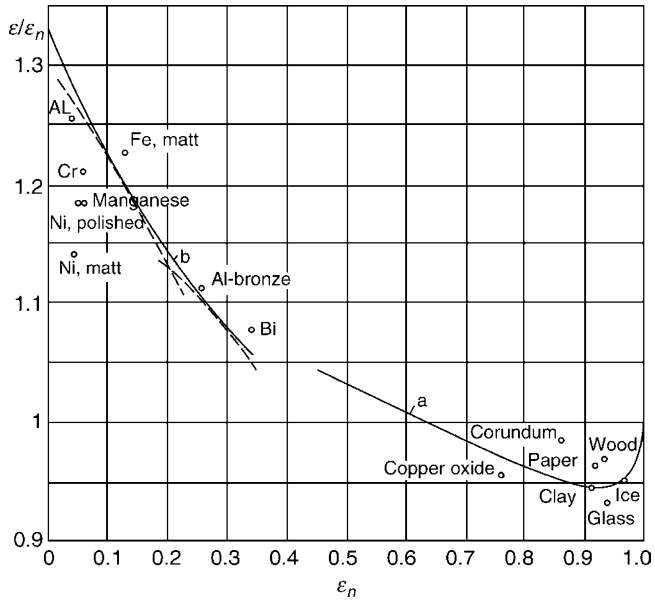
The overall hemispherical degree of absorption

$$a(T) = \frac{1}{E}\int_0^\infty a_\lambda(\lambda, T)E_\lambda(\lambda)\mathrm{d}\lambda$$

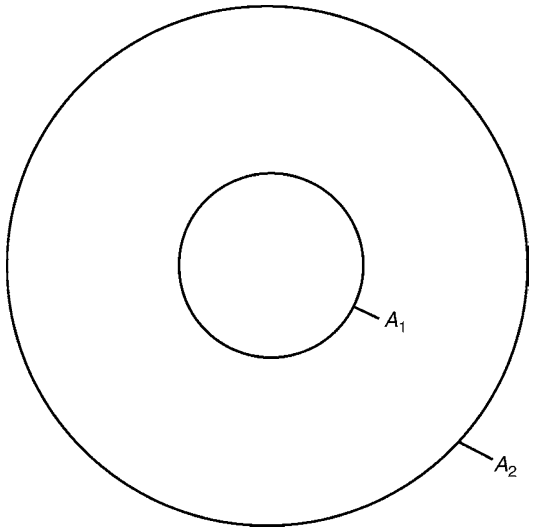
gives the part of the incoming radiation which is absorbed by the body when $a_\lambda(T, \lambda)$ is the spectral degree of absorption and $a(T)$ is the overall degree of absorption. The spectral as well as the overall degrees of absorption attain a value of one for the black body, for real bodies they are between zero and one. A directional spectral degree of absorption $a'_\lambda(\lambda, T, \beta, \varphi)$ could also be introduced. According to the first and second laws of thermodynamics, the directional spectral degree of absorption has to be equal to the directional spectral degree of emission [14]

$$a'_\lambda(\lambda, T, \beta, \varphi) = \varepsilon'_\lambda(\lambda, T, \beta, \varphi) \qquad (10)$$

for any body of temperature T. Equation (10) is known as the law of Kirchhoff, and it gives a powerful tool to calculate the degrees of absorption from the measured degrees of emission.



K1. Fig. 6. The overall degree of emission ε shown as a function of ε_n for the same material. Curve (a) is for nonconducting materials and curve (b) for metals.



K1. Fig. 7. Two concentric pipes 1 and 2.

If the real body behaves like a diffuse radiator according to Lambert's law, Eq. (10) can be extended to spectral hemispherical quantities $a_\lambda = \varepsilon_\lambda$. If the body is a gray body, Eq. (10) finally gives $a(T) = \varepsilon(T)$.

Another optical property is the degree of reflection r. The hemispherical degree of reflection is defined as

$$r(T) = \frac{1}{E}\int_0^\infty r_\lambda(\lambda, T)E_\lambda(\lambda)\mathrm{d}\lambda r_\lambda$$

as the reflected part of the incoming radiation energy flux E impinging onto a surface. $r_\lambda(T, \lambda)$ is the spectral degree of reflection. The directional spectral degree of reflection r_λ' $(T, \lambda, \beta, \varphi)$ can be measured using an ellipsometer [3].

Finally, the spectral degree of transmission τ_λ is introduced which gives the fraction of the incoming specific spectral radiation energy E_λ which passes through a body. An energy balance equation for an irradiated body gives the important relation

$$a_\lambda(\lambda, T) + r_\lambda(\lambda, T) + \tau_\lambda(\lambda, T) = 1.$$

Extensive tables that include these optical properties for many different material are, for e.g., shown in [9].

2 Radiation Heat Transfer Between Surfaces

2.1 Simple Cases

If two parallel surfaces 1 and 2 of equal size, each having black body characteristics (thus they are called black surfaces) but different temperatures, face each other, the net thermal energy transferred from the hotter surface to the colder surface is

$$\dot{Q}_{12} = \sigma A\left(T_1^4 - T_2^4\right). \tag{11}$$

For Eq. (11) to be valid the linear extension of the surfaces has to be much larger than the distance between them, also the space between the plates must be free of any participating media. If these surfaces are gray surfaces having emissivities ε_1 and ε_2, the radiation transfer between the plates becomes more complicated. This is because of the reflection which comes into play and which has to be considered by ray tracing. The equation for the net heat transfer between the gray plates now becomes

$$\dot{Q}_{12} = C_{12}A\left(T_1^4 - T_2^4\right). \tag{12}$$

in W, where the radiation exchange factor [5]

$$C_{12} = \frac{\sigma}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1} \tag{13}$$

shows the influence of geometry and emissivities. Equation (13) is valid for parallel plates only. The temperatures in Eqs. (11) and (12) are absolute temperatures in Kelvin, as in all equations regarding radiation energy transfer.

Another special geometric case is the concentric pipe situation shown in Fig. 7. The cylinders are supposed to be gray bodies again, now the radiation exchange factor is

$$C_{12} = \frac{\sigma}{\frac{1}{\varepsilon_1} + \frac{A_1}{A_2}\left(\frac{1}{\varepsilon_2} - 1\right)}. \tag{14}$$

For the calculation of the net heat flux $\dot{Q}_{12}$ from body 1 to body 2, the surface area A has to be used in Eq. (12).

Two special cases can be derived from Eq. (14). If $A_1 << A_2$, as in the case of a pipe within a big room (which does not have to be cylindrical any more), the radiation exchange factor reduces to $C_{12} = \varepsilon_1\sigma$. If on the other side, $A_1 \approx A_2$, i.e., the pipe surfaces are close to each other, the radiation exchange factor turns into the parallel plate case, Eq. (13):

$$C_{12} = \frac{\sigma}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1}$$

2.2 View Factors

The two radiation heat transfer cases treated in the foregoing section were special cases in which all radiation emitted from object 1 reached object 2. In a standard thermal radiation situation with arbitrary sized and oriented surfaces A_1 and A_2, only a fraction of the radiation emitted by A_1 actually hits A_2, and vice versa only a different fraction of all radiation emitted by A_2 reaches A_1. This fraction of radiation departing from a body i of area A_i reaching the surface of another body k with the surface area A_k, divided by all the radiation emitted by surface i, is called view factor φ_{ik}

$$\varphi_{ik} = \frac{\text{radiation energy from surface } i \text{ reaching surface } k}{\text{all radiation emitted by surface } i}.$$

The view factor φ_{ik} is a purely geometrical value, and it is defined as

$$\varphi_{21} = \frac{1}{\pi A_1} \int_{A_1} \int_{A_2} \frac{\cos\beta_1 \cos\beta_2}{s^2} \mathrm{d}A_1 \, \mathrm{d}A_2.$$

This equation is further explained in Chap. K2, which is dedicated to view factors of many different geometrical situations. The net radiation energy exchanged between two black surfaces A_1 and A_2, which is equal to the net heat flux, is calculated as the difference of the absolute radiation energies to and from these surfaces

$$\dot{Q}_{12} = \varphi_{12} \, A_1 \sigma T_1^4 - \varphi_{21} \, A_2 \sigma T_2^4. \tag{15}$$

In case of thermal equilibrium $T_1 = T_2$, the resulting net energy exchange must be zero. Thus, we have

$$\varphi_{21} = \frac{A_1}{A_2} \varphi_{12}. \tag{16}$$

Using this relation, Eq. (15) can be written as

$$\dot{Q}_{12} = \varphi_{12} \, A_1 \sigma \left(T_1^4 - T_2^4\right). \tag{17a}$$

For gray surfaces part of the radiation reaching A_2 will be reflected back to A_1. For this situation ray tracing methods have to be applied. Only for gray surfaces having degrees of emissivity ε_1 and ε_2 a simple solution can be gained by infinite series methods which reads

$$\dot{Q}_{12} = \frac{\sigma \varepsilon_1 \varepsilon_2 A_1 \varphi_{12}}{1 - (1 - \varepsilon_1)(1 - \varepsilon_2)\varphi_{12}\varphi_{21}} \left(T_1^4 - T_2^4\right). \tag{17b}$$

One of the main problems in radiation heat transfer calculation is getting the appropriate view factors. As these are of purely geometrical nature, these view factors are tabulated for many technical situations. Some of these are given in Chap. K2. Before these are introduced some important rules for handling the view factors are given.

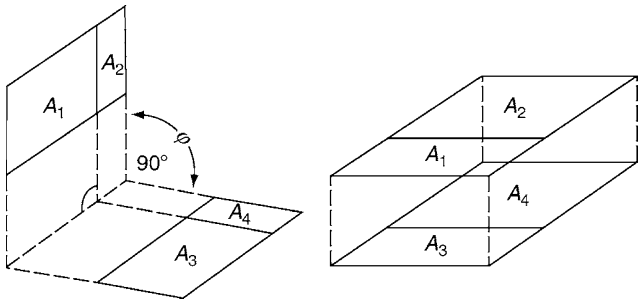
(a) *Reciprocal relation*: As shown earlier, we have

$$A_i \varphi_{ik} = A_k \varphi_{ki} \tag{18}$$

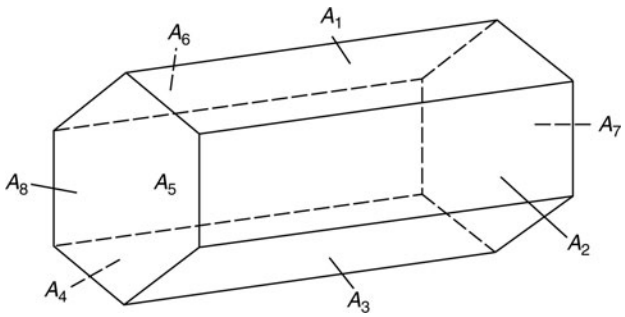
for all situations, this is known as the reciprocal relation.

(b) *Extended reciprocal relation*: This extension of Eq. (18) refers to Fig. 8, and it is valid for surfaces which are parallel to each other or which have a common border line

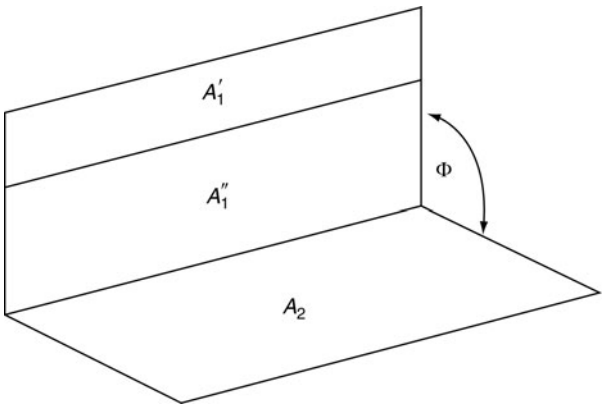
$$A_1 \varphi_{14} = A_2 \varphi_{23} = A_3 \varphi_{32} = A_4 \varphi_{41}. \tag{19}$$



K1. Fig. 8 Extended reciprocal relation.



K1. Fig. 9. Summarizing relation.



K1. Fig. 10. Splitting relation.

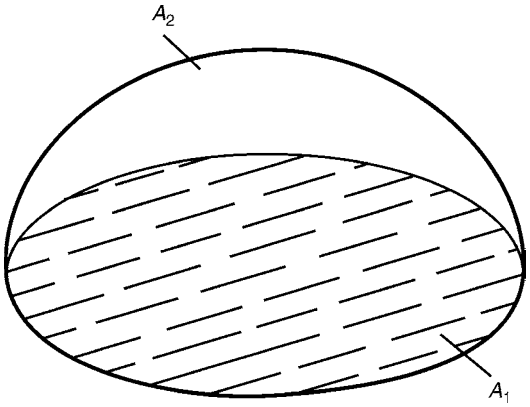
(c) Summarizing relation: If the hemisphere which is seen by surface i is completely surrounded by other surfaces k, all the radiation leaving surface i hit one of these other surrounding surfaces. The energy conservation equation then gives the summarizing relation

$$\sum_{k=1}^{n} \varphi_{ik} = 1. \tag{20}$$

which is shown in Fig. 9. Considering, for example, surface $i = 1$, the summarizing relation reads

$$\varphi_{12} + \varphi_{13} + \varphi_{14} + \varphi_{15} + \varphi_{16} + \varphi_{17} + \varphi_{18} = 1.$$

If a surface has a curvature it may happen that part of this surface can see itself. This would be true for a convex-shaped surface like the inner side of a bowl. In this situation,



K1. Fig. 11. Surfaces considered in example 1.

it has its own view factor $\varphi_{ii} > 0$. A plane surface or a concave surface always has a view factor $\varphi_{ii} = 0$.

(d) *Splitting relation*: For a situation shown in Fig. 10, we have

$$A_1 = A_1' + A_1''.$$

Then the reciprocal relation, Eq. (18), gives

$$A_1\varphi_{12} = A_1'\varphi_{12}' + A_1''\varphi_{12}'' \tag{21}$$

for all angles Φ

Example 1

A volume is surrounded by a hemisphere and a circular plane as shown in Fig. 11. The view factors for these two surfaces are calculated as

$$\varphi_{11} = 0; \qquad \varphi_{12} = 1$$

$$\varphi_{21} = \frac{A_1}{A_2}\,(\text{reciprocal relation})$$

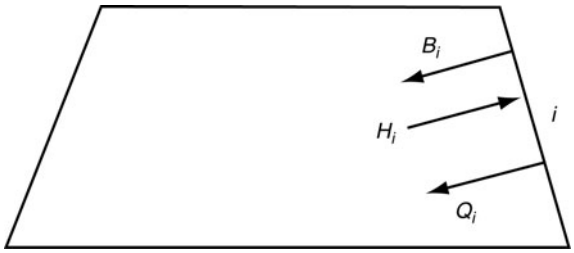
and

$$\varphi_{22} = 1 - \frac{A_1}{A_2}\,(\text{summarizing relation})$$

3 Radiation Heat Transfer Between Two or More Surfaces

3.1 Enclosure Method

In general, calculation of radiative heat transfer is extremely involved as for one surface the net radiation energy from *all* the surrounding environment in the view of this surface has to be considered a function of wavelength and solid angle. One big step to simplify such calculations is adopting the merits of a gray surface for all surfaces under consideration, so Lambert's cosine law accounts for the directional dependence and the black body spectrum, downscaled by the constant degree of emission ε, accounts for the simplified spectral behavior of each surface. The other problem, the interaction of a surface under consideration with all the surrounding surfaces in visual contact with this specific surface, can only be simplified if two surfaces have temperatures higher than the temperature of the other surfaces. Only then the Eqs. (17b) or (14) of the foregoing Sect. 2 can be applied to calculate the net radiative heat flux of a surface. If other surfaces have also to be considered, the enclosure method is recommended [3, 5].



K1. Fig. 12. The definition of some new variables needed for the enclosure method.

According to Fig. 12, some definitions have to be introduced here beforehand:

H_i sum of all radiation fluxes approaching a surface i (incoming radiation, brightness) in W/m^2

B_i sum of all radiation fluxes leaving a surface i (outgoing radiation) in W/m^2, which is the reflected part $(1 - a_i) \cdot H_i$ plus the own emission E_i. Transmission is not considered.

$\dot{Q}_i^c$ conductive or convective thermal heat flux to or from surface i in W.

With these definitions and an equation for energy conservation of surface I we get a set of n algebraic equations to solve the radiative exchange between these n surfaces forming the enclosure:

$$H_i = \sum_{k=1}^{n} B_k\varphi_{ki} \tag{22}$$

$$B_i = E_i + (1 - \varepsilon_i)\sum_{k=1}^{n} B_k\varphi_{ki} \tag{23}$$

$$Q_i^c = (B_i - H_i) \cdot A_i \text{ for } \varepsilon_i \leq 1 \tag{24}$$

$$Q_i^c = \frac{A_i}{1 - \varepsilon_i}(E_i - \varepsilon_i B_i) \text{ for } \varepsilon_i < 1. \tag{25}$$

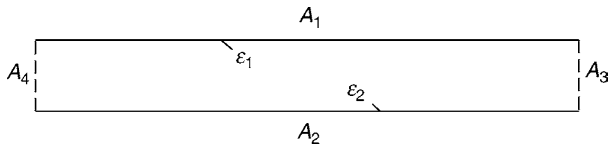
These equations hold true for the stationary case when all surfaces of the enclosure are assumed to be gray surfaces and no volumetric gas radiation is considered within the enclosure. For adiabatic surfaces within the enclosure we have

$$\dot{Q}_i = O \text{ and } H_i = B_i. \tag{26}$$

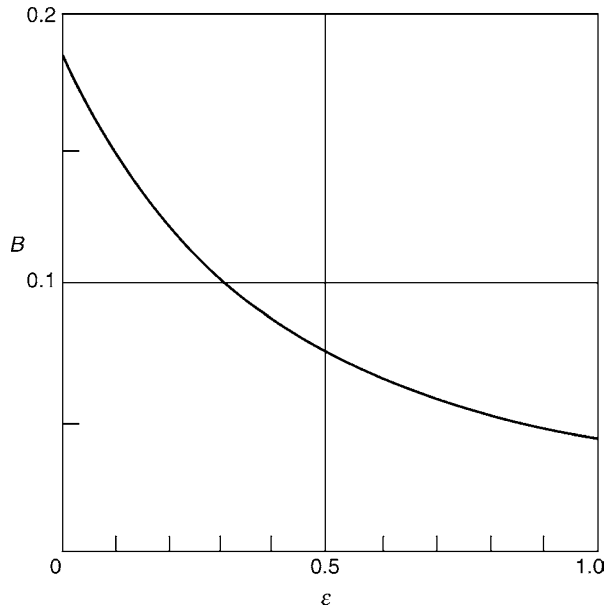
Example 2

In this example the radiative net energy flux between the two parallel planes A_1 and A_2 (see Fig. 13) is to be calculated using the enclosure method. The influence of the side surfaces A_3 and A_4 is to be neglected. The area $A_1 = A_2 = A$, the emissivities ε_1 and ε_2 as well as the temperatures T_1 and T_2 are given. Thus, we have for the view factors

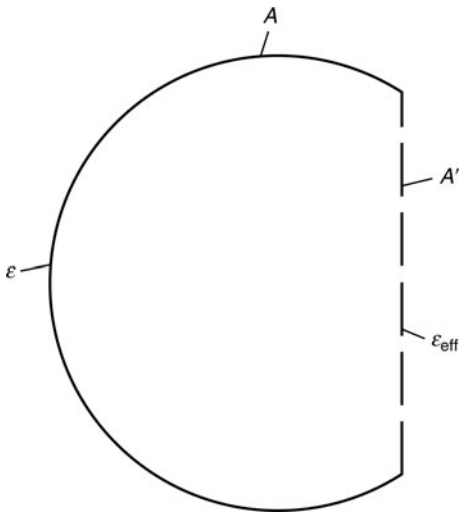
$$\varphi_{11} = \varphi_{22} = 0 \text{ and } \varphi_{12} = \varphi_{21} \simeq 1 \text{ and}$$
$$\varphi_{13} = \varphi_{23} = \varphi_{14} = \varphi_{24} \simeq 0$$



K1. Fig. 13. Radiative heat exchange between two parallel plates addressed in example 2.



K1. Fig. 14. The radiation transmission factor in Eq. (28) as a function of particle emissivity ε [18].

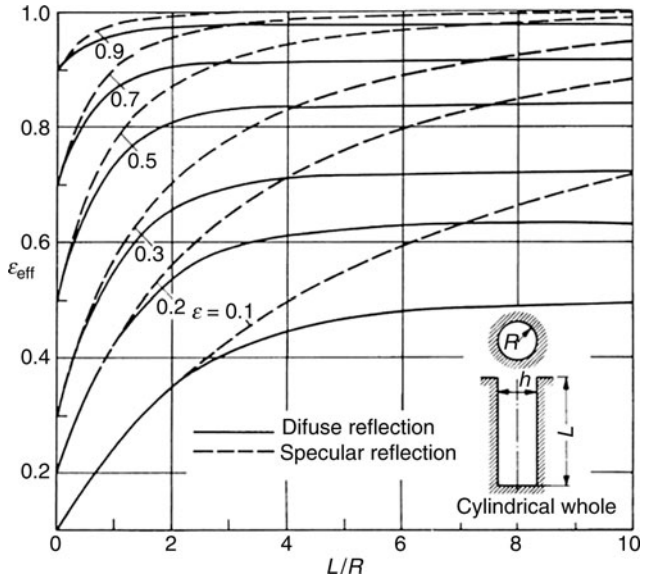


K1. Fig. 15. Effective emissivity of a hollow sphere.

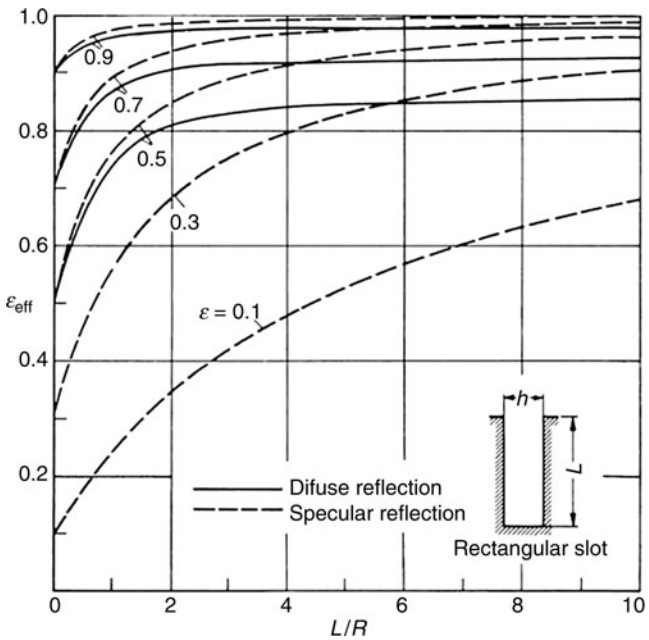
Equation (23) gives

$$B_1 = E_1 + (1-\varepsilon_1)\cdot B_2 \cdot \varphi_{21} \text{ and } B_2 = E_2 + (1-\varepsilon_2)\cdot B_1 \cdot \varphi_{12}.$$

This gives the overall outgoing emission B_1 and B_2 of each surface:



K1. Fig. 16. Effective degree of emission for cylindrical holes as a function of the aspect ratio L/R and the degree of emission of the wall [17].



K1. Fig. 17. Effective degree of emission for rectangular cavities as a function of the aspect ratio L/h and the degree of emission of the wall [17].

$$B_1 = \frac{E_1 + (1-\varepsilon_1)\cdot E_2}{\varepsilon_1 + \varepsilon_2 - \varepsilon_1\varepsilon_2} \quad \text{and} \quad B_2 = \frac{E_2 + (1-\varepsilon_2)\cdot E_1}{\varepsilon_1 + \varepsilon_2 - \varepsilon_1\varepsilon_2}$$

The net heat flux Q_i^c for surface 1 for example results from Eqs. (24) and (22)

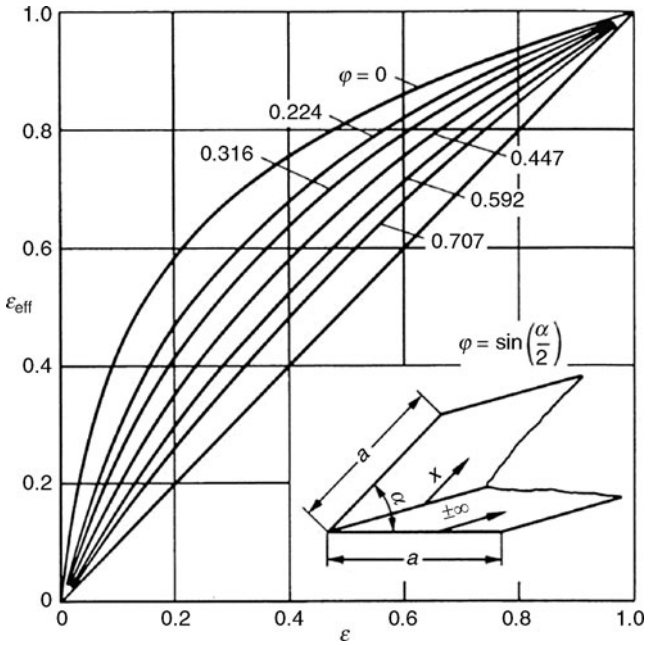
$$\dot{Q}_1 = (B_1 - H_1)A_1 = (B_1 - B_2)A_1 = \frac{\varepsilon_2 E_1 - \varepsilon_1 E_2}{\varepsilon_1 + \varepsilon_2 - \varepsilon_1\varepsilon_2} A_1 \text{ or}$$

$$\dot{Q}_1 = \frac{\sigma A_1}{\frac{1}{\varepsilon_1} + \frac{1}{\varepsilon_2} - 1}\left(T_1^4 - T_2^4\right)$$

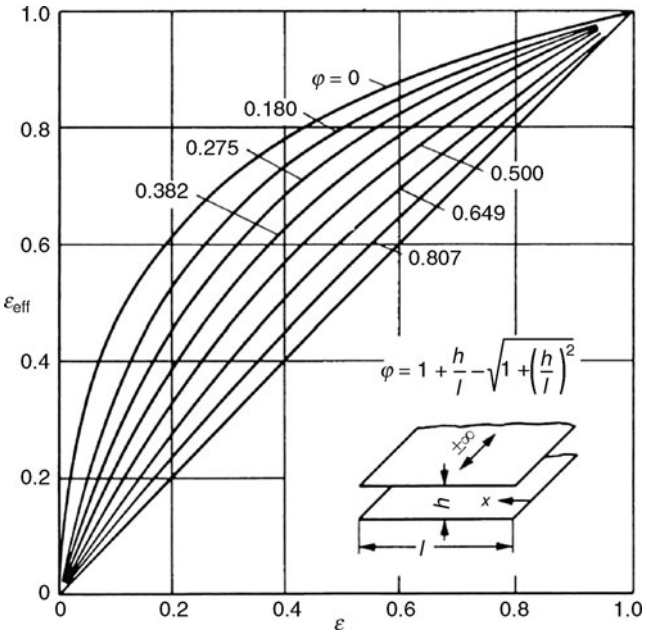
In this special case having parallel plates the result is the same as given by Eq. (12), even though Q_i^c and Q_{12} have different definitions.

3.2 Radiation Heat Transfer in Packed Beds

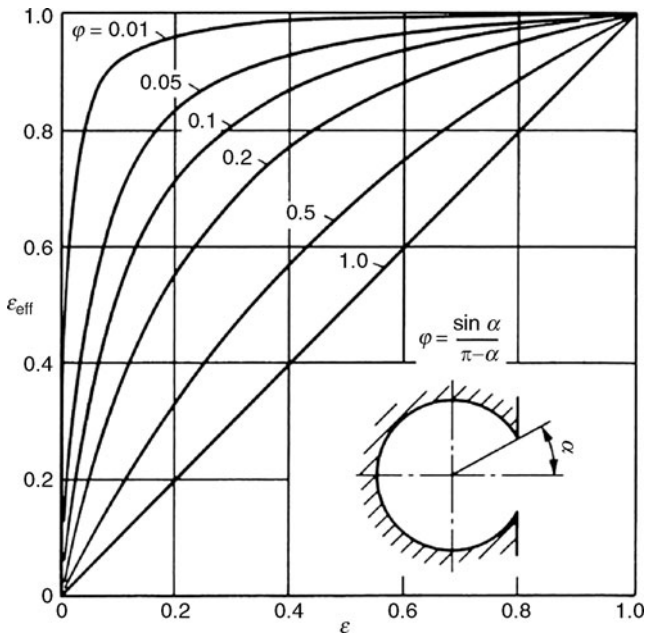
At elevated temperatures radiation heat transfer between the particles of a packed bed becomes important, especially if other heat transfer modes such as conduction and convection are low. Typically, if the particle diameter d is much larger than wavelength λ, $d >> \lambda$, a packed bed behaves like an optical dense material where the mean free length of a photon is in the order of a particle diameter. As Vortmeyer [15] has shown the radiative heat transfer may then be calculated by Fourier's law of heat conduction, using an effective radiation conductivity λ_s:



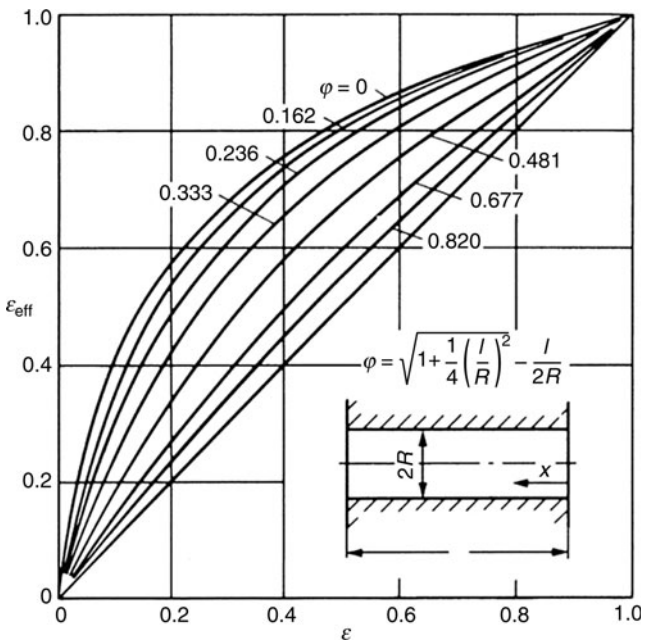
K1. Fig. 18. Effective emissivity for a wedge-type cavity of infinite length as a function of wall emissivity [19].



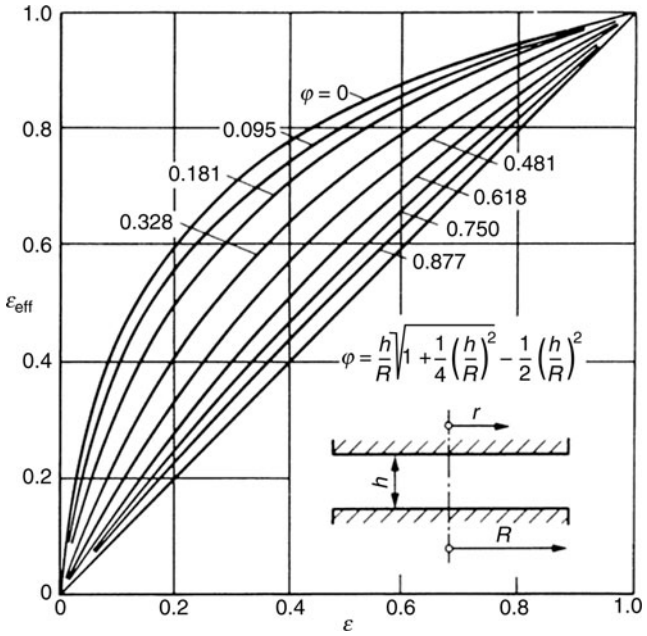
K1. Fig. 20. Effective degree of emission for a parallel wall cavity of infinite length [19].



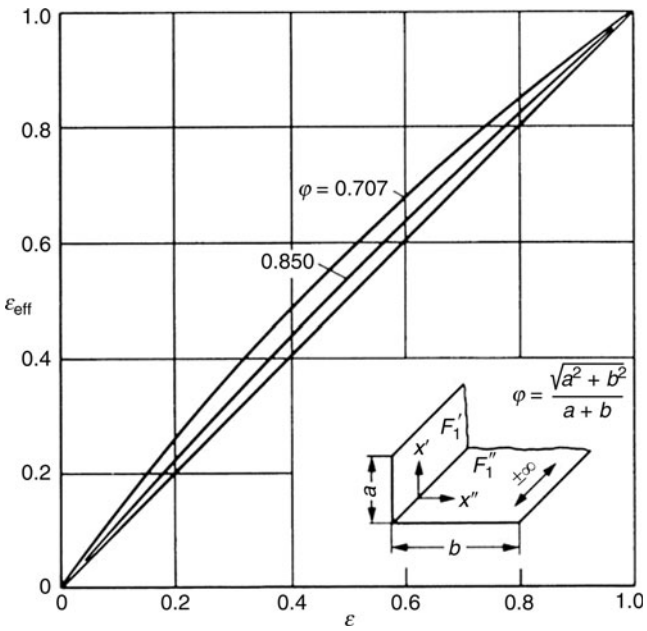
K1. Fig. 19. Effective degree of emission for a cylindrical shaped cavity of infinite length [19].



K1. Fig. 21. Effective degree of emission for a cylindrical hole with two open ends [19].



K1. Fig. 22. Effective degree of emission for parallel circle-shaped planes [19].



K1. Fig. 23. Effective degree of emission for an edge with perpendicular walls and infinite length [19].

The area specific heat flux $\dot{q}$ in W/m^2 reads

$$\dot{q} = -\lambda_s \cdot \frac{\mathrm{d}T}{\mathrm{d}x}, \tag{27}$$

were x is the coordinate along the main axis of the packed bed. The radiation conductivity λ_s is calculated by

$$\lambda_s = \frac{2B + \varepsilon(1 - B)}{2(1 - B) - \varepsilon(1 - B)} \sigma 4T^3 d, \text{ in W/(m K)}. \tag{28}$$

In Eq. (28) we have

ε emissivity of a particle within the packed bed
B radiation transmission factor (see Fig. 14)
d mean particle diameter
σ Stefan–Boltzmann constant, see Eq. (2).

The radiation transmission factor B actually also depends on the porosity of the packed bed. For the dependency on the particle degree of emission ε shown in Fig. 14 a mean porosity of 40% was assumed.

The derivation of Eq. (28) is based on the assumption that the particles of the packed bed have a high thermal conductivity λ. So this equation deviates from that of packed beds having solid particles with low thermal conductivity. More details as well as other theories on effective heat transfer within packed beds may be found in Chap. K4 and in [16].

3.3 Radiation from Cavities

Radiation escaping from an isothermal enclosure having only a small opening gives black body radiation in good approximation ($\varepsilon_{eff} \simeq 1$), independently of the degree of emissivity of the cavity surrounding material. This is because the black body radiation is physically related to "Hohlraum" radiation, i.e., radiation within any isothermal cavity. If a surface has cavities with large openings, such as a mounting table with drilling holes or slots, the degree of emissivity of this surface will be smaller than a black body surface but larger than the emissivity of the plane wall material ε. The effective degree of emissivity of a spherical cavity shown in Fig. 15, for example, is given by Eckert [17] to be

$$\varepsilon_{eff} = \frac{\varepsilon}{\varepsilon + \frac{A'}{A}(1 - \varepsilon)}.$$

Figures 16 through 23 give the effective degree of emission for cavities with different geometrical shapes, as cylindrical holes or triangular gaps. The radiation escaping from these cavities is typically *not* diffusive radiation, so Lambert's cosine law will not be truly valid even though the wall material itself may be a gray body.

K2 View Factors

Dieter Vortmeyer[1] · *Stephan Kabelac*[2]
[1]Munich, Germany
[2]Helmut-Schmidt-Universität, Universität der Bundeswehr Hamburg, Hamburg, Germany

1 Determination of View Factors

The view factor φ_{12} is a purely geometrical value which describes the fraction of the total radiation from a surface 1 that hits another surface 2; see Sect. 2.2 in Chap. K1. So in almost all cases of thermal radiation heat transfer, the first step in the calculation procedure is to determine the view factor which is valid for the two surfaces under consideration. The general formula for the view factor is

$$\varphi_{12} = \frac{1}{\pi A_1} \int_{A_1} \int_{A_2} \frac{\cos\beta_1 \cos\beta_2}{s^2} \, \mathrm{d}A_1 \, \mathrm{d}A_2, \tag{1}$$

where s is the length of the straight line which connects two differential area elements, one on each surface (Fig. 1). β_1 and β_2 are the polar angles between the normal line of these differential elements and the connecting line. Equation (1) holds true for two arbitrary surfaces obeying Lamberts cosine law, i.e., ideal diffuse radiating surfaces. As the evaluation of Eq. (1) is elaborate and as only geometrical parameters are involved, a number of solutions of Eq. (1) exist for different groupings of surfaces. These solutions are ready for application; they are explained in the following.

If one of the surfaces under consideration is small when compared to the second surface, this surface may be taken to be area element ΔA_1, so one integration is omitted and Eq. (1) simplifies to

$$\varphi_{12} = \frac{1}{\pi} \int_{A_2} \frac{\cos\beta_1 \cos\beta_2}{s^2} \, \mathrm{d}A_2. \tag{2}$$

Also for Eq. (2), special solutions exist which are introduced in the following section. The solutions given here are valid for simple geometrical settings and common technical situations. In some more complicated situations, the surfaces under consideration can be subdivided to find solutions given in this chapter. This also holds true for situations for large surfaces of nonuniform temperatures. More view factors and other methods of solution of Eq. (1), as for example the Monte–Carlo method, are described in [1–4].

The reciprocal relation [see Eq. (18) in Chap. K1]

$$A_i \varphi_{ik} = A_k \varphi_{ki} \tag{3}$$

should be kept in mind, as well as the summarizing relation

$$\sum_{k=1}^{n} \varphi_{ik} = 1 \tag{4}$$

[see Eq. (20) in Chap. K1].

2 Determination of the View Factor for Radiative Transfer from a Finite Surface to a Small Area Element

As long as the Lambert cosine law applies (see Sect. 1.2 in Chap. K1), view factors for small diffuse area elements can be determined by the graphical and analytical methods as described in this section.

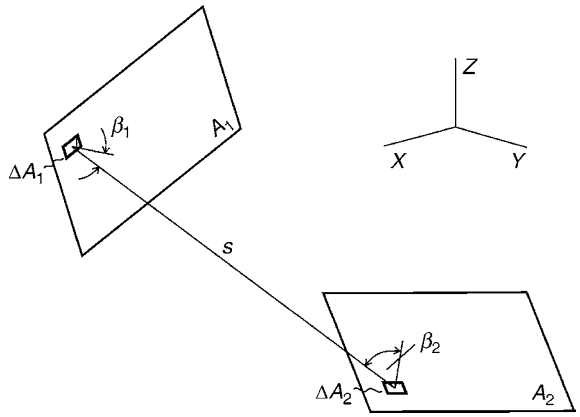
2.1 Graphical Method [5]

The graphical procedure is illustrated in Fig. 2. Thus draw a plane (x, y-plane) through the element of area ΔA_1, and describe a hemisphere around the center O. O is the center point of area element ΔA. Connect O to points on the circumference of the surface A_2 at which the radiation is intercepted, e.g., to the points a_2, b_2, c_2, and d_2 on the rectangle shown in Fig. 1, so that the straight lines Oa_2, Ob_2, Oc_2, and Od_2 intersect the hemisphere surface at the points a_0, b_0, c_0, and d_0. Then project the surface formed by these points vertically onto the x, y plane to obtain the hatched area a_1, b_1, c_1, and d_1. The ratio of this area to the area of the circle formed by the intersection of the hemisphere with the x, y plane is the view factor φ_{12} to be determined.

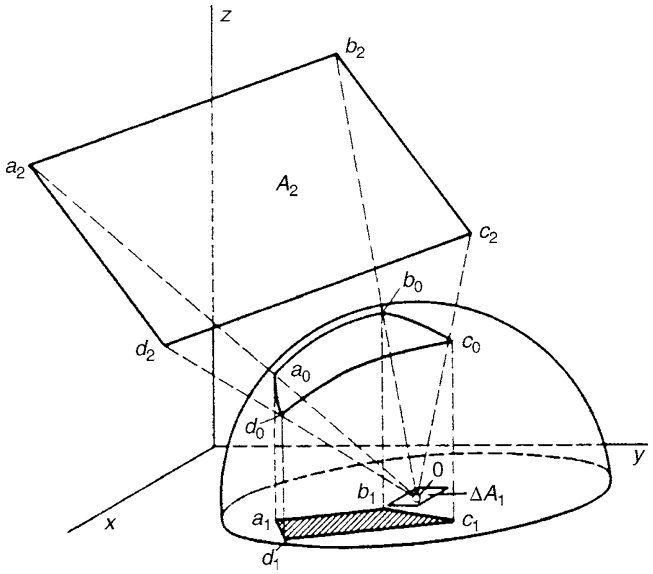
2.2 Analytical Method

In some comparatively simple cases, the view factor φ_{12} of the area element ΔA_1 from which radiation is emitted to the surface

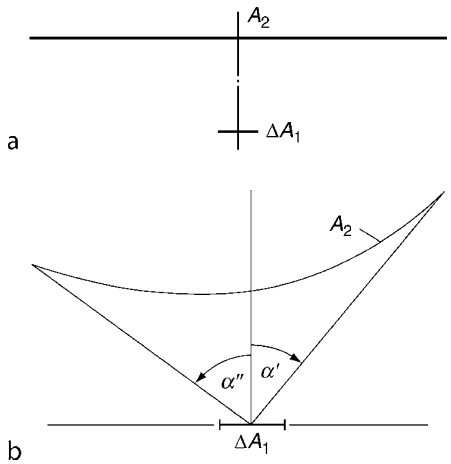
VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_41,



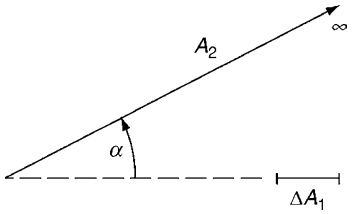
K2. Fig. 1. Two arbitrary surfaces A_1 and A_2 in space.



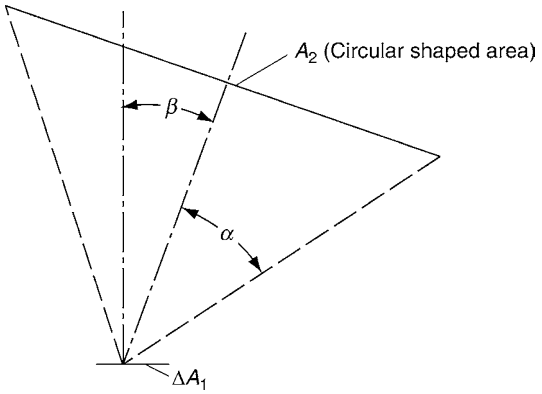
K2. Fig. 2. Graphical determination of the view factor φ_{12}.



K2. Fig. 3. (**a**) Plane parallel to ΔA_1 and of large extent as compared to the distance between ΔA_1 and A_2. In this case we have (**b**) infinitely long surface of any given profile within the space limited by the tangents drawn from the element for area ΔA_1.



K2. Fig. 4. Surface of infinite extent that intersects the plane of the element of area ΔA at an angle α.



K2. Fig. 5. Surface A_2 of circular shape arranged so that the line normal to its center passes through the element of area ΔA_1.

A_2 can be determined from the following equations or diagrams. The shape of the area A_2 and its position relative to ΔA_1 are shown in the diagrams given in each case, and the symbols used should be clear as given within Figs. 3–11:

$$\varphi_{12} = 1. \tag{5}$$

From Fig. 3b,

$$\varphi_{12} = \frac{\sin\alpha' + \sin\alpha''}{2}. \tag{6}$$

From Fig. 4, we have

$$\varphi_{12} = \frac{1}{2}(1 + \cos\alpha). \tag{7}$$

From Fig. 5,

$$\varphi_{12} = \sin^2\alpha \cdot \cos\alpha, \quad \text{if } (\alpha + \beta) \leq 90°,$$

or

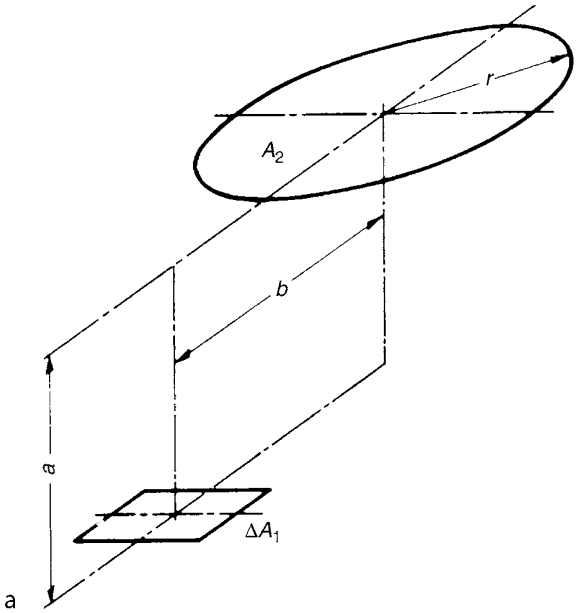
$$\varphi_{12} = \frac{\alpha - \sin\alpha \cdot \cos\alpha}{\pi}, \quad \text{for } \beta = 90°. \tag{8}$$

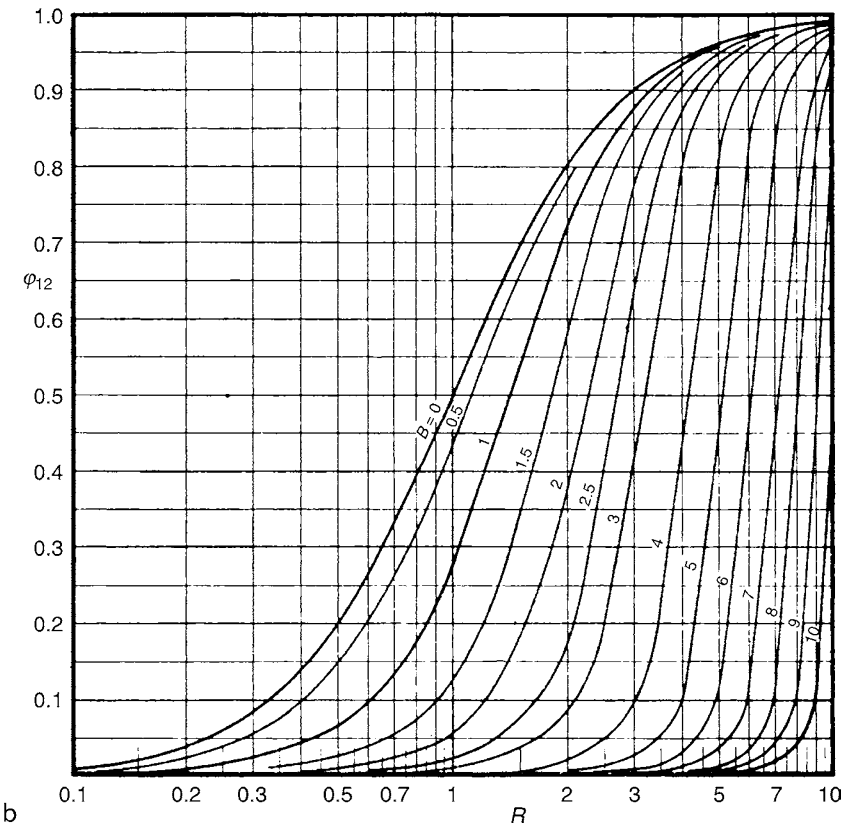
In other words, the circle A_2 is perpendicular to ΔA_1 in the second case. In this case, only the upper semicircle A_2 above the horizon of ΔA_1 is exposed to the radiation.

From Fig. 6,

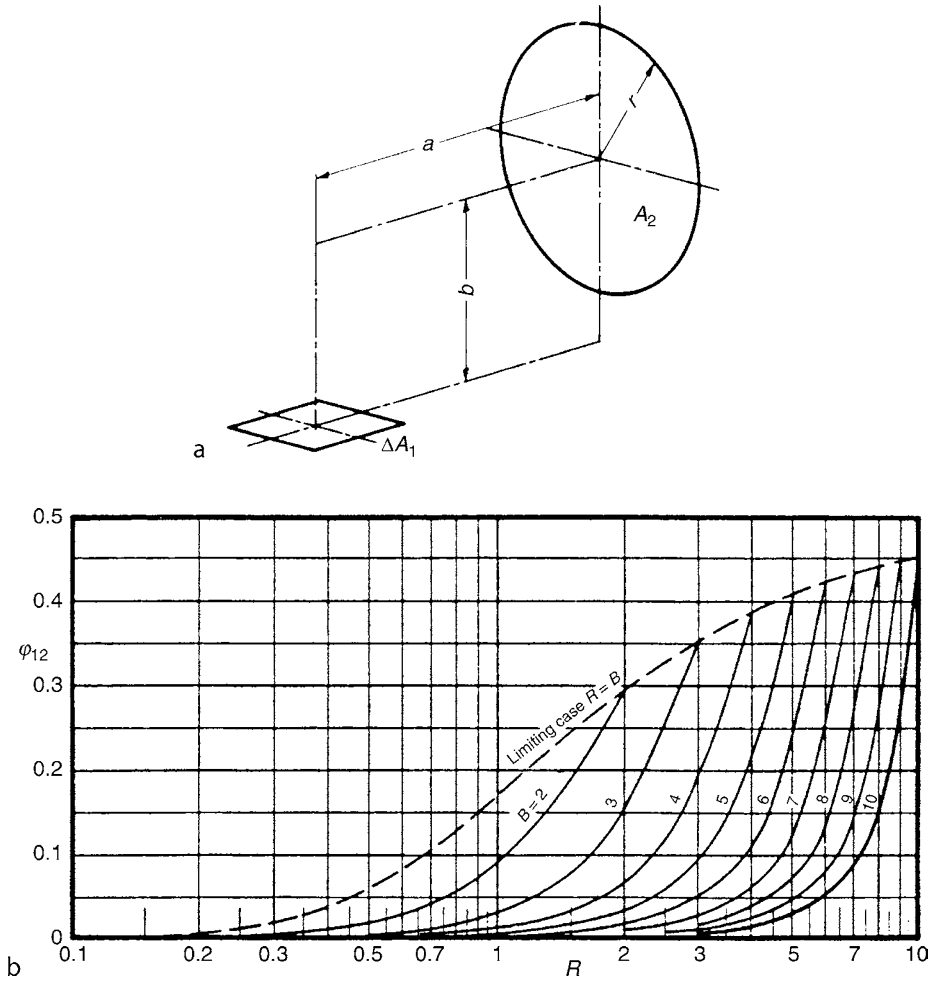
$$B = \frac{b}{a}, \quad R = \frac{r}{a},$$

$$\varphi_{12} = \frac{1}{2} - \frac{1 + B^2 - R^2}{2\sqrt{B^4 + 2B^2(1 - R^2) + (1 + R^2)^2}}. \tag{9}$$





K2. Fig. 6. (**a**) Circular surface parallel to the element of area ΔA_1; (**b**) view factor φ_{12} as a function of R and B for the radiation emanating from an element of area onto a circular surface parallel to that element.



K2. Fig. 7. (**a**) Circular surface perpendicular to the element of area; (**b**) view factor φ_{12} as a function of R and B for the radiation emanating from an element of area onto a circular surface perpendicular to that element (see Fig. 7a).

From Fig. 7,

$$B = \frac{b}{a}, \quad R = \frac{r}{a},$$

$$\varphi_{12} = \frac{1}{2B}\left[\frac{1 + B^2 + R^2}{\sqrt{B^4 + 2B^2(1 - R^2) + (1 + R^2)^2}} - 1\right]. \qquad (10)$$

Equation (7) and Fig. 7b are not valid unless $b \geq r$ which means unless the circle lies above the horizon of ΔA_1.

From Fig. 8,

$$B = \frac{b}{a}, \quad C = \frac{c}{a},$$

$$\varphi_{12} = \frac{1}{2\pi}\left(\frac{B}{\sqrt{1+B^2}}\arctan\frac{C}{\sqrt{1+B^2}} + \frac{C}{\sqrt{1+C^2}}\arctan\frac{B}{\sqrt{1+C^2}}\right). \qquad (11)$$

If the rectangle A_2 does not have any of its corners exactly on the normal line to the element of area ΔA_1, it can be subdivided into a number of smaller rectangles with a common corner that lies on the normal. Alternatively, it can be represented as the sum and difference of rectangles with a common corner of this nature. In this case, the view factors for each part of the rectangle can be determined by repeated application of Eq. (11) or Fig. 8b, and the desired value for φ of the area A_2 can be obtained by appropriate addition or subtraction.

The procedure for rectangles in a general position perpendicular to the element of area ΔA_1 as shown in Fig. 9a is similar to that stated for parallel rectangles.

From Fig. 9,

$$B = \frac{b}{a}, \quad C = \frac{c}{a},$$

$$\varphi_{12} = \frac{1}{2\pi}\left(\arctan B - \frac{1}{\sqrt{1+C^2}}\arctan\frac{B}{\sqrt{1+C^2}}\right). \qquad (12)$$

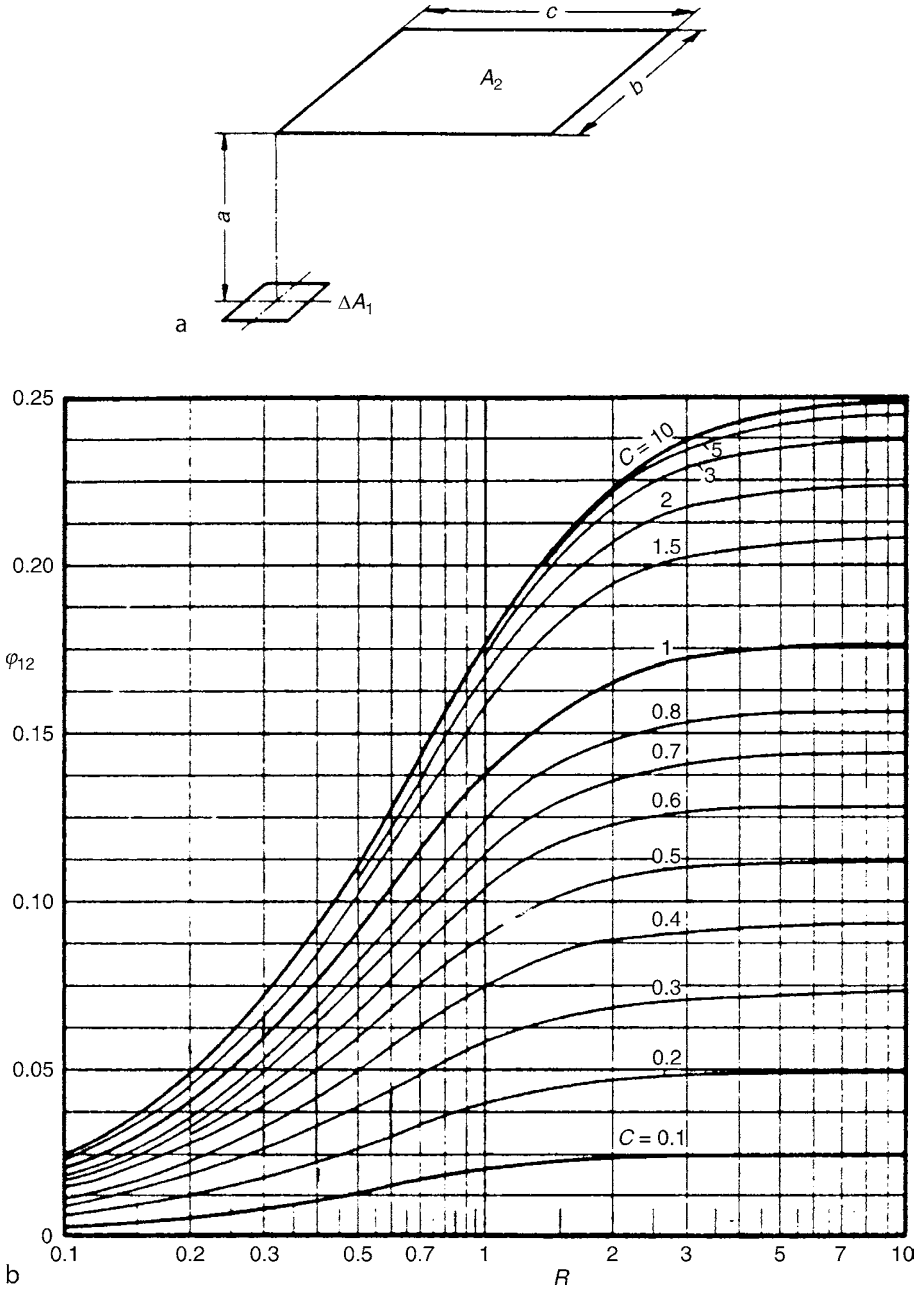
From Fig. 10,

$$A = \frac{a}{r}, \quad B = \frac{b}{r},$$
$$X = (1 + B)^2 + A^2,$$

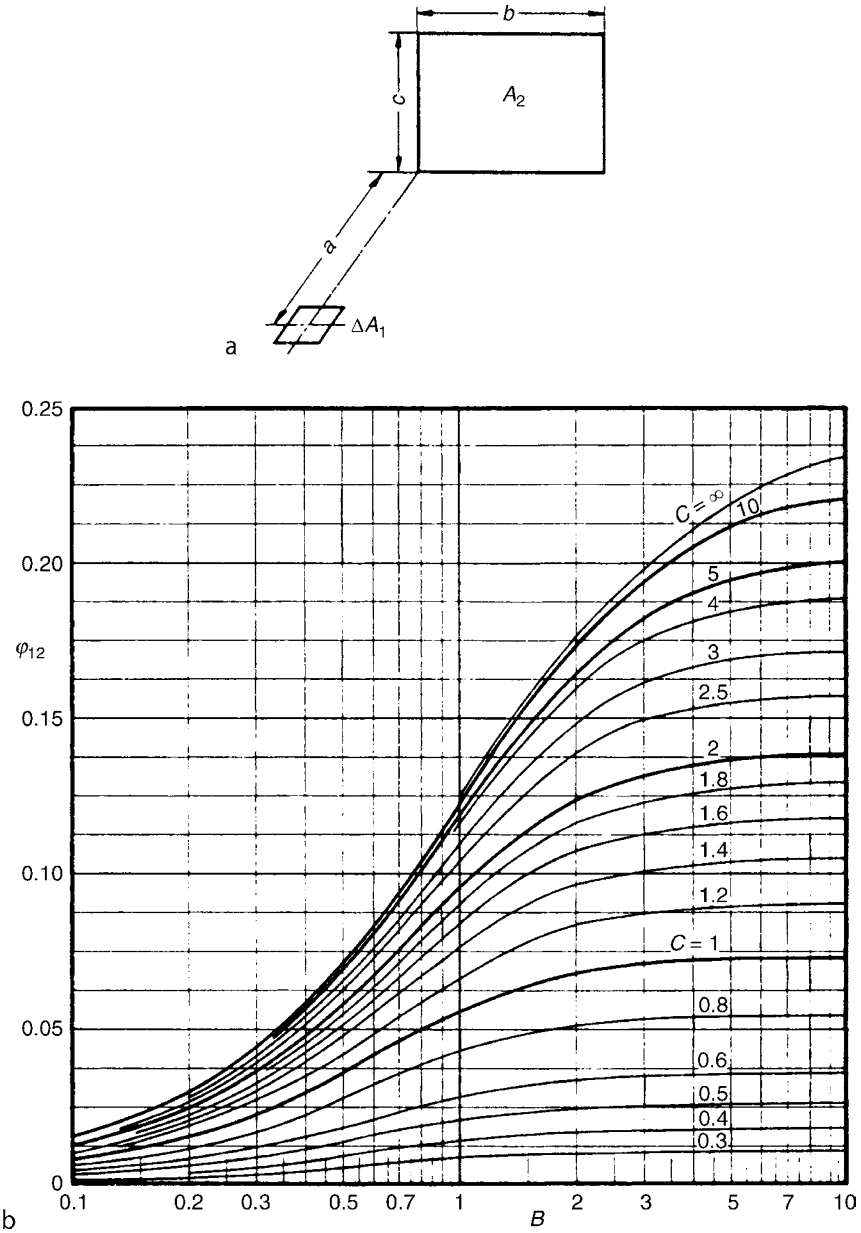
and

$$Y = (1 - B)^2 + A^2,$$

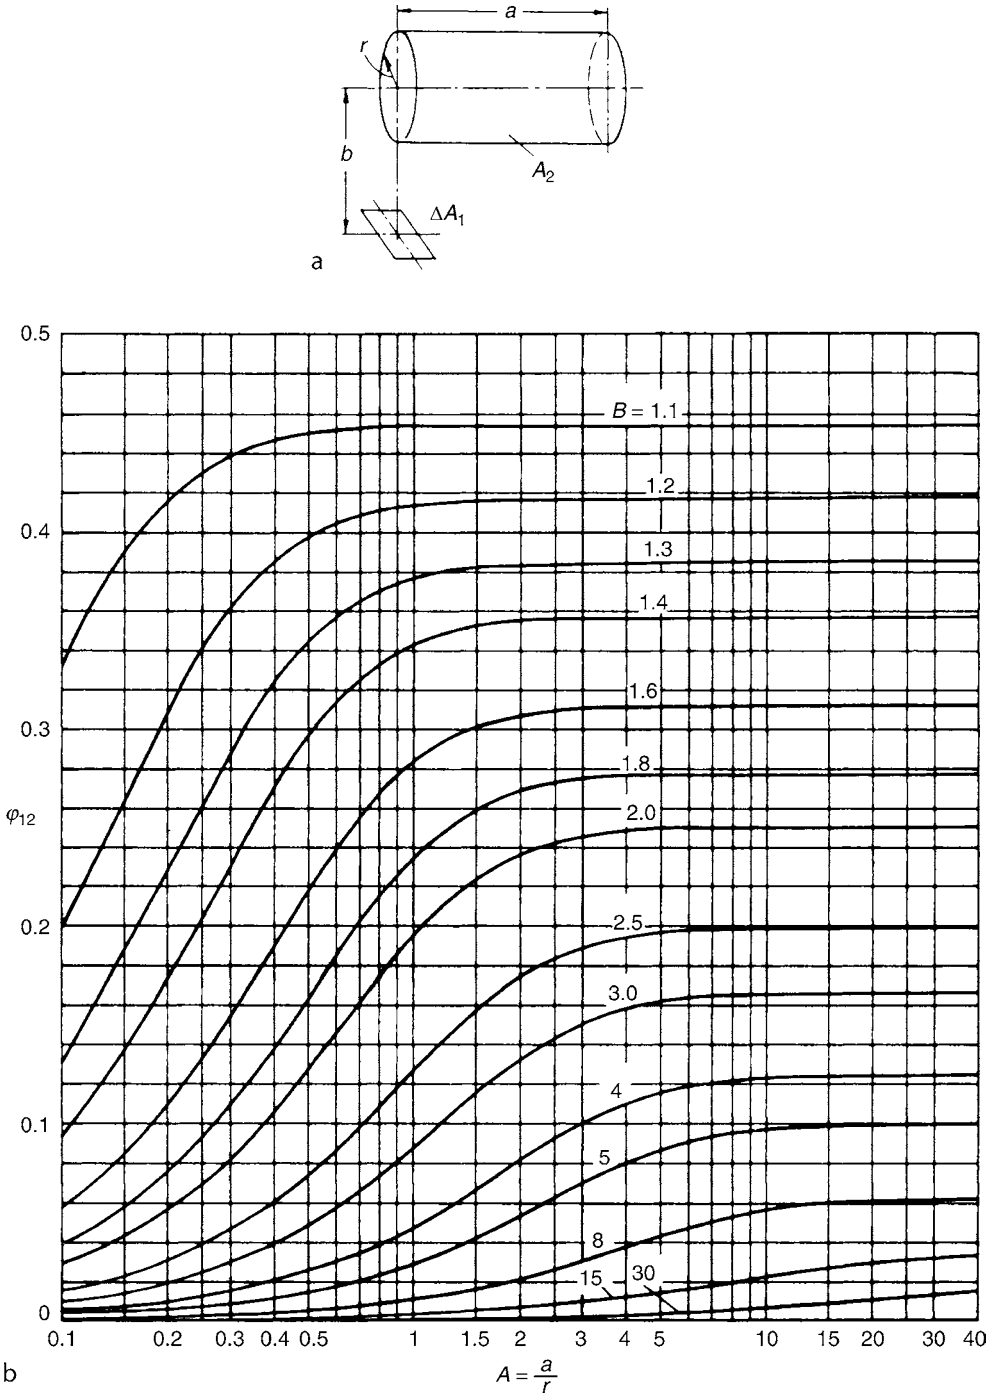
$$\varphi_{12} = \frac{1}{\pi B}\arctan\frac{A}{\sqrt{B^2 - 1}} + \frac{A}{\pi}\left[\frac{X - 2B}{B\sqrt{XY}}\arctan\sqrt{\frac{X(B-1)}{Y(B+1)}} - \frac{1}{B}\arctan\sqrt{\frac{B-1}{B+1}}\right]. \qquad (13)$$



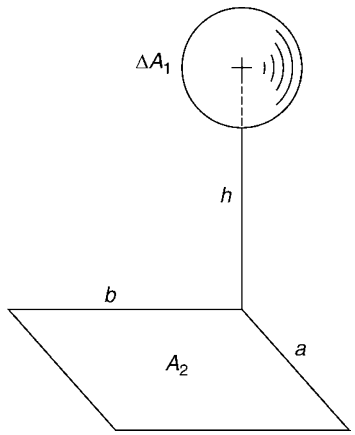
K2. Fig. 8. (**a**) Parallel rectangular surface A_2 with a corner that lies on the vertical to the center of the element of area ΔA_1; (**b**) view factor φ_{12} as a function of B and C for the radiation emanating from an element of area ΔA_1 onto a rectangular surface A_2 parallel to that element.



K2. Fig. 9. (**a**) Rectangular surface A_2 perpendicular to the element of area ΔA with the one side in the plane of the element and with one corner which is the normal to the line that passes through ΔA_1; (**b**) view factor φ_{12} as a function of B and C for the radiation emanating from an element of area onto a rectangular surface perpendicular to that element (see Fig. 9a).



K2. Fig. 10. (**a**) Cylinder with the circumferential surface A_2 and the axis parallel to the element of area ΔA_1. The vertical line through the center of the element ΔA_1 intersects the axis at one front face of the cylinder; (**b**) view factor φ_{12} as a function of A and B for radiation between an element of area ΔA_1 and a cylinder (see Fig. 10a).



K2. Fig. 11. Radiation between a plane surface A_2 and a small differential spherical surface ΔA_1 [8].

From Fig. 11,

$$A = \frac{a}{h}, \quad B = \frac{b}{h},$$
$$\varphi_{12} = \frac{1}{8} - \frac{1}{4\pi} \arctan \sqrt{\frac{1 + A^2 + B^2}{A^2 B^2}}. \tag{14}$$

More solutions for the view factor of different geometrical situations can be found in literature [1–4].

3 Determination of the View Factor φ_{12} for Radiative Transfer Between Finite Surfaces

In Sect. 2, the view factor φ_{12} was given for cases where one of the two surfaces exchanging radiation was small as compared to the other surface. In this situation, which is favorable in cases where one surface has to be subdivided into small surface elements, Eq. (2) has to be solved. Now cases are described in this section below, where both areas A_1 and A_2 are of finite size. In these cases, Eq. (1) could be solved and complete solutions for the entire surfaces are available. The heat flux transferred by radiation is then calculated by means of Eqs. (17a) or (17b) in Chap. K1.

From Fig. 12,

$$R_1 = \frac{r_1}{a}, \quad R_2 = \frac{r_2}{a},$$
$$\varphi_{12} = \frac{1}{2R_1^2}\left(1 + R_1^2 + R_2^2 - \sqrt{(1 + R_1^2 + R_2^2)^2 - 4R_1^2 R_2^2}\right). \tag{15}$$

Circles of the same radius are regarded as a special case, i.e., $r_1 = r_2 = r$; $R = r/a$

$$\varphi_{12} = \frac{1}{2R^2}\left(1 + 2R^2 - \sqrt{1 + R^2}\right). \tag{16}$$

From Fig. 13,

$$B = \frac{b}{a}, \quad C = \frac{c}{a},$$
$$\varphi_{12} = \frac{1}{\pi}\left[\frac{1}{BC}\ln\frac{(1+B^2)(1+C^2)}{1+B^2+C^2} - \frac{2}{B}\arctan C - \frac{2}{C}\arctan B + \frac{2}{C}\sqrt{1+C^2}\arctan\frac{B}{\sqrt{1+C^2}} + \frac{2}{B}\sqrt{1+B^2}\arctan\frac{C}{\sqrt{1+B^2}}\right]. \tag{17}$$

A special case of parallel rectangles of the same size is shown in Fig. 13c:

$$B = \frac{b}{a}, \quad C = \frac{c}{a} = \infty,$$
$$\varphi_{12} = \sqrt{\frac{1 + B^2 - 1}{B}}. \tag{18}$$

Note that the length c is infinite.

From Fig. 14,

$$B = \frac{b}{a}, \quad C = \frac{c}{a},$$
$$\varphi_{12} = \frac{1}{\pi}\left(\frac{C}{\sqrt{1+C^2}}\arctan\frac{B}{\sqrt{1+C^2}} + \frac{\sqrt{1+B^2}}{B}\arctan\frac{C}{\sqrt{1+B^2}} - \frac{1}{B}\arctan C\right). \tag{19}$$

If the two sides of each surface A_1 and A_2 do not lie one above the other, the aim of the calculation can be achieved by applying the last equation or diagram twice. Whether the two values of φ_{12} thus obtained have to be added or subtracted depends on the position of A_1.

From Fig. 15,

$$B = \frac{b}{a}, \quad C = \frac{c}{a},$$
$$\varphi_{12} = \frac{1}{\pi}\left[\arctan\frac{1}{B} - \frac{B}{\sqrt{B^2+C^2}}\arctan\frac{1}{\sqrt{B^2+C^2}} - \frac{B}{2}\ln\frac{(B^2+C^2)(1+B^2)}{(1+B^2+C^2)B^2}\right]. \tag{20}$$

From Fig. 16,

$$B = \frac{b}{a}, \quad C = \frac{c}{a},$$
$$\varphi_{12} = \frac{1}{\pi B}\left\{B\cdot\arctan\frac{1}{B} + C\cdot\arctan\frac{1}{C} - \sqrt{B^2+C^2}\arctan\frac{1}{\sqrt{B^2+C^2}} + \frac{1}{4}\left[B^2\ln\frac{(1+B^2+C^2)B^2}{(B^2+C^2)(1+B^2)} + C^2\ln\frac{(1+B^2+C^2)C^2}{(B^2+C^2)(1+C^2)} - \ln\frac{1+B^2+C^2}{(1+B^2)(1+C^2)}\right]\right\}. \tag{21}$$

Figure 16c is an example for the general case of two vertical rectangular surfaces at a right angle to one another.

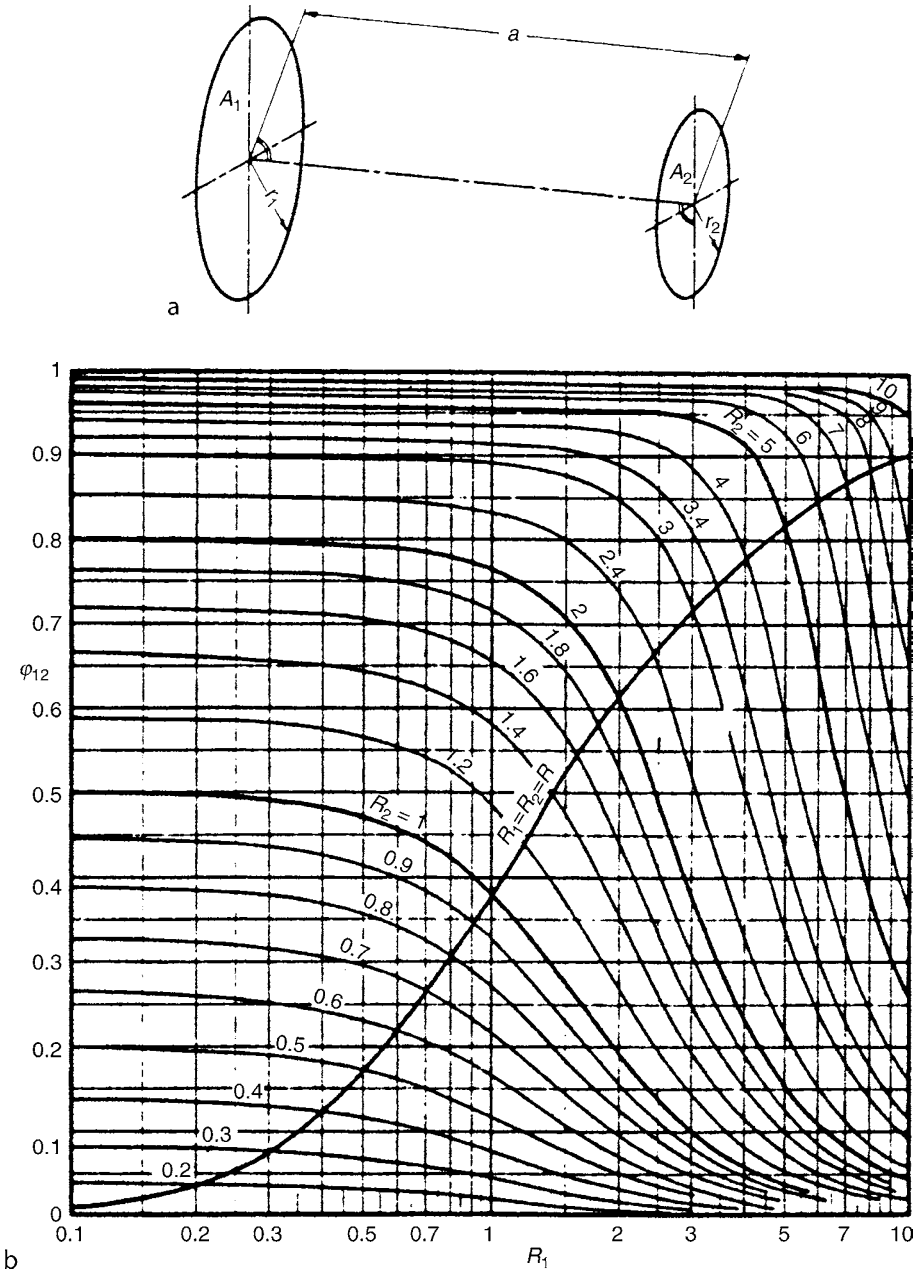
The above equation must be applied several times in this case in order to obtain the desired result:

$$\varphi_{12} = \varphi_{A_1A_2} = \frac{B''(\varphi_{B''C''} - \varphi_{B''C'}) - B'(\varphi_{B'C''} - \varphi_{B'C'})}{B'' - B'}. \tag{22}$$

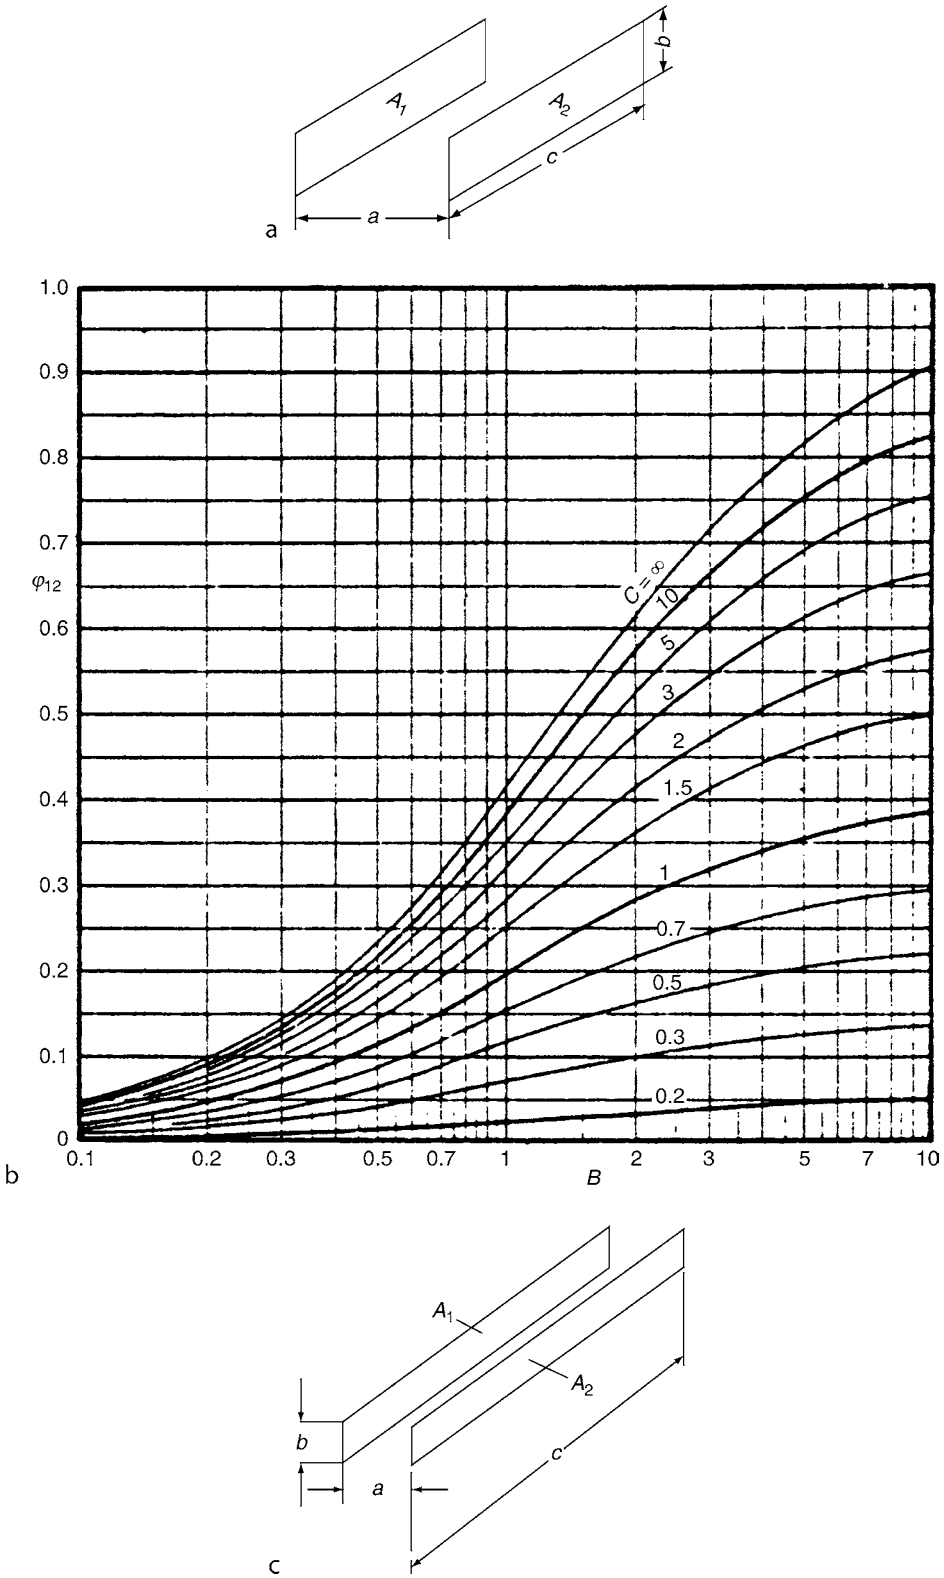
The individual view factors involved in this equation become clear by the subscripts and by referring to Fig. 16c.

From Fig. 17,

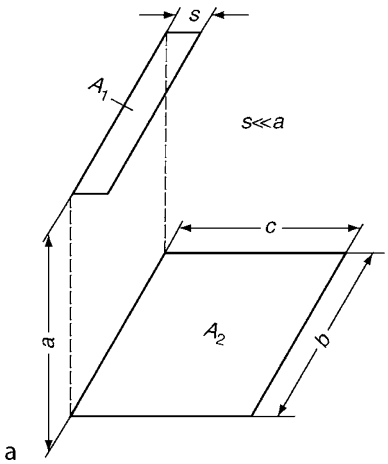
$$\varphi_{12} = \frac{\cos\beta_1 \cos\beta_2}{\pi s^2} A_2 = \frac{n_1 n_2}{\pi s^4} A_2, \tag{23}$$

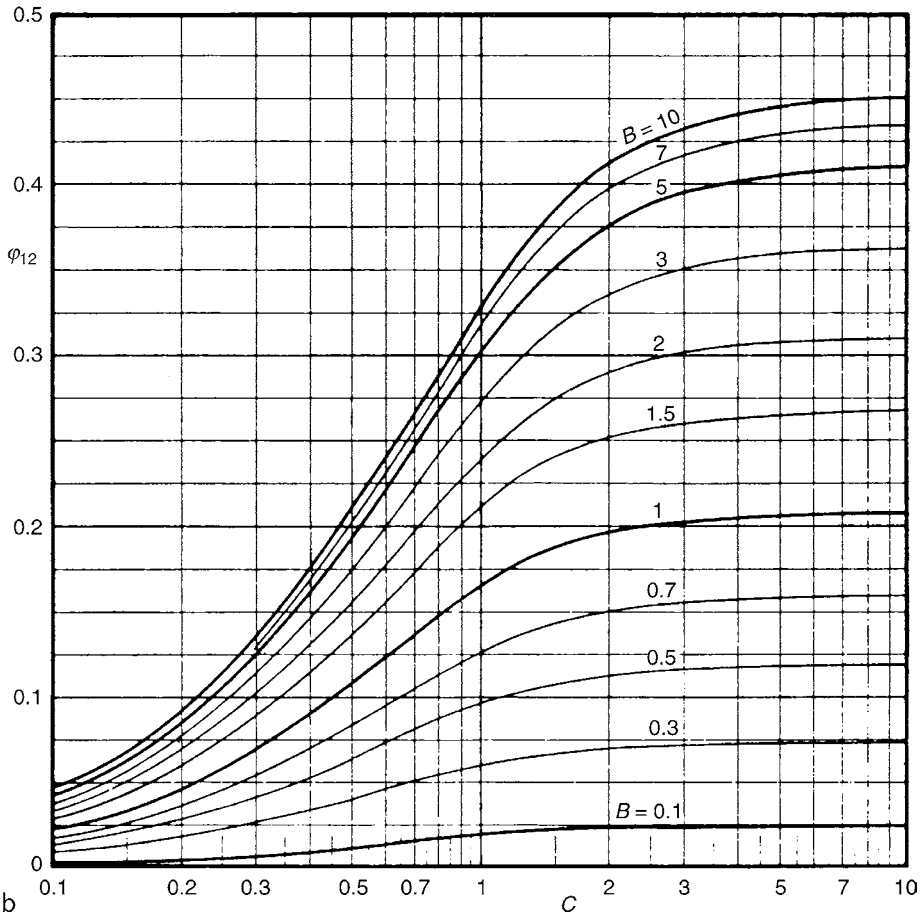


K2. Fig. 12. (**a**) Radiation between two parallel circular surfaces with a common vertical line through their centers; (**b**) view factor φ_{12} as a function of R_1 and R_2 for radiation between parallel circular surfaces with a common vertical line through their centers (see Fig. 12a).

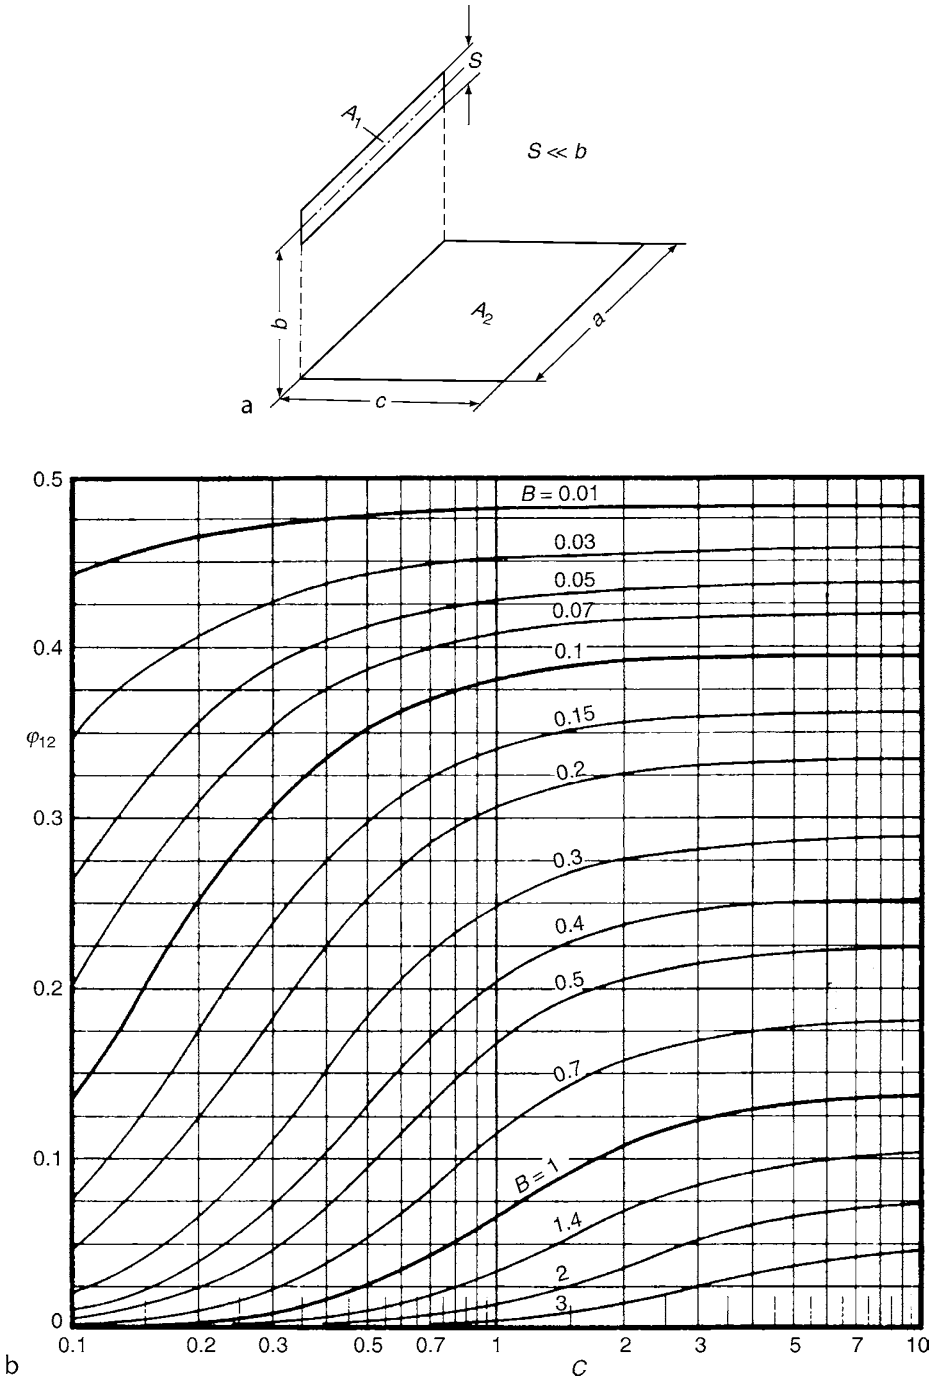


K2. Fig. 13. (**a**) Radiation between two parallel and opposite rectangular surfaces of the same size; (**b**) view factors φ_{12} as a function of B and C for radiation between two parallel and opposite rectangular surfaces of the same size; (**c**) special case of pairs of strips, where the length c of both stripes is infinite.

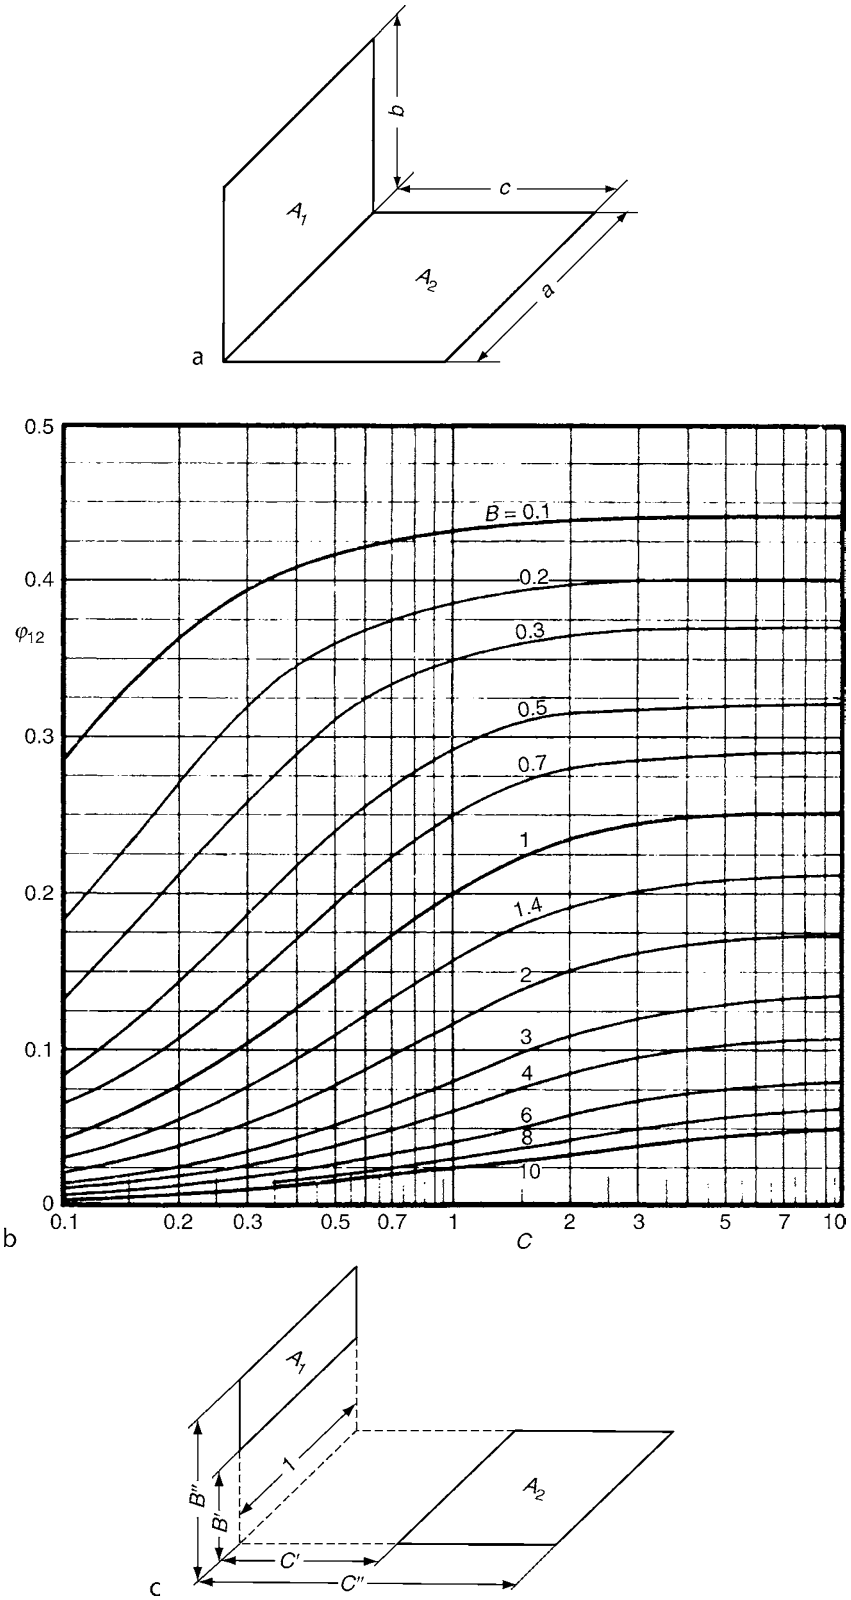




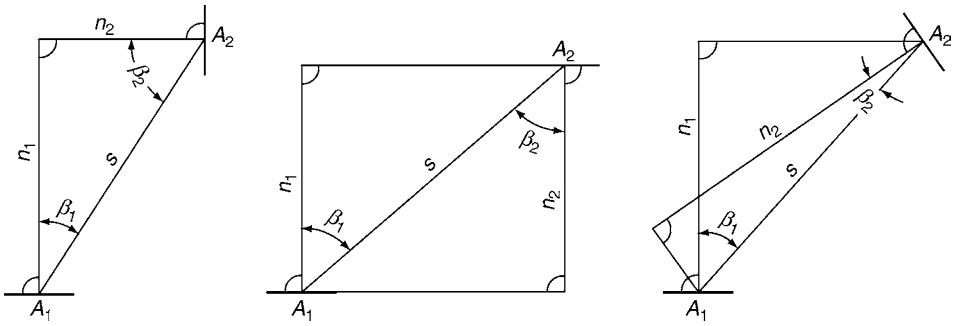
K2. Fig. 14. (**a**) Radiation from a stripe A_1 onto a parallel rectangular surface A_2 with the same length of side; (**b**) view factor φ_{12} as a function of B and C for radiation from a stripe onto a parallel rectangular surface with the same length of side (see Fig. 14a).



K2. Fig. 15. (**a**) Radiation between a plane stripe A_1 and a vertical rectangular surface A_2 with the same length of side and in a perpendicular position; (**b**) view factor φ_{12} as a function of B and C for radiation between a plane stripe and a rectangular surface at a right angle to it (see Fig. 15a).



K2. Fig. 16. (**a**) Radiation between two surfaces A_1 and A_2 joined at a right angle to one another having one common side; (**b**) view factor φ_{12} as a function of B and C for radiation between two rectangular surfaces with a common side meeting at a right angle (see Fig. 16a); (**c**) general case for two rectangular surfaces A_1 and A_2 at a right angles to one another.



K2. Fig. 17. Radiation between surfaces that are small compared to the spacing between them.

where β_1 (or β_2) is the angle between the normal to the surface of A_1 (or A_2) and the straight line s joining the centers of the two surfaces. n_1 (or n_2) is the vertical distance between the plane at the surface of A_1 (or A_2) and the center of A_2 (or A_1).

These conditions are sketched in Fig. 17 for the special case in which the verticals to the center points of both surfaces lie within one plane.

From Fig. 18,

$$X = \frac{b}{a}, \quad Y = \frac{c}{a},$$

$$A = Y^2 + X^2 - 1, \quad B = Y^2 - X^2 + 1,$$

$$\varphi_{11} = 1 - \frac{1}{X} + \frac{2}{\pi X}\arctan\frac{2\sqrt{X^2-1}}{Y} - \frac{Y}{2\pi X}\left\{\frac{\sqrt{4X^2+Y^2}}{Y}\arcsin\left[\frac{4(X^2-1)+\frac{Y^2}{X^2}(X^2-2)}{Y^2+4(X^2-1)}\right] - \arcsin\frac{X^2-2}{X^2} + \frac{\pi}{2}\left(\frac{\sqrt{4X^2+Y^2}}{Y} - 1\right)\right\}, \tag{24}$$

$$\varphi_{12} = \frac{1}{X} - \frac{1}{\pi X}\left\{\arccos\frac{B}{A} - \frac{1}{2Y}\left[\sqrt{(A+2)^2-4X^2}\cdot\arccos\frac{B}{XA} + B\cdot\arcsin\frac{1}{X} - \frac{\pi A}{2}\right]\right\}, \tag{25}$$

$$\varphi_{13} = \frac{1}{2}(1 - \varphi_{12} - \varphi_{11}). \tag{26}$$

Note that in this case radiation from surface A_1, i.e., the inner surface of the outer cylinder, sees itself, so part of this radiation from A_1 will hit other parts of A_1 and thus φ_{11} is not zero.

From Fig. 19,

$$\varphi_{12} = \frac{(\overline{AA'D} + \overline{BC'C}) - (\overline{AC} + \overline{BD})}{2AB}. \tag{27}$$

From Fig. 20,

$$A = \frac{r_2}{r_1}, \quad B = \frac{s}{r_1}, \quad C = 1 + A + B,$$

$$\varphi_{12} = \frac{1}{2\pi}\left[\pi + \sqrt{C^2-(A+1)^2} - \sqrt{C^2-(A-1)^2} + (A-1)\arccos\left(\frac{A}{C} - \frac{1}{C}\right) - (A+1)\arccos\left(\frac{A}{C} + \frac{1}{C}\right)\right]. \tag{28a}$$

For the special case of $r_2 = r_1$, the view factor φ_{12} is simplified to give

$$\varphi_{12} = \frac{1}{2\pi}\left[\pi + \sqrt{C^2-4} - C - 2\arccos\left(\frac{2}{C}\right)\right]. \tag{28b}$$

From Fig. 21,

$$A = \frac{a}{r}, \quad B = \frac{b}{r}, \quad C = \frac{c}{r},$$

$$\varphi_{12} = \frac{1}{B-A}\left(\arctan\frac{B}{C} - \arctan\frac{A}{C}\right). \tag{29}$$

From Fig. 22,

$$A = \frac{a}{r}, \quad B = \frac{b}{r}, \quad C = \frac{c}{r},$$

$$X = A^2 + C^2 + g^2 - 1,$$

$$Y = C^2 - A^2 - g^2 + 1,$$

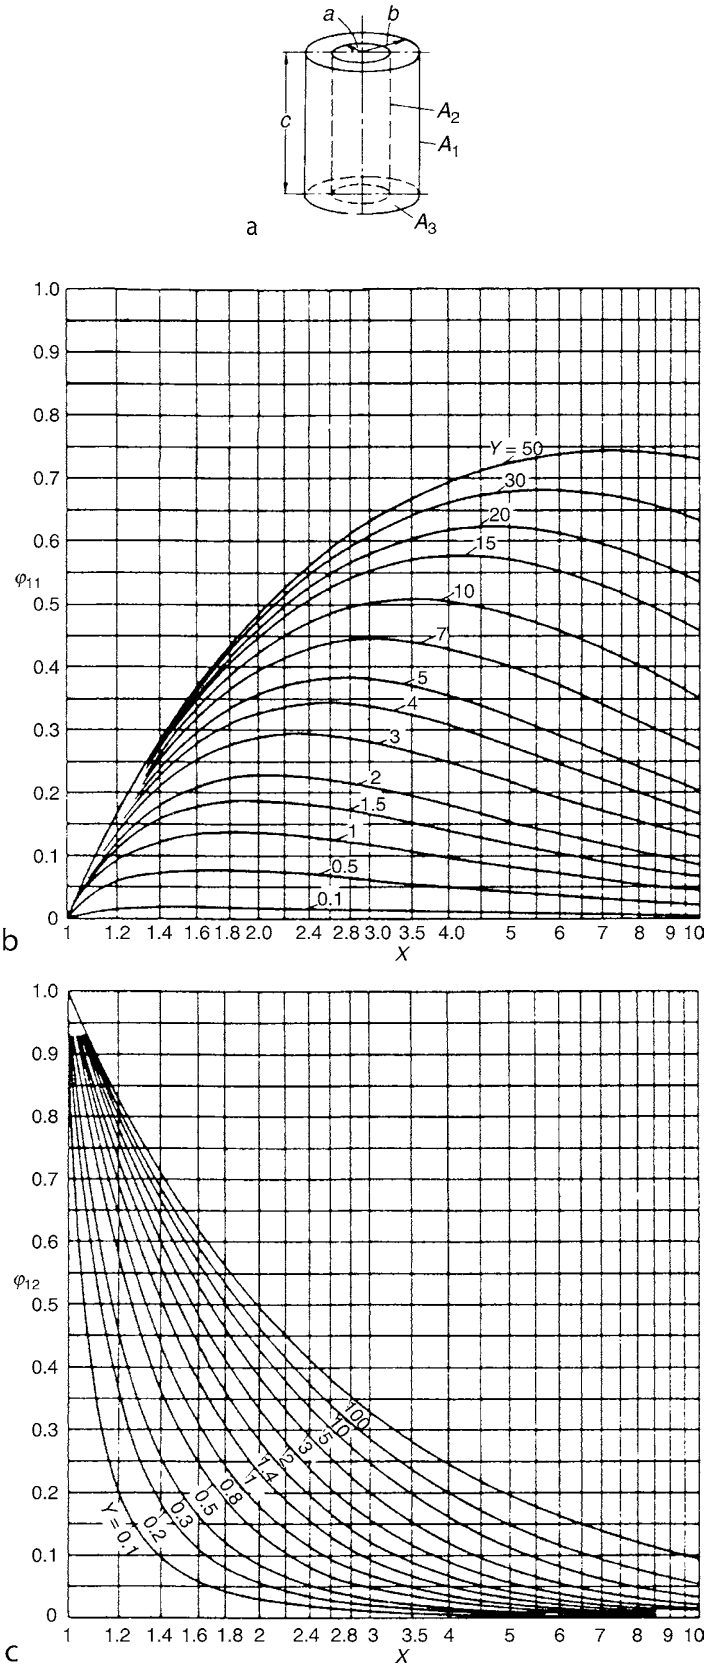
$$\varphi_{12} = \frac{2}{B}\int_0^{B/2} f(g)\,\mathrm{d}g, \tag{30a}$$

$$f(g) = \frac{A}{A^2+g^2} - \frac{A}{\pi(A^2+g^2)}\cdot\left\{\arccos\frac{Y}{X} - \frac{1}{2C}\left[\sqrt{X^2+4C^2}\arccos\frac{Y}{X\sqrt{A^2+g^2}} + Y\arcsin\frac{1}{\sqrt{A^2+g^2}} - \frac{\pi X}{2}\right]\right\}. \tag{30b}$$

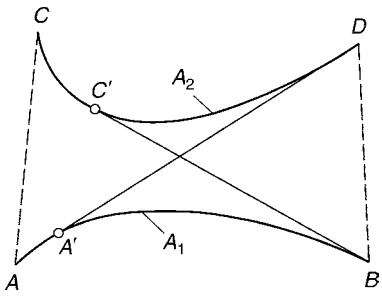
After inserting the dimensionless numbers A, B, C and the dependent variables X and Y into Eq. (30b), the view factor φ in Eq. (30a) can be determined by a simple numerical integration along the variable g.

4 Radiation from Tube Banks

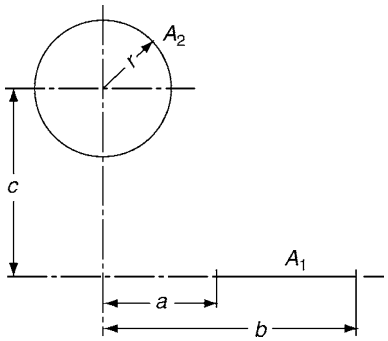
An important factor in the design of boilers and furnaces is the heat transferred by radiation onto the banks of tubes that line the walls or that are integrated into them. The method of



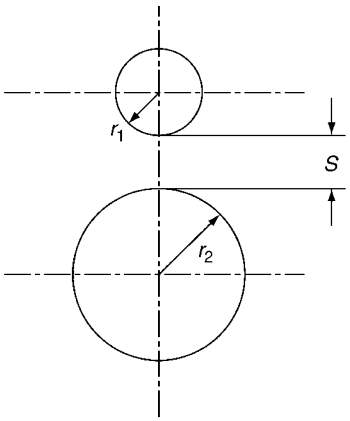
K2. Fig. 18. (**a**) Radiation between the surfaces of two concentric cylinders A_1 and A_2 of finite length c; (**b**) view factor φ_{11} as a function of X and Y for radiation from the outer cylinder onto itself; (**c**) view factor φ_{12} as a function of X and Y for radiation from the outer cylinder onto the inner cylinder A_2 (see Fig. 18a).

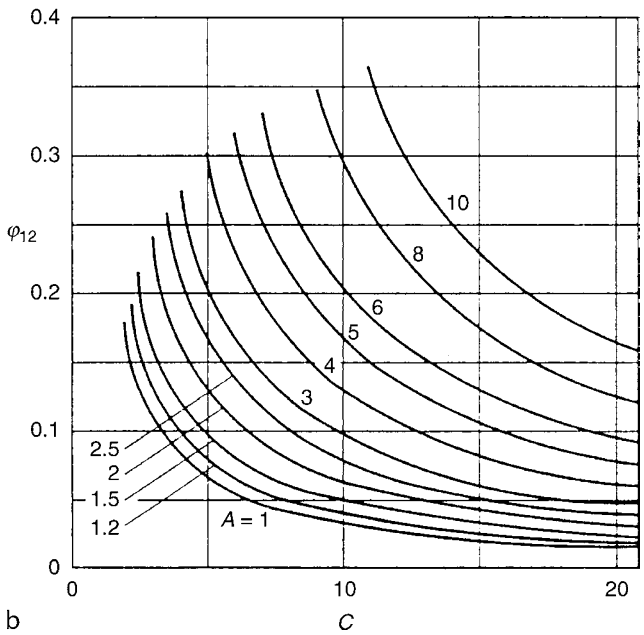


K2. Fig. 19. Radiation between curved surfaces A_1 and A_2 with parallel surface generating lines $\overline{AC}$ and $\overline{BD}$ and of infinite longitudinal extent.

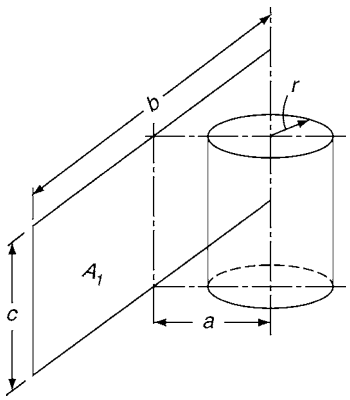


K2. Fig. 21. Radiation between a cylinder A_2 and a surface stripe A_1 that is parallel to the cylinder and of infinite extent.





K2. Fig. 20. (**a**) Radiation between two parallel tubes of infinite length; (**b**) view factor φ_{12} as a function of C and A for two parallel tubes (see Fig. 20a).



K2. Fig. 22. Radiation between a cylinder and a finite rectangular surface A_1 that is parallel to it.

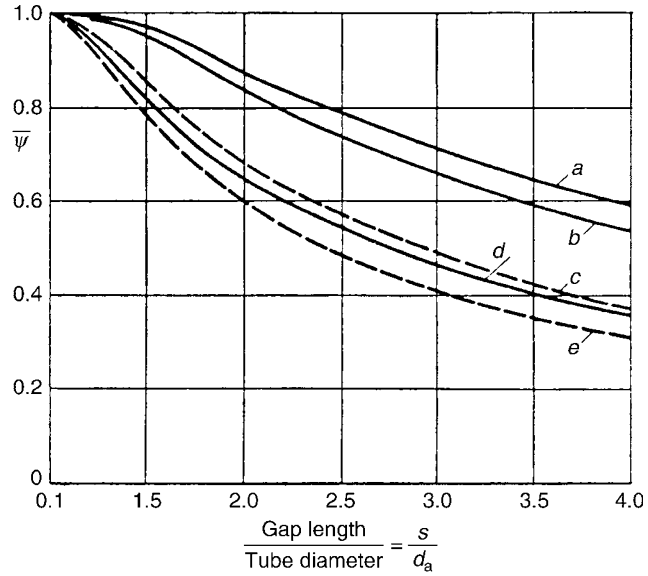
calculation is analogous to that adopted for the radiation from electric rod resistance heaters in electric ovens. View factors calculated by Eckert [6] and Hottel [7] are presented in Figs. 23–25 for the determination of the radiant flux emanating from a radiating surface and intercepted by banks of tubes. In this particular case, the view factor φ_{12} is also referred to as the area ratio $\bar{\Psi}$.

In using these diagrams, a distinction must be made between the view factors that apply to the direct exchange between the wall and the tubes and those that refer to the *overall* total energy exchange. The derivation of the latter has been based on the assumption that the refractory wall behind the tube banks is adiabatic, i.e., it throws back all incident radiation, and that the tubes and the emitting surface are black body radiators.

Experience has shown that the emissivity of the tubes ε_R and that of the radiating wall ε_w are close to unity, i.e., black bodies. Consequently, if the reflected fractions are ignored, the heat flux brought about by radiation can be written as

$$\dot{q}_W = \varepsilon_W \varepsilon_R \sigma \bar{\Psi} \, (T_W^4 - T_R^4), \qquad (31)$$

where $\dot{q}_W$ is the heat flux per unit area of the radiating wall.



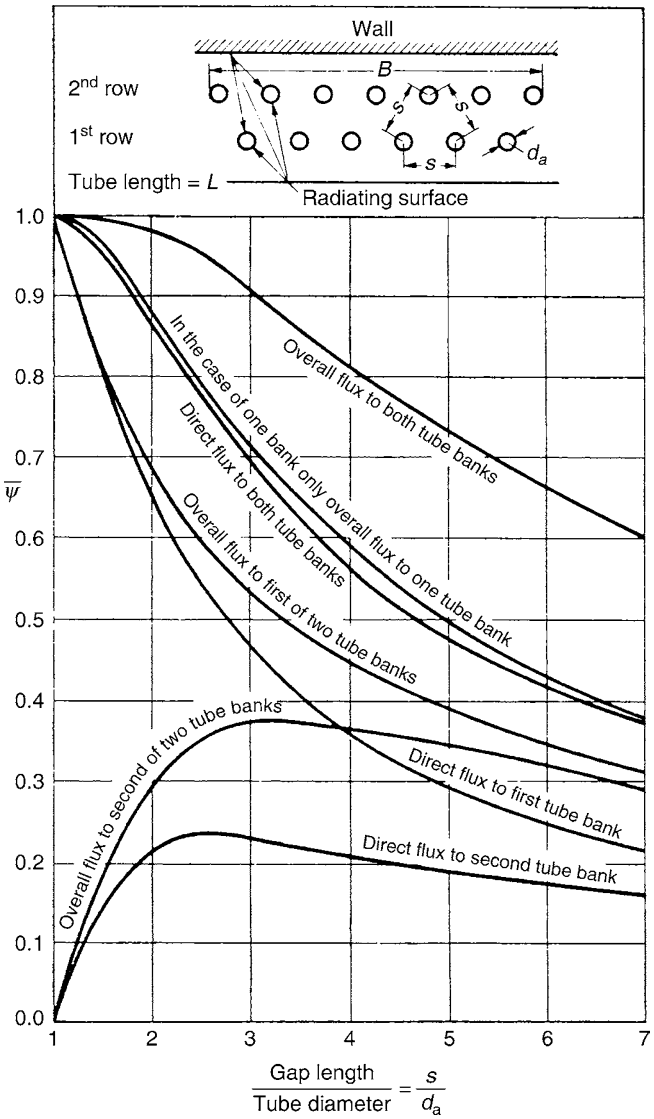
Case 1: $e > s$  Curve *a*, *d*

Case 2: $e < s$  Curve *b*, *d*

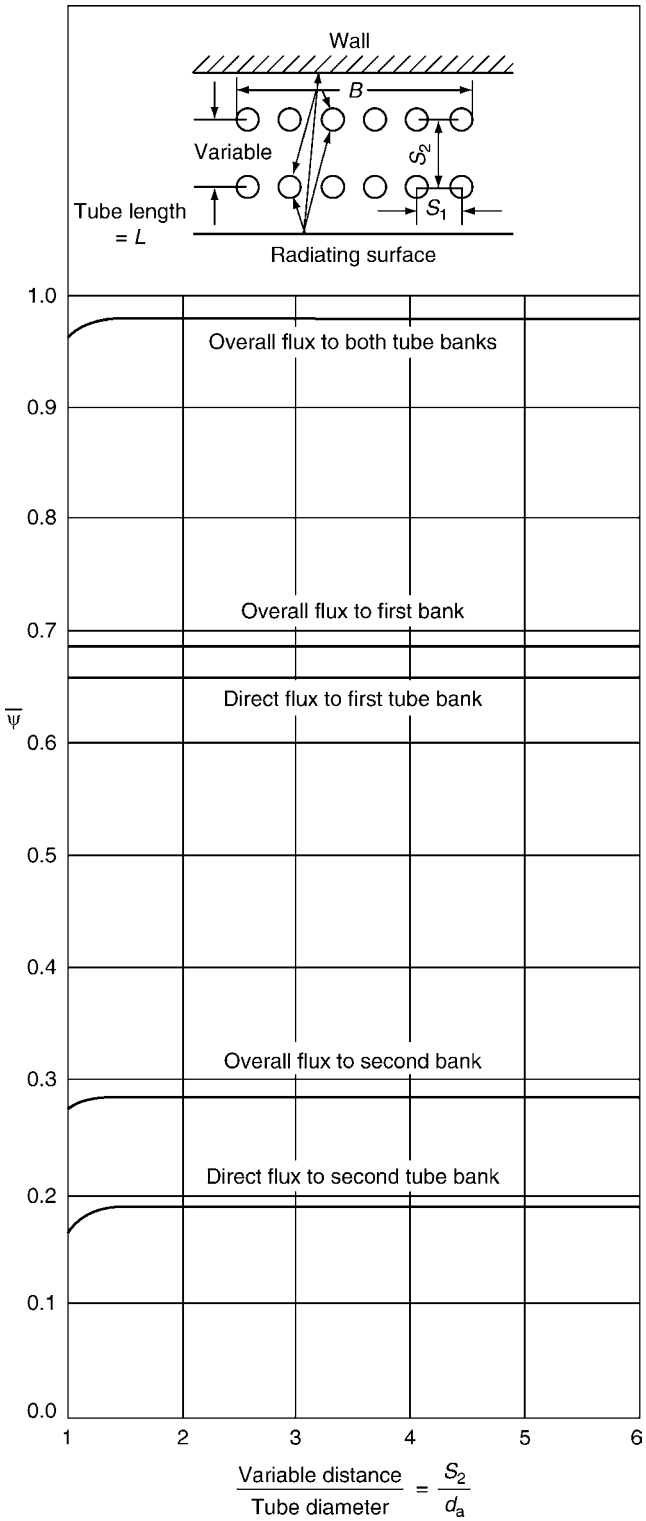
Case 3: $e = 0$  Curve *c*, *e*

K2. Fig. 23. Area ratio $\bar{\Psi}$ for a surface *A* covered by a bank of tubes [2]

Curve *a*	Total overall radiation incident on bank as in case 1 with $e > s$
Curve *b*	As in Case 2
Curve *c*	As in Case 3
Curve *d* or *e*	Direct radiation onto the wall surface as in Cases 1 and 2 or Case 3 for curve *e*.



K2. Fig. 24. Area ratio $\bar{\Psi}$ for surface $A = B \times L$ lined by a tube bank consisting of two staggered rows [6, 7]. The width of the surface is *B*, the length is *L*.



K2. Fig. 25. Area ratio $\bar{\Psi}$ for surface $A = B \times L$ lined by a row of tubes or by two rows arranged in line (spacing $s_1 = 2d_a$) [7].

If s is the center-to-center distance between the tube axes, as shown in Fig. 23, the radiant energy transferred per unit area of tube surface by the one bank of tubes is

$$\dot{q}_R = \frac{\dot{q}_W s}{d_a \pi}, \tag{32a}$$

and by two banks of tubes,

$$\dot{q}_R = \frac{\dot{q}_W s}{2 d_a \pi}. \tag{32b}$$

The values of $\bar{\Psi}$ for each of the two rows in a double bank of tubes can be obtained from Figs. 24 and 25. The heat applied to each row can be then determined from these figures.

K3 Gas Radiation: Radiation from Gas Mixtures

Dieter Vortmeyer[1] · *Stephan Kabelac*[2]
[1]Munich, Germany
[2]Helmut-Schmidt-Universität, Universität der Bundeswehr Hamburg, Hamburg, Germany

Gases emit thermal radiation, just as liquids and solids do, when they are at a temperature $T > 0$ K. Radiation from gases is typically much less intense, as the volumetric density of the source of radiation, the molecules, is low. According to Kirchhoff's law, see ❯ Chap. K1, gases that emit radiation also absorb radiation. Unfortunately, the intensity and wavelength of emittance and absorbance are dependent on the structure of the gas molecules and are quite complicated. Dry air, elementary gases – e.g., O_2, N_2, H_2, – and the noble gases are practically diathermanous, i.e., transparent to thermal radiation. Other gases and vapors – e.g., H_2O, CO_2, CO, O_3, SO_2, HCl, NH_3, and CH_4 are selective radiators, i.e., they emit and absorb within narrow wavelength bands. Hydrocarbons also display characteristic emissivity and absorption to an extent that increases with the number of atoms in their molecules. In general, the spectral absorption and emission is a fingerprint of molecular structures which is used extensively for chemical spectroscopic analysis.

1 Radiant Intensity

Intensity is an important expression in formulating the laws of absorption and emission. If $\Delta\dot{E}$ is the radiant energy emitted from the small area ΔA within the beam formed by the solid angle $\Delta\Omega$ as is shown in Fig. 1, the intensity is defined by

$$I = \frac{\Delta\dot{E}}{(\Delta A \cos\beta\Delta\Omega)_{\Delta A,\Delta\Omega\to 0}} . \tag{1}$$

If the emission is within a vacuum, the intensity remains constant regardless of the distance from the radiating surface. It is for this reason that the laws of absorption are always formulated in terms of the intensity.

2 Absorption and Radiation in Gases at Constant Temperature

The decrease in intensity dI along a path ds is given by *Bouguer's law*, i.e.,

$$\mathrm{d}I = -aI\ \mathrm{d}s. \tag{2}$$

Equation (2) can be written in a spectral way as follows to show the dependence on wavelength λ:

$$\mathrm{d}I_\lambda = -a_\lambda I_\lambda \mathrm{d}s.$$

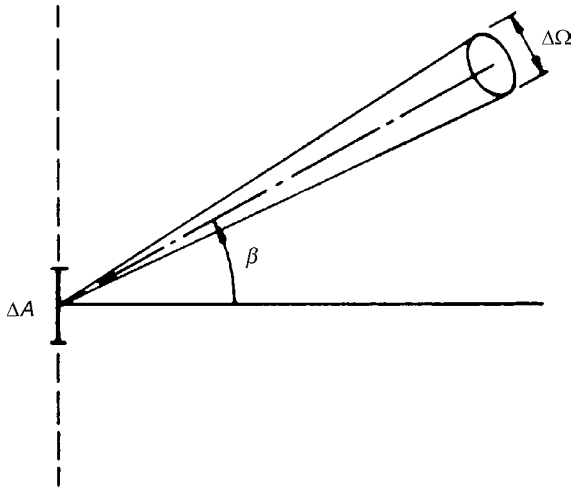
Thus, the decrease in intensity is proportional to the incident intensity multiplied by the element of length ds of the path traversed through the absorbing medium. The constant of proportionality a is known as the linear absorption coefficient. It contains the spectral absorptance a_λ and is dependent on temperature and pressure. With the assumption that a is proportional to the number of absorbing molecules in a given volume and that this number, in accordance with the ideal gas law, is related to the pressure, *Beer* converted the constant a into a product kp to obtain the law named after him, i.e.,

$$\mathrm{d}I = -kpI\mathrm{d}s. \tag{3}$$

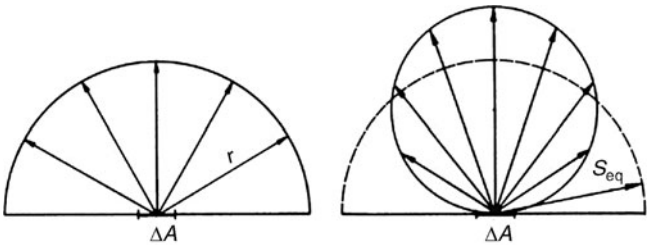
If absorption takes place in gases at a constant temperature, the integration of Eqs. (2) and (3) gives

$$I = I_0 \mathrm{e}^{-as} \tag{4}$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_42,



K3. Fig. 1. Definition of radiant intensity (see Eq. (1)).



K3. Fig. 2. Effect of gas space geometry on the radiative exchange between the (a) wall element dA and (b) gas.

or

$$I = I_0 e^{-kps}. \tag{5}$$

The total intensity absorbed along the path s is

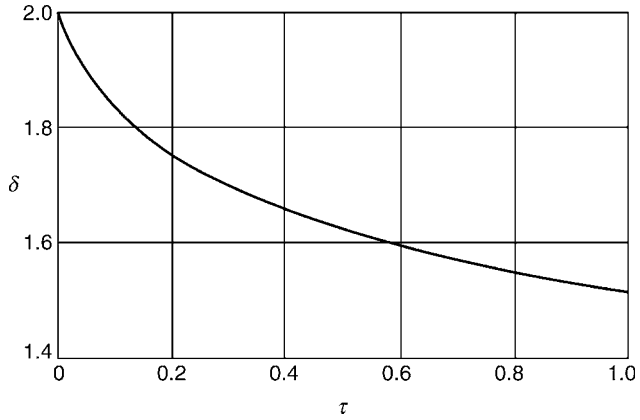
$$I_0 - I = I_0(1 - e^{-kps}). \tag{6}$$

Equation (6) describes the absorption of thermal radiation energy along a given "beam of intensity." However, the exchange of diffuse radiation between a diffuse radiating wall and the gas involves the additional problem of the geometry of the gas volume. To get the radiation energy flux exchange between an element dA of the wall and the gas, it has to be integrated along all the gas volume which is seen by the wall element. A hemisphere and a sphere have been taken as examples to illustrate the effect of the geometry.

In the hemisphere case (Fig. 2a), all the "beams of intensity" emitted by the element of area ΔA traverse paths of the same length r, but in the spherical space (Fig. 2b), the paths are each of different length. On its passage through the hemispherical gas volume, the energy emitted by ΔA is reduced by the amount absorbed, i.e.,

$$(1 - e^{-ar}). \tag{7}$$

It would be useful if the aforementioned notation for the absorptances, which are exactly valid only for the hemisphere case (Fig. 2a), could be applied to other geometries. This can be achieved by introducing an equivalent radius or the equivalent layer thickness s_{eq} (Fig. 2b) for r in Eq. (7).



K3. Fig. 3. Layer of infinite extent between two parallel walls with distance D as an example to illustrate the relationship between the equivalence factor δ and the optical density τ, i.e., $\delta = s_{eq}/D$.

Thus

$$A_v = 1 - e^{-as_{eq}}, \tag{8}$$

where A_v is the geometry-dependent absorptance.

The equivalent layer thickness for the sphere shown in Fig. 2b, which may be regarded as representative for various other geometries, is the radius of the hemisphere that absorbs exactly the same amount of radiation as a hemisphere with radius $s_{eq.}$ A major disadvantage of this method is that s_{eq} for a given geometry still depends on the optical density of the absorbing gas medium. This is demonstrated by Fig. 3, in which exact values for $s_{eq}/D = \delta$ have been plotted against the optical density τ for a plane gas volume between two parallel walls with D being the distance between the walls, i.e., the beam length in this case.

Typical values derived from calculations of this nature are listed in Table 1, which are valid for optical densities of the order of about $\tau = 0.2$.

An approximate value for the equivalent radius s_{eq} for geometries not included in the table can be obtained from the equation

$$s_{eq} = 0.9\frac{4V}{A}, \tag{9}$$

where V is the gas volume under consideration and A is the wall area around the gas body.

The aforementioned remarks on absorption apply equally well to the emission of radiation from gas volumes at constant temperature.

The optical density is the product of a beam length s and the absorptance a and is designated by $\tau =$ s.a.

2.1 Emissivity of Carbon Dioxide and Water Vapor at a Total Pressure of $p = 1$ bar

Radiation by carbon dioxide and water vapor is an extremely important factor in thermal engineering design. Basically, the total radiant energy emitted by a gas of a given volume can be calculated if the spectral emissivity ε_λ is known, which has to be

K3. Table 1. Equivalent layer thickness $s_{eq} = \delta D$ for various gas bodies and for $\tau \approx 0.2$ (valid only for surfaces that emit diffuse radiation).

Gas body and nature of incident radiation	Characteristic dimension	Equivalence factor δ

integrated over wavelength λ. The corresponding methods were developed by Nusselt [1], Schack [2], Hottel [3], Hertel [4], Goody [5], and Plass [6]. A summary of these methods is given in [7]. The need for these emissivities gave rise to extensive measurements at the temperatures, pressures, and layer thicknesses encountered in engineering practice. Thus, measurements performed by Schmidt, Eckert, Hottel, Mangelsdorf, Egbert [8–11], and others are still of fundamental significance.

The total emissivity ε_g was determined by experiment for various gases. It depends on the temperature, the thickness of the layer, the partial pressure p_g of the radiant gas, and – to a varying extent – on the total pressure p of the gas mixture.

According to Beer's law, see Eq. (3), the emission should depend solely on the product of the partial pressure and the thickness of the layer ($p_g s_{eq}$), but this could not be confirmed in all cases. Consequently, Hottel and Egbert compiled diagrams that retained the product $p_g s_{eq}$ as an important parameter but applied corrections for water vapor and carbon dioxide. Thus, Fig. 4 contains emissivities for carbon dioxide at a total pressure of $p = 1$ bar and for all partial pressures ($p_{CO_2} < 1$bar). Fig. 5b applies to water vapor with corrections given as a correction parameter f in accordance with Fig. 5a.

Figures 6–8 give the overall emissivity for the gases ammonia NH_3, sulfur dioxide SO_2, and methane CH_4, respectively, at a pressure of $p = 1$ bar.

2.2 Emissivity of Carbon Dioxide and Water Vapor at Elevated Total Pressures

Cheng and Nguyen [15] recommend a method that was developed by Leckner [16] for the determination of emissivity at elevated pressures. It consists of applying a correction factor for elevated pressures to the figures for the emissivity at $p = 1$ bar.

The following procedure applies for the emissivity of water vapor at elevated pressure $p > 1$ bar:

$$\varepsilon_{H_2O}(p) = f_{p,H_2O} \cdot \varepsilon_{H_2O}(p_{H_2O} s_{eq}, \text{Fig. 4}). \tag{10}$$

The correction parameter f_{p,H_2O} is given by

$$f_{p,H_2O} = 1 + (A-1)\exp\left[-0.5\left(\log\frac{0.132(T_g/1{,}000)^2}{p_{H_2O} s_{eq}}\right)^2\right], \tag{11}$$

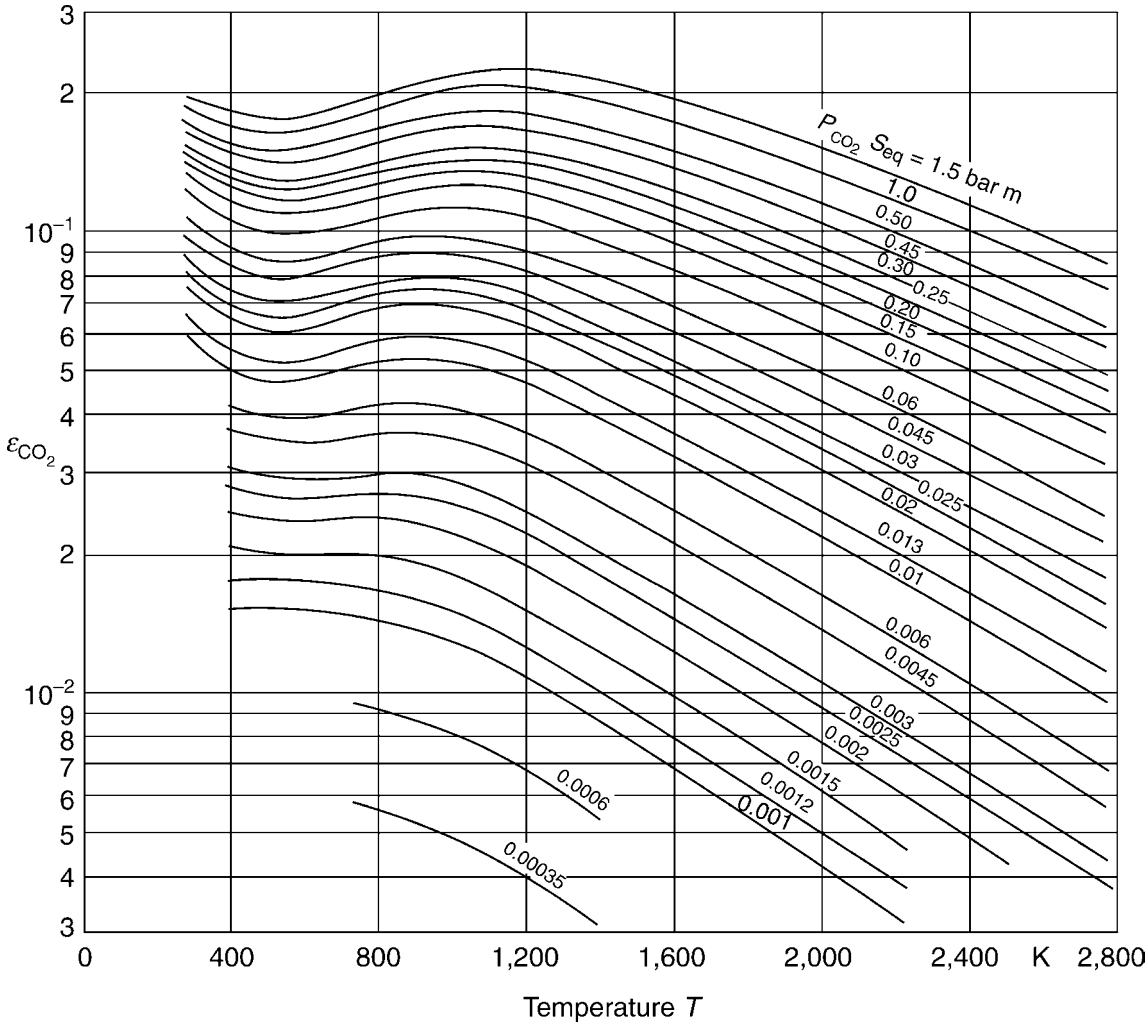
$$A = \frac{(1{,}888 - 2{,}053\log\tau)p\left(1 + 4.9\frac{p_{H_2O}}{p}\sqrt{\frac{273}{T_g}}\right) + 1.10\left(\frac{T_g}{1{,}000}\right)^{-1.4}}{0.888 - 2{,}053\log\tau + p\left(1 + 4.9\frac{p_{H_2O}}{p}\sqrt{\frac{273}{T_g}}\right) + 1.10\left(\frac{T_g}{1{,}000}\right)^{-1.4}}, \tag{12}$$

where

$$\begin{aligned} &\tau = 0.75 \text{ for } T_g \le 750 \text{ K and} \\ &\tau = T_g/1{,}000 \text{ for } T_g > 750 \text{ K}. \end{aligned} \tag{13}$$

If the number for f_{p,H_2O} determined from Eq. (11) is higher than that for A determined from Eq. (12), the value to be taken is $f_{p,H_2O} = A$.

The method is recommended for the $1 \le p \le 100$ bar pressure range and for temperatures $T_g \ge 700$ K. There is no need to apply a correction for the partial pressure that relates to a total pressure of $p = 1$ bar, as indicated in Fig. 5a, because allowance



K3. Fig. 4. Emissivity ε_{CO_2} of carbon dioxide at a total pressure of 1 bar as a function of temperature and the product of $p_{H_2O}s_{eq}$ [12].

for the relationship between the correction factor and the partial pressure has been already been made in Eqs. (11) and (12).

2.2.1 Carbon dioxide

The emissivity of carbon dioxide at elevated pressures is given by

$$\varepsilon_{CO_2}(p) = f_{p,CO_2} \cdot \varepsilon_{CO_2}(p_{CO_2} s_{eq}, \text{Fig. 5}). \tag{14}$$

The pressure correction factor f_{p,CO_2} is given by

$$f_{p,CO_2} = 1 + (A-1)\exp\left[-0.5\left(\log\frac{B}{100 p_{CO_2} s_{eq}}\right)^2\right], \tag{15}$$

$$A = \frac{\left[0.1\left(\frac{T_g}{1{,}000\text{K}}\right)^{-1.45}+1\right]p\left(1+0.28\frac{p_{CO_2}}{p}\right)+0.23}{0.1\left(\frac{T_g}{1{,}000\text{K}}\right)^{-1.45}+p\left(1+0.28\frac{p_{CO_2}}{p}\right)+0.23}, \tag{16}$$

$$B = 0.225\left(\frac{T_g}{1{,}000\text{K}}\right)^2 \text{ for } T_g \geq 700 \text{ K},$$

$$B = 0.054\left(\frac{T_g}{1{,}000\text{ K}}\right)^2 \text{ for } T_g \leq 700 \text{ K}. \tag{17}$$

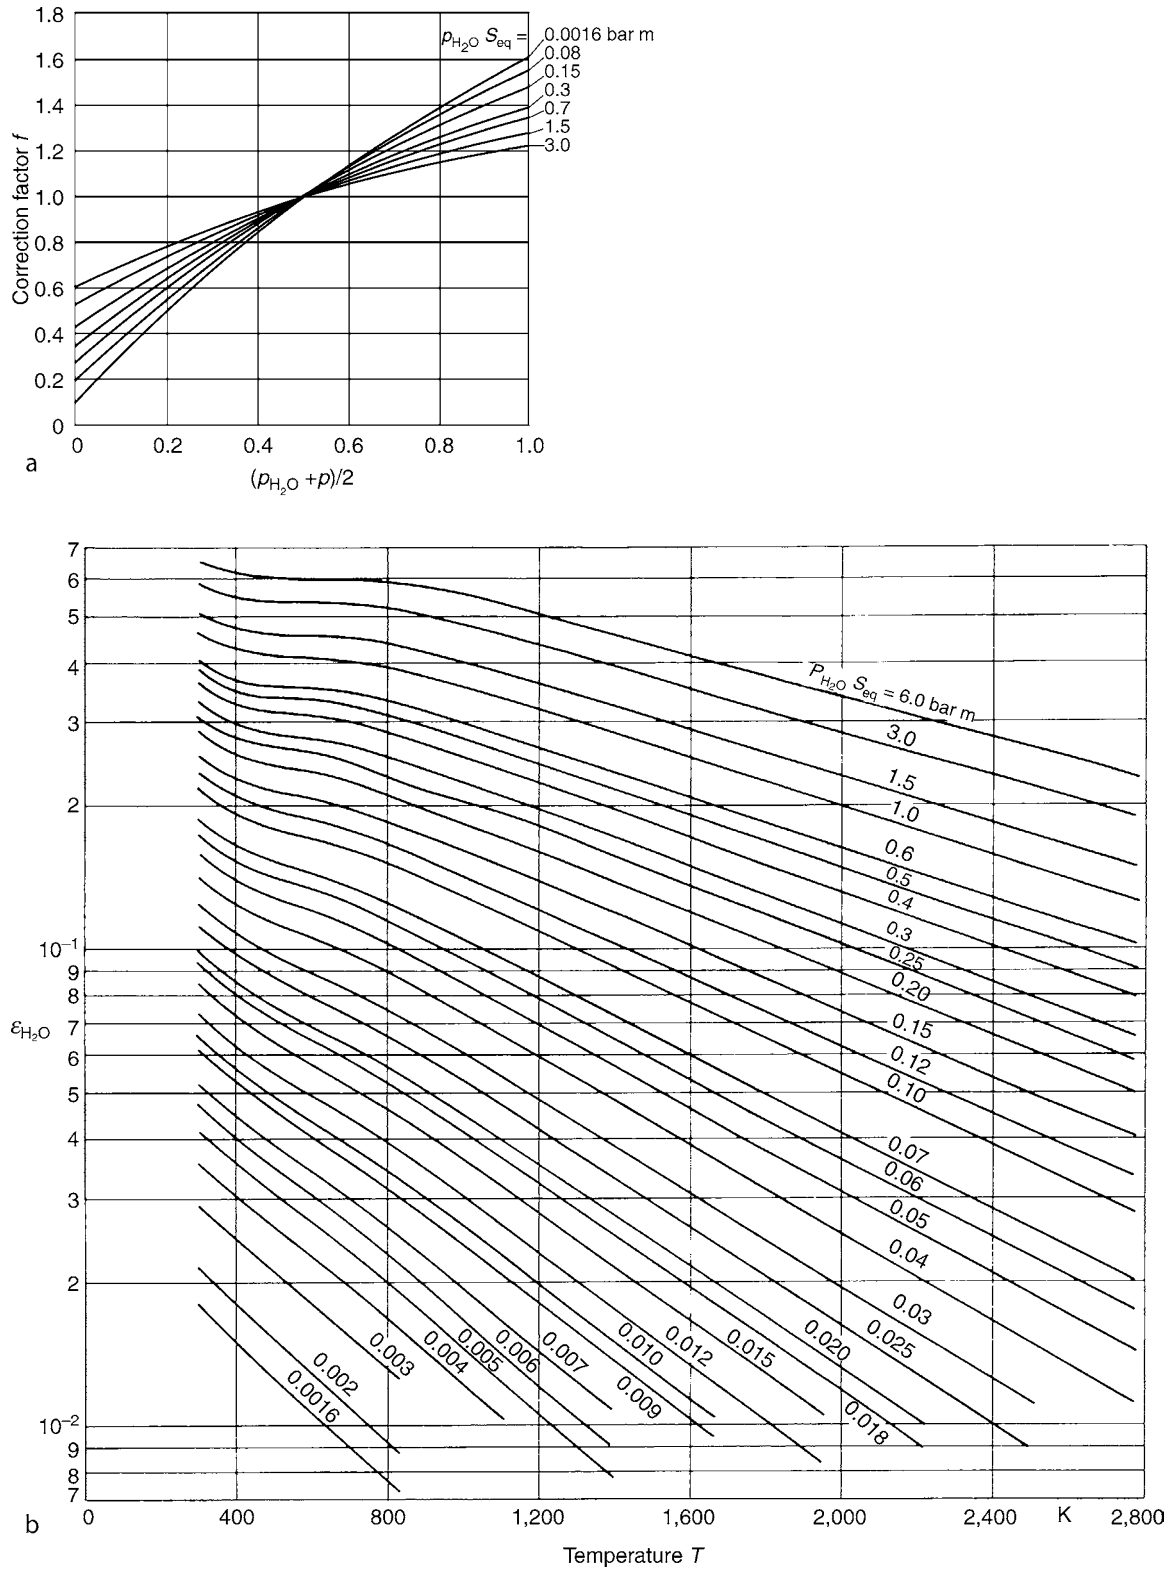
If the figure for f_{p,CO_2} determined by Eq. (15) is greater than that for A determined by Eq. (16), the value to be taken is $f_{p,CO_2} = A$. The method can be applied in the $0 \leq p \leq 100$ bar pressure range and for temperatures $T_g \geq 600$ K.

3 Radiative Exchange Between Gas and Wall

The following equation applies for the net flow rate of thermal radiation energy between a volume of gas and the wall that encloses the gas space:

$$\dot{Q}_{gw} = A\sigma\frac{\varepsilon_w}{1-(1-\varepsilon_w)(1-A_v)}(\varepsilon_g T_g^4 - A_v T_w^4). \tag{18}$$

It is valid only if the temperature, density, and concentration of the gas are constant in space, and its application requires a knowledge of the gas emissivity and absorptance. The emissivity depends solely on the equivalent layer thickness s_{eq} and the state of the gas (T_g, total pressure p, and partial pressure p_g of the gas



K3. Fig. 5. (**a**) Correction factor f for water vapor (total pressure $p \leq 1$ bar) [12]; (**b**) emissivity ε_{H_2O} of water vapor at a total pressure of 1 bar as a function of temperature and the product $p_{H_2O}s_{eq}$.

components). The absorptance however, also depends on the wall temperature T_w. Thus,

$$\varepsilon_g = \varepsilon_g(p, T_g, s_{eq}p_g),$$

$$A_v = A_v(p, T_g, T_w, s_{eq}p_g).$$

In all other cases reference is made to the corrections proposed by Hottel and Sarofim [17].

3.1 Water Vapor

$$A_v = \varepsilon_{gw}\left(\frac{T_g}{T_w}\right)^{0.45} \text{ for } p = 1 \text{ bar}.$$

The emissivity ε_{gw} can be read from Fig. 5b by taking into account the wall temperature T_w and the water vapor partial pressure $p_{H_2O}(T_w/T_g)$ which is converted to the value at the wall temperature

$$A_v = \left(\frac{T_g}{T_w}\right)^{0.45} \cdot \varepsilon_g\left(T_w; s_{eq} \cdot p_{H_2O} \cdot \frac{T_w}{T_g}\right) \text{ for } p = 1 \text{ bar}. \quad (19)$$

A correction factor f must be introduced to allow for the effect of the total pressure and the water vapor partial pressure on the wavelength ranges of spectral emission. This correction factor is shown in Fig. 5a for a pressure of up to 1 bar, and can be calculated from Eq. (11) for a pressure of $p > 1$ bar:

$$A_v = f\left(\frac{T_g}{T_w}\right)^{0.45} \cdot \varepsilon_g\left(T_w; s_{eq} \cdot p_{H_2O} \cdot \frac{T_w}{T_g}\right). \quad (20)$$

3.2 Carbon dioxide

$$A_v = f_{p,CO_2}\left(\frac{T_g}{T_w}\right)^{0.65} \cdot \varepsilon_g\left(T_w; s_{eq} \cdot p_{CO_2} \cdot \frac{T_w}{T_g}\right), \quad (21)$$

in which f_{p,CO_2} is given by Eq. (15) or $f_{p,CO_2} = 1$ for $p = 1$ bar.

3.3 Sulfur dioxide

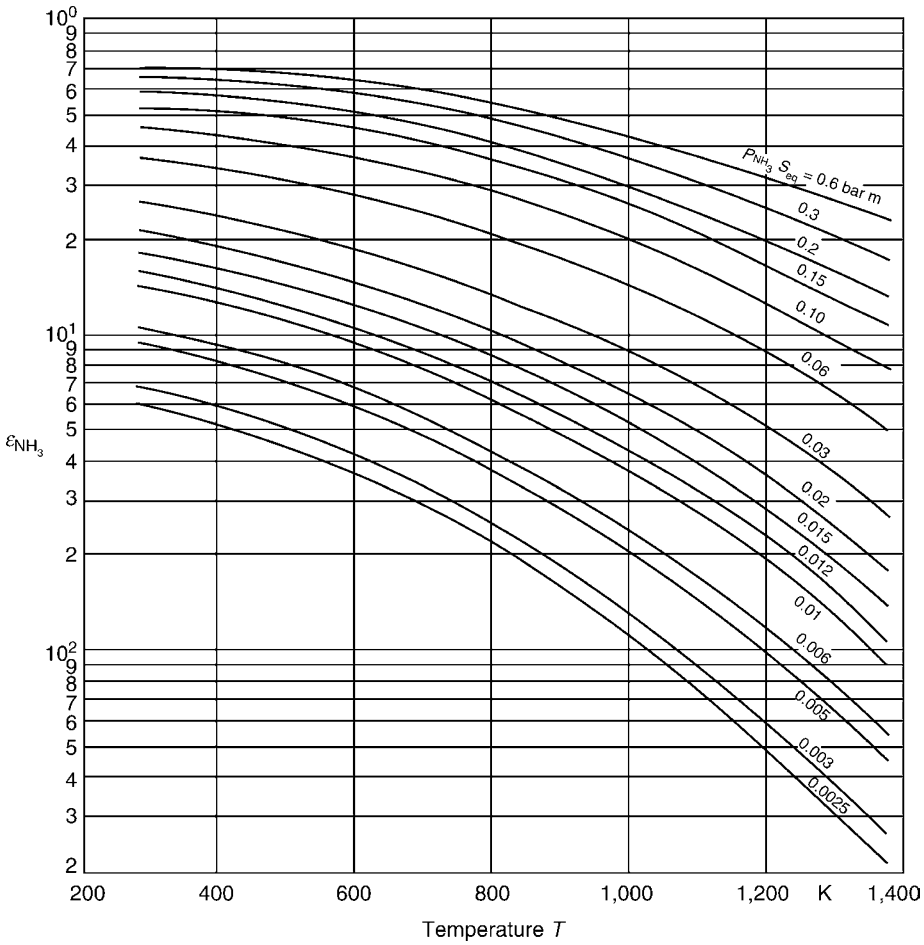
$$A_v = \left(\frac{T_g}{T_w}\right)^{0.5} \cdot \varepsilon_g\left(T_w; s_{eq} \cdot p_{SO_2} \cdot \left(\frac{T_w}{T_g}\right)^{1.5}\right) \quad (22)$$

for $p = 1$ bar.

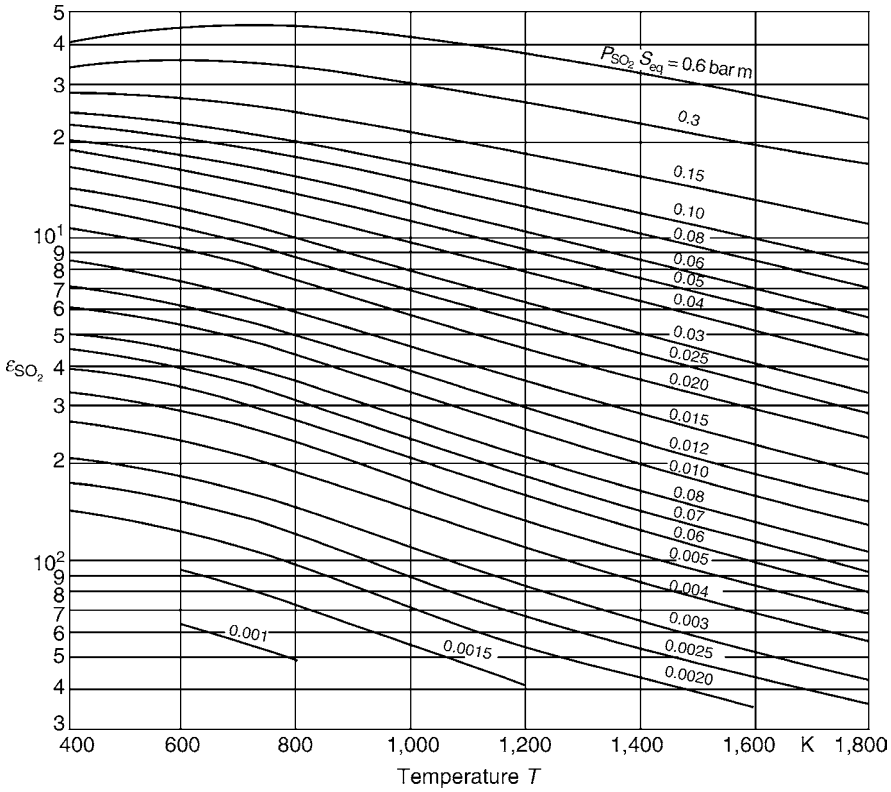
No corrections are known for other total pressures.

3.4 Ammonia and Methane

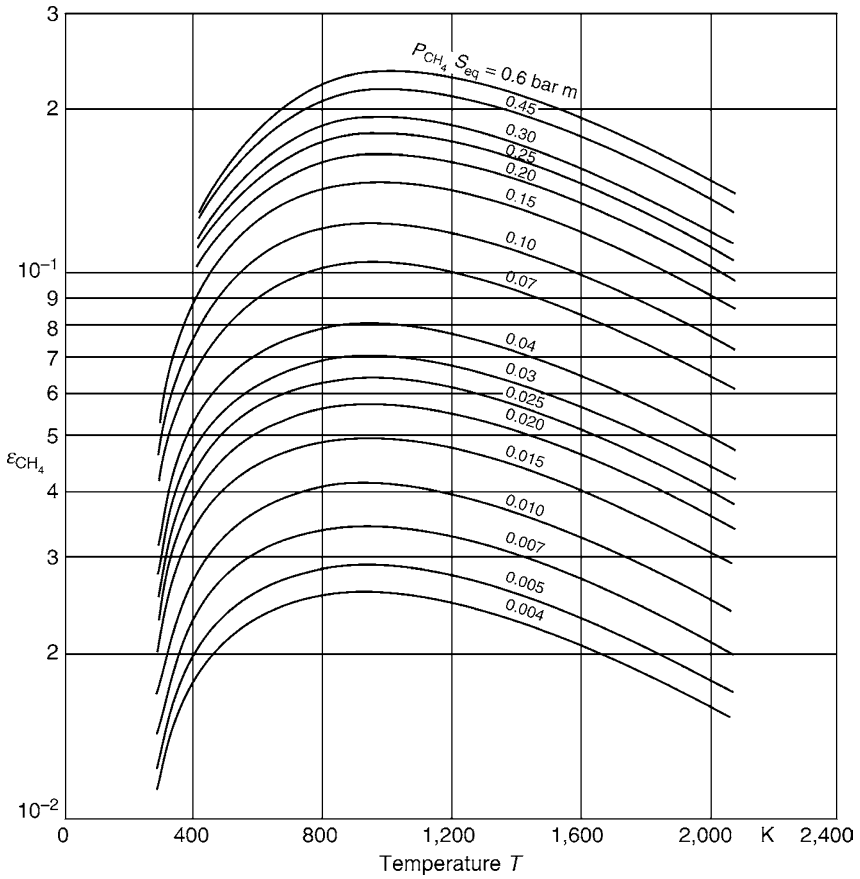
Emissivities for ammonia and methane can be obtained from Figs. 6 and 8. No formulae yet exist for converting A_v for these



K3. Fig. 6. Emissivity of ammonia at a total pressure of 1 bar as a function of temperature and $p_{NH_3}s_{eq}$ [12].



K3. Fig. 7. Emissivity of sulfur dioxide at a total pressure of 1 bar as a function of temperature and $p_{SO_2} s_{eq}$ [13].



K3. Fig. 8. Emissivity of methane at a total pressure of 1 bar as a function of temperature and $p_{CH_4} s_{eq}$ [14].

gases, nor are there any correction factors for pressures other than 1 bar. For this reason, the relationship $\varepsilon_g = A_v$ should be adopted in radiative exchange calculations for these gases.

Other methods for the calculation of the radiant heat flux $\dot{Q}_{gw}$ have been suggested by Eckert [9] and – in an improved form – by Elgeti [18]. The results thus obtained for carbon dioxide and water vapor agree satisfactorily with those determined by Eq. (18).

4 Gas Mixtures

Hottel and Egbert [11] have suggested the following equations for the determination of the emissivity and absorptance of mixtures consisting of carbon dioxide, water vapor, and nonradiant components:

$$\varepsilon_g = \varepsilon_{H_2O} + \varepsilon_{CO_2} - (\Delta\varepsilon)_g, \tag{23a}$$

$$A_v = A_{vH_2O} + A_{vCO_2} - (\Delta\varepsilon)_w. \tag{23b}$$

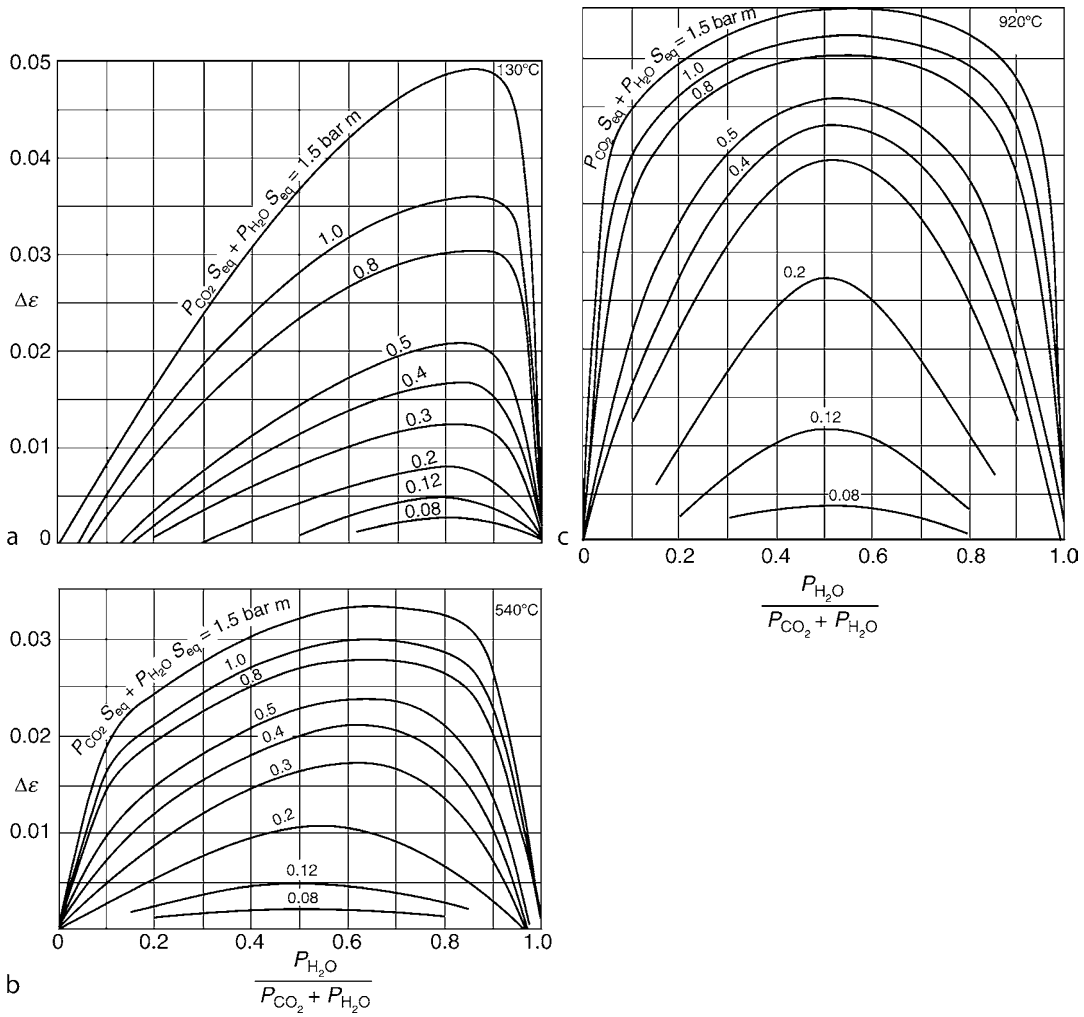
The values of $(\Delta\varepsilon)_g$ and $(\Delta\varepsilon)_w$ at the corresponding gas and wall temperatures are obtained from Fig. 9a–c. This correction is necessary because of the overlap of the individual emission bands of the gases involved. The emissivities and absorptances for each of the components are read from the diagrams given earlier for the partial pressures at hand.

Example 1

Determine the net flow rate of radiant energy in a cube filled with gas under the following conditions:

Length of side of cube	$D = 1$ m
Wall temperature	$T_w = 600°C$
Gas temperature	$T_g = 1{,}400°C$
Wall emissivity	$\varepsilon_w = 0.9$

The gas contains 11% of water vapor and 10% of carbon dioxide (by volume). The rest is a nonradiant component. The total pressure is 1 bar.



K3. Fig. 9. Correction $\Delta\varepsilon$ for mixtures of carbon dioxide and water vapor at (**a**) 130°C, (**b**) 540°C, and (**c**) 920°C and above [14].

From Table 1 the equivalent length for a cube is $s_{eq} = 0.6D$.

$$p_{CO_2} s_{eq} = 0.06 \text{ bar} \cdot \text{m} \text{ and } p_{H_2O} s_{eq} = 0.066 \text{ bar m}.$$

The following values for ε_{CO_2} and ε'_{H_2O} can be read from the diagrams in Figs. 4 and 5:

$$\varepsilon'_{H_2O} = 0.052 \text{ (uncorrected) and } \varepsilon_{CO_2} = 0.063.$$

Applying the correction factor f_{H_2O} obtained from Fig. 5a gives

$$\varepsilon_{H_2O} = 0.052 \cdot 1.08 = 0.0562.$$

The total emissivity of the gas, as obtained from Fig. 9c and Eq. (25), is $\varepsilon_g = 0.108$.

The absorptance of the individual gases is determined from Eqs. (19) and (21). First of all, the emissivities $(\varepsilon_{H_2O})_w$ and $(\varepsilon_{CO_2})_w$ are read off from Figs. 4, 5, and 5a, but in this case against the wall temperature and the corrected product of the partial pressure and the equivalent thickness of the layer. Thus,

$$(\varepsilon_{CO_2})_w = 0.078; \quad (\varepsilon_{H_2O})_w = 0.079.$$

It follows that $A_{vCO_2} = 0.119$ and $A_{vH_2O} = 0.106$.

The term for correcting the total absorptance of the mixture is read off against the wall temperature T_w in Fig. 9b. Thus, $(\Delta\varepsilon)_w = 0.005$.

Therefore, the total absorptance is $A_{vtot} = 0.22$.

Inserting this value in Eq. (18) gives a net radiant energy flow rate of $\dot{Q}_w = 238$ kW.

Example 2

A gas at a temperature $T = 1{,}600$ K and a pressure $p = 10$ bar contains 20% of water vapor. Determine the emissivity for an equivalent layer thickness $s_{eq} = 0.1$ m.

An emissivity of $\varepsilon_{H_2O}(p = 1 \text{ bar}) = 0.122$ can be read for a temperature $T = 1{,}600$ K and $p_{H_2O} \cdot s_{eq} = 0.2$ bar m.

From Eq. (13) $\tau = 1.6$; and from Eq. (12), $A = 1.4095$. Inserting this value for A in Eq. (11) $f_{p,H_2O} = 1{,}399$ for the pressure correction factor. Hence, the emissivity is $\varepsilon_{H_2O}(p = 10 \text{ bar}) = 1{,}399 \cdot 0.122 = 0.171$.

5 Analytical Calculation of the Emissivities of H_2O, CO_2 and their Mixtures

For computer-based calculations the total emissivities and absorptivities of real gases can be determined using the "gray-and-clear gas approximation" [17] (also called "weighted sum of gray gases model"). For carbon dioxide CO_2 at a total gas pressure of $p = 1$ bar and a partial pressure of 0.01 mbar $< p_{CO_2} s_{eq} <$ 10 mbar and at temperatures between 300 K $< T_g <$ 1,800 K [19], we have

$$\varepsilon_{CO_2} = Z - \sum_{i=1}^{6} a_i \exp(-k_i p_{CO_2} s_{eq}),$$

$$Z = c_1 + c_2 \frac{T_g}{1{,}000 \text{ K}} + c_3 \left(\frac{T_g}{1{,}000 \text{ K}}\right)^2,$$

$$a_i = b_{1i} + b_{2i} \frac{T_g}{1{,}000 \text{ K}} + b_{3i} \left(\frac{T_g}{1{,}000 \text{ K}}\right)^2. \quad (24)$$

The values of the coefficients in Eq. (24) are summarized below.

i	b_{1i}	b_{2i}	b_{3i}	k_i (1/mbar)
1	0.1074	−0.10705	0.072727	0.036
2	0.027237	0.10127	−0.043773	0.3586
3	0.058438	−0.001208	0.0006558	3.06
4	0.019078	0.037609	−0.015424	14.76
5	0.056993	−0.025412	0.0026167	102.28
6	0.0028014	0.038826	−0.020198	770.6

$c_1 = 0.27769$, $c_2 = 0.03869$ and $c_3 = 1.4249 \cdot 10^{-5}$.

For water vapor H_2O at a total gas pressure of $p = 1$ bar, temperatures between 700 K $< T_g <$ 1,500 K, and partial pressures between 0.05 mbar $< p_{H_2O} s_{eq} <$ 0.5 mbar or 0.5 mbar $< p_{H_2O} s_{eq} <$ 2 mbar [19] we have

$$\varepsilon_{H_2O} = Z - a \exp(-k p_{H_2O} s_{eq}),$$

$$Z = b_1 + b_2 \frac{T_g}{1{,}000 \text{ K}},$$

$$a = b_3 + b_4 \frac{T_g}{1{,}000 \text{ K}}. \quad (25)$$

The coefficients in Eq. (25) are as follows:

$p_{H_2O} s_{eq}$	0.05 . . . 0.5	0.5 . . . 2
b_1	0.43265	0.66439
b_2	−0.1089	−0.17389
b_3	0.3273	0.4572
b_4	−0.043821	−0.1317
k (1/mbar)	3.5829	0.84652

For a mixture of H_2O and CO_2 at a total pressure of $p = 1$ bar for $p_{H_2O}/p_{CO_2} = 1$, temperatures between 1,100 K $< T_g <$ 1,800 K, and equivilant layer thickness between 0.2 m $< s_{eq} <$ 6 m [20] we have

$$\varepsilon_{H_2O+CO_2} = \sum_{i=1}^{3} a_i \left[1 - \exp\left(-k_i (p_{H_2O} + p_{CO_2}) s_{eq}\right)\right],$$

$$a_i = b_{1i} + b_{2i} \frac{T_g}{1{,}000 \text{ K}}. \quad (26)$$

The coefficients for Eq. (26) are as follows:

i	b_{1i}	b_{2i}	k_i (1/mbar)
1	0.130	0.265	0
2	0.595	−0.15	0.824
3	0.275	−0.115	25.91

The corresponding degrees of absorption are readily calculated by using the same Eqs. (24–26) when the temperature of the emitting wall T_w is used instead of the temperature of the gas T_g.

6 Radiation from Gas Volumes at Nonuniform Temperatures

No simple solutions can be offered for this very difficult mathematical task, and reference must be taken to the literature [17, 21, 22]. However, the publications available are concerned more with the solutions of one-dimensional than of three-dimensional problems. An interesting contribution in this connection was made by Pandaya [23], who observed that the radiation in a space through which gas flowed and in which the temperature profile was curved (i.e., the temperature at the center was higher than that at this sides) could be adequately described by the arithmetic mean temperature.

Another subject that attracts great attention is radiation from luminous flames, in which case the emission from the carbon dioxide and water vapor is considerably augmented by that from small particles of incandescent soot. The formation of carbon particles depends on the entire conditions and still defies mathematical analysis. Another difficulty is the determination of the exact temperature of particles that can still enter into chemical reactions. In view of the importance attached to the problem, numerous studies have been performed on flames, with the consequence that at least some information is available on the estimation of radiation effects for certain types of flame. Details are given in publication by Hottel [17] and Schack [2, 24].

7 Combined Heat Transport by Conduction and Radiation in Gases, Liquids, and Molten Glass

A mathematical description of this subject entails integral–differential equations. Simplifications can be made if the radiant medium is optically dense, and transport by radiation can therefore be determined by a Fourier-type equation for thermal radiation (diffusion approximation). The first fundamental studies in this sector were performed on molten glass by Czerny and Genzel [25, 26] and Walther et al. [27].

More information on combined heat transport calculations is given by Sparrow and Cess [21].

It is not surprising that the proportion of radiation in the total heat flux becomes greater at high temperatures. However, Poltz [28] and Schödel and Grigull [29] have demonstrated that substantial proportions of radiation are present in the heat flux from liquids at temperatures of the order of 298 K. These proportions depend on the radiation characteristics of the liquid and geometric factors. The authors last cited made use of interferometry in order to present the hook-shaped temperature profile determined mathematically by Walther et al. [27] in a visible form.

8 Symbols

T_g	gas temperature (K)
T_w	wall temperature (K)
ε_g	emissivity of the gas (–)
ε_w	emissivity of the wall which surrounds the gas (–)
ε'_g	emissivity of the gas without pressure correction (–)
ε_{gw}	emissivity of the gas, based on wall temperature (–)
$\Delta\varepsilon$	correction parameter for calculating gas mixtures (–)
A_v	absorptance of the gas, being a function of geometry (–)
T	optical density (–)
R	radius (m)
s_{eq}	equivalent layer thickness (m)
p_g	partial pressure of a gas component (bar)
I	intensity (W m^{-2} sr^{-1})
$\dot{Q}_{gw}$	radiation heat flux between gas body and wall (W)
Δ	equivalence ratio (–)
D	characteristic length (m)
A	degree of absorption (–)

K4 Thermal Radiation of Gas–Solids–Dispersions

Hans-Gerd Brummel
Siemens Power Generation, Berlin, Germany

1 Introduction

Particles, e.g., fly ash entrained in the combustion gas flow of a steam generator, can considerably increase the radiant energy emitted by those hot gases. Depending on the wavelength as well as on the spectral optical properties (i.e., the complex refractive index) and size distribution of the particles, thermal radiation is being emitted, absorbed and scattered by the dispersed solids. For the emissivity of the dispersed particles their concentration in the gas (in the following referred to as "load") is the most governing parameter.

Two mathematical models, designed for different applications and boundary conditions, are presented in this section for the determination of the emissivity of a particle cloud.

The particle load represents the parameter, which has the highest impact on the emissivity of the dispersed solids. In cases, where the load of particles is low, as found in combustion chambers of oil and pulverized coal fired steam generators, a simple model can be applied with good accuracy, which is only taking into account the absorption/emission of the particles, neglecting any sort of radiation scattering by those solids.

This simple radiation model shall be presented here at first (see Sect. 2 of this chapter). It is comparable with the particle radiation approach of Chap. K5 ("Thermal Radiation in Combustion Environments"), which combines the heat transfer phenomena resulting from gas, soot, fly ash, and coal/coke radiation.

For technical processes which are characterized by small particle sizes combined with higher particle loads, a more complex radiation model will be presented in Sect. 3 of this Chapter, which also takes into account scattering effects, caused by those particles. This model fully includes the above-mentioned simple model as a special case, it is generally applicable, but is characterized by a slightly higher calculation effort.

After dealing with the particle radiation in greater detail (see in particular various calculation examples in Sect. 4 of this Chapter), the combination of particle and carrier gas radiation (topic of Chap. K3) will be covered subsequently in Sects. 5 and 6 of this Chapter.

2 Particle Radiation: Simplified Thermal Radiation Model for Low Particle Loads

For applications with operating conditions, where the exponent in Eqs. (1) or (2) does not exceed a limiting absolute value of 0.5, which is usually the case in conventional pulverized coal-fired boilers with combustion chambers of small to medium size, the emissivity of the particle cloud can be determined by a simple absorption model [1], neglecting any scattering of radiation by the particles (see Sect. 7 of this Chapter for symbol definitions).

$$\varepsilon_\mathrm{p} = 1 - \exp(-\bar{Q}_\mathrm{abs} A L_\mathrm{p} l_\mathrm{mb}) \tag{1}$$

or

$$\varepsilon_\mathrm{p} = 1 - \exp\left(-k \frac{3}{2\rho_\mathrm{p}} d_\mathrm{p}^{-2/3} L_\mathrm{p} l_\mathrm{mb}\right), \tag{2}$$

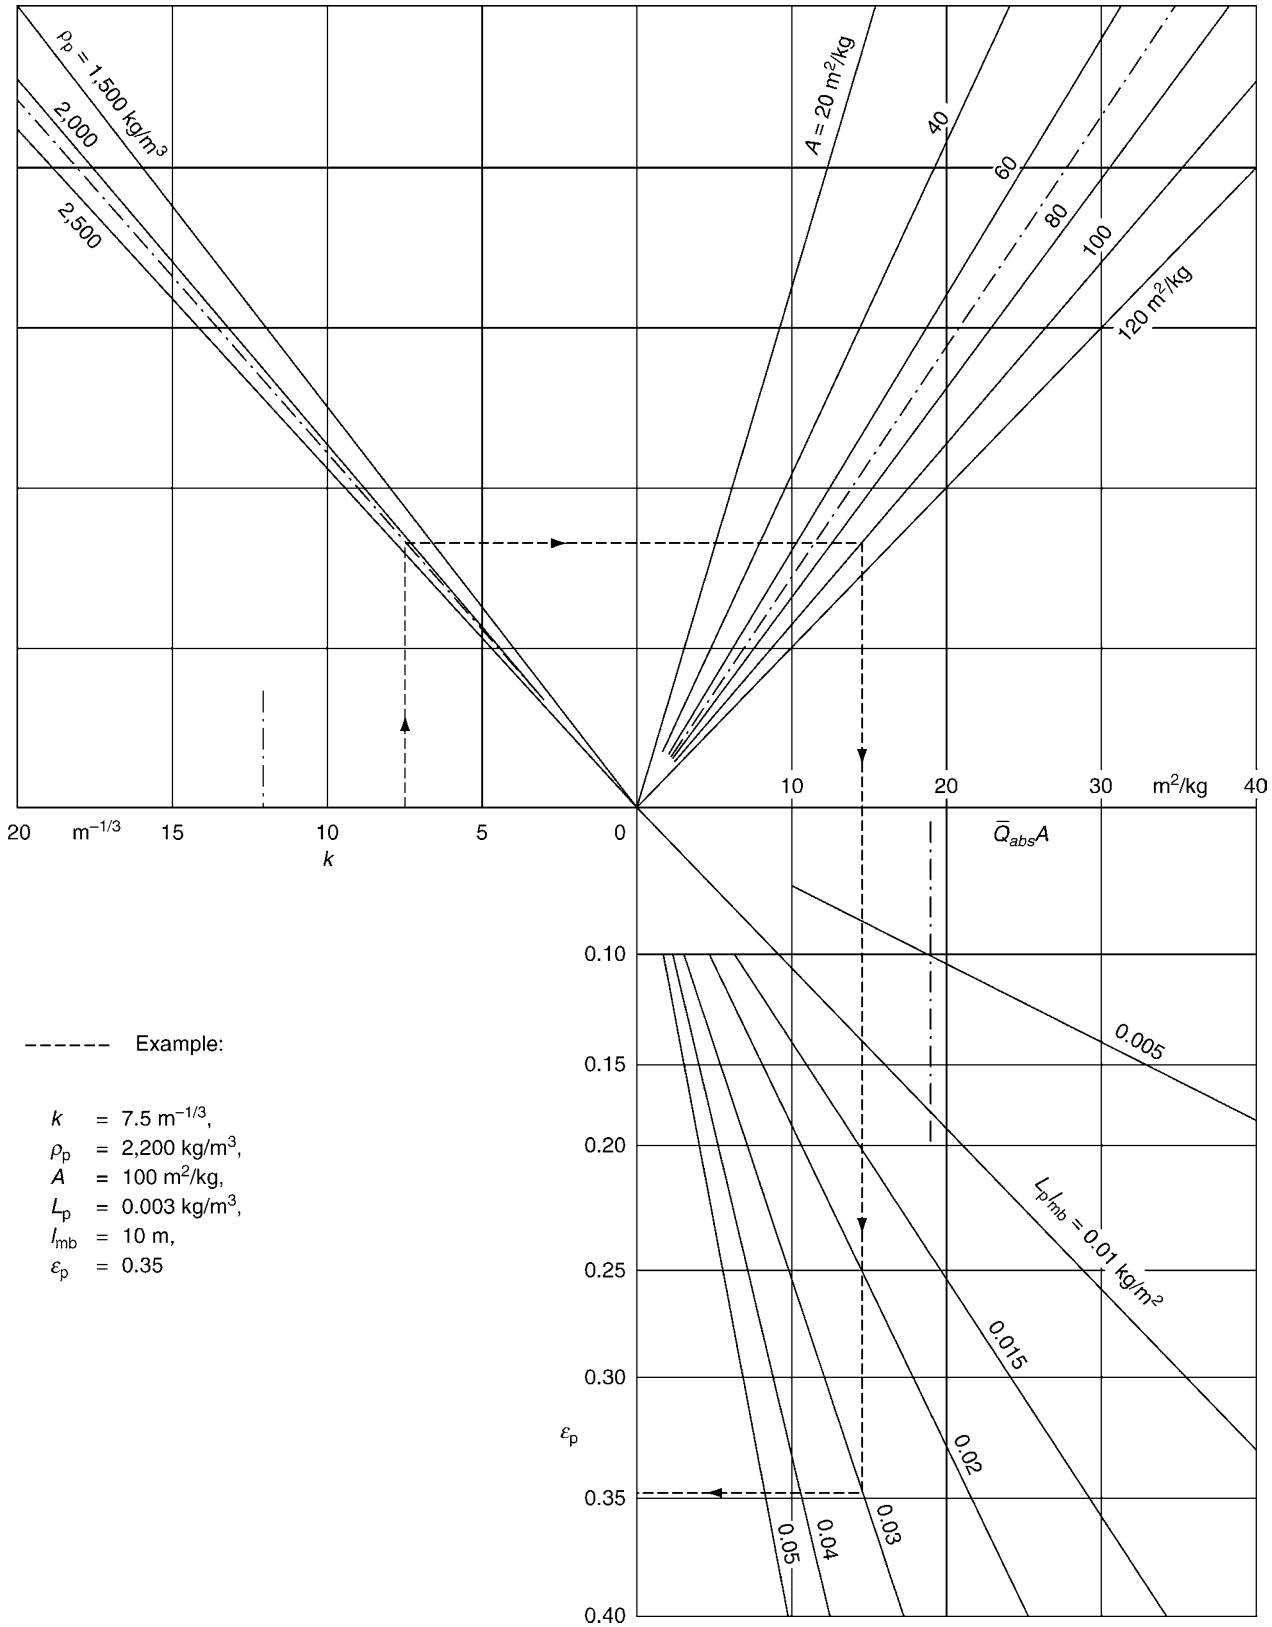
with

$$d_\mathrm{p} = \frac{3}{2\rho_\mathrm{p} A} \tag{3}$$

and

$$k = \bar{Q}_\mathrm{abs} d_\mathrm{p}^{-1/3}. \tag{4}$$

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_43,



K4. Fig. 1. Nomogram for the determination of the dispersed particles emissivity ε_p as a function of the particle substance constant k (in $m^{-1/3}$) or the effective absorption projection area $\bar{Q}_{abs}A$ (in m^2/kg), respectively, the material density ρ_p, the particle load L_p (in kg/m^3), and the mean beam length l_{mb} (in m).

The nomogram shown in Fig. 1 can be applied alternatively to Eqs. (1) or (2).

The data required for the application of this calculation model or the nomogram were determined by Biermann and Vortmeyer [1] in studies on fly ash, compiled in Table 1. Data for particle load L_p and density of the fly ash material ρ_p were the easiest to obtain. The fly ash density was measured by means of a pycnometer (see VDI 2031). The surface measurements for the determination of the specific projection area of the particles A and the mean particle diameter d_p were performed with the Blaine permeabilimeter (by VDI 2031 method, other methods may result in different figures). The only way of determining the parameters $\bar{Q}_{abs}$ or k, respectively, characterizing the absorption of the particles, was by means of emission measurements. A wide range of data for $\bar{Q}_{abs}$, which actually were found independent of temperature (investigated range 723–1,323 K), are listed in Table 1. It has to be noted that these data are only valid for the related mean particle diameter d_p, also listed in the table.

Remarks

These data for the mean relative absorption efficiency $\bar{Q}_{abs}$ (or the substance constant k, respectively), which are compiled in Table 1 for 20 fly ashes cannot be used directly any longer, because most of the coal mines do not exist anymore and blending of imported coal nowadays is a common practice.

Nevertheless, the figures are still valid to provide an orientation concerning the range of the mean relative absorption efficiencies for coal ashes in general.

These data were also used as basis to derive representative optical properties for fly ashes in conjunction with the more complex radiation model presented in the following section.

3 Particle Radiation Model for Higher Particle Loads

Experiences have shown [1, 9] that the equations presented above in Sect. 2 of this Chapter show a tendency to overestimate the heat transfer from clouds of small ash particles to heating surfaces for processes with higher loads than found in conventional atmospheric pulverized coal fired boilers, such as fluidized bed combustion, entrained pressurized coal gasification, and pressurized pulverized coal combustion.

The root cause for this overestimation is the scattering of the radiation by the particles. The backwards scattered fraction attenuates the radiation heat transfer to the enclosure walls.

Figure 2 shows schematically the angular intensity distribution of the radiation, scattered by a spherical particle in dependency of the particle size parameter p, which is defined as a function of the diameter of the sphere d_{sph} and the wavelength λ of the incident radiation.

In the context of his experimental studies (see Sect. 2 of this Chapter above), Biermann together with Vortmeyer developed also a two-flux model [1] for the determination of the particle

K4. Fig. 2. Angular distribution of the scattered intensity of incident radiation of wavelength λ hitting a spherical particle, in dependency of the particle size parameter p. Principal diagram of intensity distribution, taken from [10].

emissivity, taking scattering into account. Here the total scattered radiation is split into a forward and a backward fraction (backscattering). Forward scattering is treated in the model as having no impact on the radiation (in a two-flux model incident radiation and scattered radiation have the same direction), but backward scattering attenuates the emissivity, redirecting part of the radiation in the opposite direction.

In principle, the angular scattering distribution and also the radiation absorption of a particle can be calculated by means of the generally applicable electromagnetic theory published by Mie [2] in 1908 for scattering and absorption of radiation, caused by homogeneous spheres of arbitrary size. Scattering in the backward direction becomes significant when the wavelength of the radiation and the size of the sphere are of the same magnitude. For larger spheres forward scattering is dominant.

The backscattering fraction for the two-flux model can be obtained by integration of the angular scattered intensities over the backward-oriented hemisphere. At the time of the formulation of the two-flux model, it could hardly be used in practice, as complex Mie-calculations were very time consuming for the computers of the late 1960s. Even more important, there were no properties available at that time to describe the scattering characteristics of fly ashes.

In the second half of the 1980s, Brummel and Kakaras developed a thermal radiation model for gas–solid-dispersions, which incorporated the full Mie-algorithms [3], but still there were only very rare data available for the complex refractive indices of fly ashes, the most important input parameter needed for the Mie-calculations.

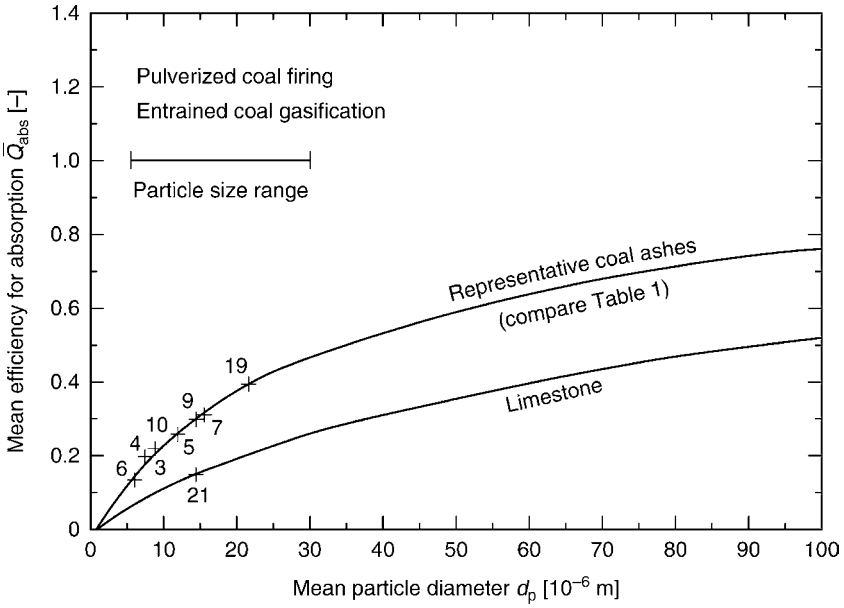
Therefore, Brummel reversed the calculation procedure (see [5, 13] for details). He determined mean complex indices of refraction iteratively in a comprehensive calculation procedure including the Mie-theory, using those singular data points for the mean relative efficiency absorption $\bar{Q}_{abs}$ as basis, which have been determined experimentally earlier by Biermann and Vortmeyer [1] and which are compiled in Table 1.

It was found that nearly half of the fly ashes listed there had very similar optical properties. Therefore, it was possible to work out representative curves for fly ash for the mean relative efficiencies for absorption $\bar{Q}_{abs}$ and even more important also for backscattering $\bar{Q}_{bsc}$, which are needed as input parameters in the above-mentioned two-flux model of Biermann and Vortmeyer [1]. By application of the full Mie-theory, these figures could not only be determined for the concrete mean particle diameters of the Biermann investigations (there is only one mean diameter listed per fly ash species – compare Table 1) but also for all other particle sizes with the same relative size distribution (see Figs. 3 and 4).

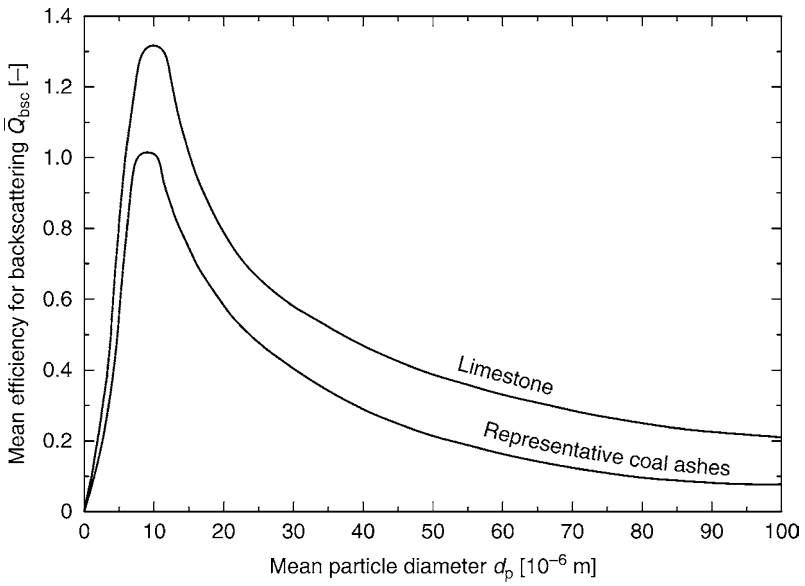
For estimates of the radiation by dispersed particles, i.e., without knowing the actual values for the mean relative efficiencies $\bar{Q}_{abs}$ and $\bar{Q}_{bsc}$ for the fly ash of interest, these curves can be taken as representative for coal ashes in general, as those efficiencies are located almost in the center of the bandwidth for all ashes of the experimental investigations carried out by Biermann.

For limestone, which is an additive in fluidized bed combustion, the figures differ from those of the representative fly ashes and therefore have been plotted separately in Figs. 3 and 4.

The displayed range for the mean particle diameter d_p from 0 to $100 \cdot 10^{-6}$ m in Figs. 3 and 4 covers the fly ash sizes found in the technical applications “pulverized coal combustion” and



K4. Fig. 3. Calculated mean relative absorption efficiency $\bar{Q}_{abs}$ for representative fly ashes and limestone as a function of the mean particle diameter d_p according to [4, 5, 13] (compare Table 1, curves match well with the measured data points "+" for fly ash nos. 3, 4, 5, 6, 7, 9, 10, and 19 of the Biermann investigations [1]).



K4. Fig. 4. Calculated mean relative backscattering efficiency $\bar{Q}_{bsc}$ for representative fly ashes and limestone as a function of the mean particle diameter d_p (acc. to [4, 5, 13]).

"entrained coal gasification" to the full extend. For fluidized beds with much larger mean particle diameters, Table 2 has to be applied.

With the $\bar{Q}_{abs}$ and $\bar{Q}_{bsc}$ data for limestone from Figs. 3 and 4 and Table 2, the dispersed particles emissivities for ashes from circulating fluidized beds, which were determined experimentally by Stapper [6], could be reproduced with good accuracy (see [5] for more details).

Investigations by Neubronner and Vortmeyer [7, 11], dealing in particular with analyses of the chemical compositions and size distributions for ashes from numerous pulverized coal fired power plants, combined with Mie-calculations based on spectral optical properties for fly ash components measured by Goodwin and Mitchner [8, 12], show under certain conditions a strong impact of the actual size distribution of the fly ash on the mean relative backscattering efficiency.

K4. Table 2. Calculated mean relative efficiencies for absorption $\bar{Q}_{abs}$ and backscattering $\bar{Q}_{bsc}$ for representative fly ashes and limestone listed for a range of larger mean particle diameters d_p (acc. to [4, 5]). Applicable for fluidized bed combustion. To obtain data for mean particle sizes not directly listed, linear interpolation can be applied

Mean particle diameter d_p (10^{-6} m)	Representative coal ashes		Limestone

K4. Fig. 5. Diagram for the determination of the dispersed particles emissivity based on the radiation properties of representative fly ashes (acc. to [5, 13], application range 0 µm $\leq L_p l_{mb} \rho_p^{-1} \leq$ 1,000 µm).

3.1 Model Equations

According to the two-flux-model by Biermann and Vortmeyer [1] the dispersed particles emissivity under consideration of backward scattering can be expressed as

$$\varepsilon_p = (1-\beta)\left(\frac{1-\exp(-\Phi_p)}{1+\beta\exp(-\Phi_p)}\right), \tag{5}$$

with

$$\gamma = \left(1+\frac{2\bar{Q}_{bsc}}{\bar{Q}_{abs}}\right)^{1/2}, \tag{6}$$

$$\beta = \frac{\gamma-1}{\gamma+1}, \tag{7}$$

$A = \dfrac{3}{2\rho_p d_p}$ derived from Eq. (3), see Sect. 2 of this Chapter

$$\Phi_p = \bar{Q}_{abs} A L_p l_{mb} \gamma. \tag{8}$$

Data for $\bar{Q}_{abs}$ can be taken from Fig. 3 and data for $\bar{Q}_{bsc}$ can be taken from Fig. 4, as a function of the mean particle diameter. For larger mean particle diameters, $d_p > 100 \cdot 10^{-6}$ m data for $\bar{Q}_{abs}$ and $\bar{Q}_{bsc}$ are listed in Table 2.

Under negligence of backscattering, which is viable for values of the product $\Phi_p = \bar{Q}_{abs} A L_p l_{mb} < 0.5$, Eqs. (1) or (2) for the simplified model, described in Sect. 2 of this Chapter, can be derived as a special case from the set of Eqs. (5–8).

For mean particle diameters $d_p \leq 30$ µm, i.e., in particular for the technical applications pulverized coal combustion and entrained coal gasification, Figs. 3 and 4 as well as Eqs. (5–8) have been combined to a diagram (Fig. 5) for practical use. With known data for the fly ash density, particle load, and mean

beam length, which are generally easy to obtain, the dispersed particles emissivity can directly be read from the diagram in dependency from the mean "Sauter" particle diameter (derived from Eq. (3)).

Calculation example: d_p = 15 µm; ρ_p = 2,400 kg/m^3, L_p = 0.02 kg/m^3, and l_{mb} = 2.6 m. The mathematical term $L_p l_{mb} \rho_p^{-1}$ results in 21.67 µm and a dispersed particles emissivity ε_p of 0.48 can be read from the diagram (Fig. 5).

4 Particle Radiation: Calculation Examples

4.1 Simplified Dispersed Particles Radiation Model (See Sect. 2 of this Chapter)

Example 1: Low particle load
Application of simple model [Eqs. (2) and (3) or nomogram (Fig. 1)]

k = 9.5 m$^{-1/3}$,
ρ_p = 2,200 kg/m^3,
A = 100 m^2/kg,
L_p = 0.001 kg/m^3,
l_{mb} = 10 m.

Results

$d_p = 6.8 \cdot 10^{-6}$ m	acc. to Eq. (3)
ε_p = 0.165	acc. to Eq. (2)
ε_p = 0.17	acc. to nomogram Fig. 1 alternatively

Example 2: Increased particle load
Application of simple model [Eqs. (2) and (3) or nomogram (Fig. 1)]

k = 9.5 m$^{-1/3}$,
ρ_p = 2,200 kg/m^3,
A = 100 m^2/kg,
L_p = 0.02 kg/m^3,
l_{mb} = 10 m.

Results

$d_p = 6.8 \cdot 10^{-6}$ m	acc. to Eq. (3)
ε_p = 0.973	acc. to Eq. (2)

The simplified model, Eqs. (1) or (2) or nomogram (Fig. 1) cannot be applied anymore, due to the model-based overestimation of the emissivity (criterion: Absolute value of exponent in Eq. (2) > 0.5, see Sect. 2 of this chapter).

4.2 Dispersed Particle Radiation Model with Integration of the Mie-Theory (See Sect. 3.1 of this Chapter)

Application of the more sophisticated calculation model taking backward scattering into account.

Dispersed particles emissivity ε_p determination acc. to Eqs. (5–8) and Figs. 3 and 4.

Example 3: Low particle load, same input data as for Example 1
ρ_p = 2,200 kg/m^3,
A = 100 m^2/kg,
L_p = 0.001 kg/m^3,
l_{mb} = 10 m.

Particle substance: Fly ash

Results

$d_p = 6.8 \cdot 10^{-6}$ m	acc. to Eq. (3)
$\bar{Q}_{abs}$ = 0.18	read from Fig. 3
$\bar{Q}_{bsc}$ = 0.245	read from Fig. 4
ε_p = 0.164	acc. to Eqs. (5)–(8)

At low particle loads there is hardly any difference between the results obtained by the simple model (compare Example 1) and by the more complex model, which takes backward scattering into account.

Example 4: Increased particle load, same input data as for Example 2
ρ_p = 2,200 kg/m^3,
A = 100 m^2/kg,
L_p = 0.02 kg/m^3,
l_{mb} = 10 m.

Particle substance: Fly ash

Results

$d_p = 6.8 \cdot 10^{-6}$ m	acc. to Eq. (3)
$\bar{Q}_{abs}$ = 0.18	read from Fig. 3
$\bar{Q}_{bsc}$ = 0.245	read from Fig. 4
ε_p = 0.682	acc. to Eqs. (5–8)

The dispersed particles emissivity calculated by means of the complex Mie particle radiation model yields a result, which is only approximately 2/3 of the figure obtained by the simple model (compare Example 2), as the Mie-model takes into account the attenuation of the radiation caused by backscattering.

Example 5: Even more increased particle load
ρ_p = 2,200 kg/m^3,
A = 100 m^2/kg,
L_p = 0.2 kg/m^3,
l_{mb} = 10 m.

Particle substance: Fly ash

Results

$d_p = 6.8 \cdot 10^{-6}$ m	acc. to Eq. (3)
$\bar{Q}_{abs}$ = 0.18	read from Fig. 3
$\bar{Q}_{bsc}$ = 0.245	read from Fig. 4
ε_p = 0.683	acc. to Eqs. (5–8)

If backward scattering is taken into account, the dispersed particles emissivity asymptotically approaches a limiting figure <1 (compare Examples 3, 4, and 5; see [3, 5] for details).

By application of the simplified model the dispersed particles emissivity asymptotically approaches a figure of 1, which is the emissivity of a black body, which may lead to a significant overestimation of the radiative heat transfer.

The calculation examples 1–5 show that in particular for small mean particle diameters in the range of $10 \cdot 10^{-6}$ m and higher particle loads the more sophisticated model has to be applied, as in those cases, backscattering has a strong impact on the thermal radiation by the particles. For larger mean particle diameters ($d_p > 100 \cdot 10^{-6}$ m), backward scattering does not play a significant role. Here the results of the simplified model and the more sophisticated calculation procedure again match closer.

This fits well to the general scattering theory formulated by Mie. Highest scattering occurs, when particle size and wavelength are of the same magnitude. For larger particles scattering occurs mainly in the forward directions.

4.3 Thermal Radiation of Mixtures of Dispersed Particles

Example 6

The dispersed particles emissivity of a mixture of 20 wt% limestone with a mean particle diameter of $200 \cdot 10^{-6}$ m and 80 wt% fly ash (fly ash no. 7 from Table 1) with a mean particle diameter of $30 \cdot 10^{-6}$ m has to be determined. The overall particle load should equal 0.1 kg/m^3 and the mean beam length is assumed as 3.0 m.

(*Remark*: The input data of this example are fictitious with the goal to primarily describe the calculation procedure, the data do not refer to any real technical application.)

Due to the magnitude of the particle load the use of the sophisticated dispersed particles radiation model is necessary.

Particle substance 1: Fly ash (Index "1")

$\rho_{p\ 1}$ = 2,270 kg/m^3	taken from Table 1 "fly ash no. 7"
A_1 = 22.03 m^2/kg	acc. to Eq. (3)
$\bar{Q}_{abs\ 1}$ = 0.47	read from Fig. 3
$\bar{Q}_{bsc\ 1}$ = 0.087	read from Fig. 4

Particle substance 2: Limestone (Index "2")

$\rho_{p\ 2}$ = 2,700 kg/m^3	taken from Table 1 "limestone"
A_2 = 2.78 m^2/kg	acc. to Eq. (3)
$\bar{Q}_{abs\ 2}$ = 0.715	read from Table 2
$\bar{Q}_{bsc\ 2}$ = 0.030	read from Table 2

Averaging of the specific projection area and the mean relative efficiencies by weight is recommended for practical applications (index: "tot" for total):

A_{tot} = (80 wt% · 22.03 m^2/kg + 20 wt% · 2.78 m^2/kg)/100 wt%
= 18.18 m^2/kg,
$\bar{Q}_{abs\ tot}$ = 0.519,
$\bar{Q}_{bsc\ tot}$ = 0.076,

leads to the following result:

$\varepsilon_{p\ tot}$ = 0.896 acc. to Eqs. (5–8).

5 Combined Gas and Dispersed Particle Radiation

Also for the coupling of gas and particle phase radiation it makes sense to differentiate between low and higher particle loads.

5.1 Low Particle Load

If the thermal radiation of the gas body (see Chap. K3) is not scattered significantly by the dispersed particles, which is only the case for rather small particle loads ($L_p \leq 0.005$ kg/m^3), the total emissivity of the gas–solids–mixture can be described by the following equation, where the dispersed particles as well as the gas are assumed as gray bodies

$$\varepsilon_{g+p} = \varepsilon_g + \varepsilon_p - \varepsilon_g \varepsilon_p. \tag{9}$$

For absorption calculations the total absorptance is

$$\alpha_{g+p} = A_v + \varepsilon_p - A_v \varepsilon_p. \tag{10}$$

The radiative heat transfer between the gas–solid mixture and a wall can be described by the following correlation analogue Eq. (18) in Chap. K3

$$\dot{q}_{g+p,w} = \frac{\varepsilon_w}{\alpha_{g+p} + \varepsilon_w - \alpha_{g+p}\varepsilon_w} \sigma [\varepsilon_{g+p} T_g^4 - \alpha_{g+p} T_w^4]. \tag{11}$$

5.2 Increased Particle Load

At higher particle loads again the situation gets more complex. Regarding exclusively the radiation of the dispersed particles (solid phase) according to Eqs. (5–8), with increasing load or optical thickness, respectively, the dispersed particles emissivity will asymptotically approach a limiting value <1.

So due to backward scattering the thermal radiation of the particle phase cannot be raised by a further increase of the particle load.

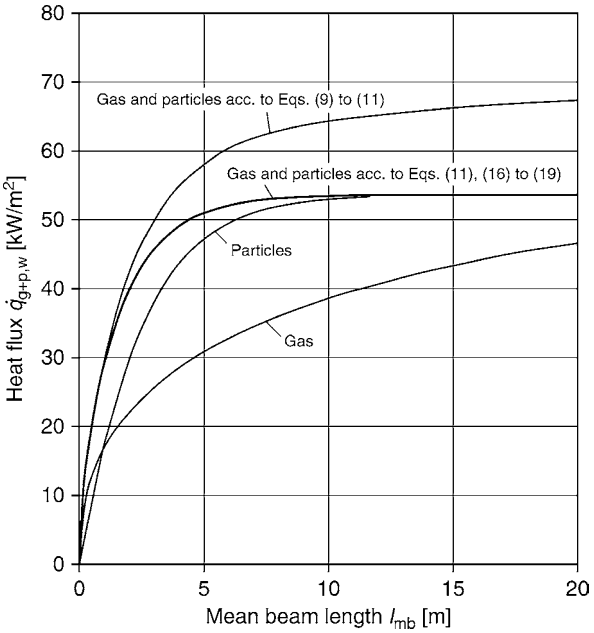
For a mixture of gas phase and solid phase, this limiting dispersed particles emissivity (asymptote) is also the limiting value for the total emissivity of the gas–solid mixture. If more particles cannot increase the emissivity, the additional gas present also cannot raise it.

Nevertheless, applying the radiation coupling correlations for the gas and particle phases Eqs. (9) and (10), this will result in contrast to the statements above to increased figures for emissivity and absorptance even in that asymptotic range. This is shown in Fig. 6, where conditions of a medium particle load are displayed exemplarily.

To simulate the phenomena more realistically according to the laws of physics, a modified calculation procedure has to be applied, which will be described in the following.

By means of Eqs. (14) and (15), the absorption coefficients of the gas body $K_{emi,\ g}$ and $K_{abs,\ g}$ can be calculated, if the mean beam length l_{mb}, the emissivity ε_g, and the absorptance A_v of the gas body are known.

The parameters ε_g and A_v can be determined, as described in detail in Chap. K3, via the diagrams by Hottel et al. as a



K4. Fig. 6. Superimposition of the thermal radiation of the gas and the dispersed particle phase for a medium particle load as a function of the mean beam length. Comparison of the coupling correlations for low particle loads (Eqs. (9–11)) with a more realistic coupling method, which also takes into account the scattering of gas radiation at the particles (Eqs. (11) and (16–19)).

function of temperature, the partial pressures of the gas components, and the mean beam length.

Finally, the mean beam length l_{mb} can be calculated using the geometry data of the enclosure for the gas–solid mixture (see Chap. K3, Eq. (9)).

Based on the definition equations for the emissivity of a gas body ε_g

$$\varepsilon_g = 1 - \exp(-K_{emi,g} l_{mb}) \tag{12}$$

and for the absorptance A_ν (compare Chap. K3, Eq. (8))

$$A_\nu = 1 - \exp(-K_{abs,g} l_{mb}), \tag{13}$$

the emission and absorption coefficients for the gas phase can be determined as

$$K_{emi,g} = -\ln(1 - \varepsilon_g)/l_{mb}), \tag{14}$$

$$K_{abs,g} = -\ln(1 - A_\nu)/l_{mb}). \tag{15}$$

As the absorption and emission coefficients of the gas and the solid phases can be coupled in an additive manner (under the assumption of an identical mean beam length l_{mb} for both phases), Eqs. (5–8), which were originally derived for a cloud of dispersed particles exclusively, can now be transferred into the following terms.

The total emissivity of the gas–solid mixture can be described similar to Eq. (5) in Sect. 3.1 of this Chapter

$$\varepsilon_{g+p} = (1 - \beta)\left(\frac{1 - \exp(-\Phi_{emi,g+p})}{1 + \beta \exp(-\Phi_{emi,g+p})}\right), \tag{16}$$

with the auxiliary terms

$$\gamma = \left(1 + \frac{2\bar{Q}_{bsc}}{\bar{Q}_{abs}}\right)^{1/2} \quad \text{see Sect. 3.1} \qquad \text{Eq. (6)}$$

and

$$\beta = \frac{\gamma - 1}{\gamma + 1} \quad \text{see Sect. 3.1,} \qquad \text{Eq. (7)}$$

and the optical thickness for the gas–solid mixture (compare Eq. (8) for the particle phase)

$$\Phi_{emi,g+p} = (\bar{Q}_{abs} A L_p + K_{emi,g}) l_{mb} \gamma. \tag{17}$$

The total absorptance of the gas–solid mixture can be described analogously by the following correlation

$$\alpha_{g+p} = (1 - \beta)\left(\frac{1 - \exp(-\Phi_{abs,g+p})}{1 + \beta \exp(-\Phi_{abs,g+p})}\right) \tag{18}$$

again with the auxiliary terms

$$\gamma = \left(1 + \frac{2\bar{Q}_{bsc}}{\bar{Q}_{abs}}\right)^{1/2} \quad \text{and} \quad \beta = \frac{\gamma - 1}{\gamma + 1}$$

and the optical thickness for absorption

$$\Phi_{abs,g+p} = (\bar{Q}_{abs} A L_p + K_{abs,g}) l_{mb} \gamma. \tag{19}$$

For the resulting heat flux $\dot{q}_{g+p,w}$ between a hot gas–solid mixture and a cooled wall.

Eq. (11) is valid, which shall be repeated here for reasons of clarity

$$\dot{q}_{g+p,w} = \frac{\varepsilon_w}{\alpha_{g+p} + \varepsilon_w - \alpha_{g+p}\varepsilon_w} \sigma[\varepsilon_{g+p} T_g^4 - \alpha_{g+p} T_w^4].$$

Remark

It is generally recommended to apply the more sophisticated coupling calculation model even for operating conditions with low particle loads, as in the age of powerful personal computers the additional calculation effort is not an issue anymore, as it was some decades ago.

5.3 Calculation Examples

The total heat flux density resulting from the thermal radiation exchange between a hot, particle laden flue gas of homogeneous temperature and cooled enclosure walls, will be determined, whereas again two cases with different particle loads shall be analyzed.

Case 1 (low particle load)

Input data

ε_g = 0.43	acc. to Chap. K3
A_ν = 0.58	acc. to Chap. K3
l_{mb} = 7.5 m	
A = 68.5 m²/kg	
L_p = 0.001 kg/m³	reference volume in operational state (at actual temperature and pressure)
d_p = 10 · 10⁻⁶ m	
ε_w = 0.7	
T_{g+p} = 1,073 K	
T_w = 673 K	

The mean efficiencies for the dispersed fly ash particles can be taken from Figs. 3 and 4 (Sect. 3 of this Chapter)

$\bar{Q}_{abs} = 0.22$,
$\bar{Q}_{bsc} = 0.21$.

Results

$\varepsilon_p = 0.1062$	acc. to Eqs. (5–) to (8) with Figs. (3) and (4) or acc. to Fig. 5 alternatively
$K_{emi,g} = 0.0749\ m^{-1}$	acc. to Eq. (14)
$K_{abs,g} = 0.1157\ m^{-1}$	acc. to Eq. (15)
$\varepsilon_{g+p} = 0.4668$	acc. to Eqs. (16) and (17)
$\alpha_{g+p} = 0.5722$	acc. to Eqs. (18) and (19)
$\dot{q}_{g+p,w} = 22828.3\ W\ m^{-2}$	acc. to Eq. (11)

The application of Eqs. (9–11), which are valid only for low particle loads, would result in a heat flux of 23351.9 W m^{-2}, an overestimation of just 2.3%.

Case 2 (high particle load)
Input data

$\varepsilon_g = 0.43$	acc. to Chap. K3
$A_v = 0.58$	acc. to Chap. K3
$l_{mb} = 7.5$ m	
A = 68.5 m^2/kg	
$L_p = 0.2$ kg/m^3	reference volume in operational state (at actual temperature and pressure)
$d_p = 10 \cdot 10^{-6}$m	
$\varepsilon_w = 0.7$	
$T_{g+p} = 1073$ K	
$T_w = 673$ K	

The mean efficiencies for the dispersed fly ash particles can be taken from Figs. 3 and 4 (Sect. 3 of this Chapter)

$\bar{Q}_{abs} = 0.22$,
$\bar{Q}_{bsc} = 0.21$.

Results

$\varepsilon_p = 0.7392$	acc. to Eqs. (5–8) with Figs. (3) and (4) or acc. to Fig. 5 alternatively
$K_{emi,g} = 0.0749\ m^{-1}$	acc. to Eq. (14)
$K_{abs,g} = 0.1157\ m^{-1}$	acc. to Eq. (15)
$\varepsilon_{g+p} = 0.7392$	acc. to Eqs. (16) and (17)
$\alpha_{g+p} = 0.7392$	acc. to Eqs. (18) and (19)
$\dot{q}_{g+p,w} = 35662.1\ W\ m^{-2}$	acc. to Eq. (11)

The formal application of Eqs. (9–11), which are valid only for low particle loads, would result in this case in a heat flux of 38815.7 W m^{-2}, an overestimation of 8.8%.

6 Closing Remarks

At higher figures for the (geometrically determined) mean beam length and very high particle loads, a thermal insulation of the hot core zone of a gas–solid mixture can occur. The radiation of the core zone cannot reach the enclosure walls anymore, as the layer of the gas solids mixture close to the walls turns out to be opaque, insulating as well gas as particle radiation from the core zone. This insulation effect is even higher, when relatively cold particles trickle downwards in that region next to the enclosure walls. These phenomena are covered in greater detail in [5].

7 Symbols

ε_p	dispersed particles emissivity (–)
$\bar{Q}_{abs}$	mean relative absorption efficiency of a particle (integrated over the wavelength spectrum) (–)
L_p	particle load at operation conditions (i.e., at given temperature and pressure) (kg/m^3)
A	specific projection area of the dispersed particles (m^2/kg)
l_{mb}	mean beam length (m)
d_p	mean particle diameter (definition acc. to Eq. (3)) (m)
k	substance constant linked with $\bar{Q}_{abs}$ (definition acc. to Eq. (4)) ($m^{-1/3}$)
ρ_p	density of the substance of the particles (material density) (kg/m^3)
β, γ	calculation parameters acc. to Eqs. (6) and (7) (–)
Φ_p	optical thickness of particle cloud (–)
$\bar{Q}_{bsc}$	mean relative backscattering efficiency of a particle (integrated over the wavelength spectrum) (–)
ε_{g+p}	total emissivity of a particle laden gas (–)
ε_g	emissivity of the gas body (–)
ε_p	emissivity of the dispersed particles (–)
α_{g+p}	total absorptance of a particle laden gas (–)
A_v	geometry-dependent absorptance of the gas body (–)
$\dot{q}_{g+p,w}$	radiative heat flux between particle laden gas and enclosure wall (W m^{-2})
ε_w	wall emissivity (–)
σ	Stefan–Boltzmann constant $5.67 \cdot 10^{-8}$ W m^{-2} K^{-4} (W m^{-2} K^{-4})
T_g	homogeneous gas (and particle) temperature (K)
T_w	wall temperature (K)
$K_{emi,g}$	emission coefficient of the gas phase (m^{-1})
$K_{abs,g}$	absorption coefficient of the gas phase (m^{-1})
$\Phi_{emi,g+p}$	optical thickness of the gas solid dispersion for emission (–)
$\Phi_{abs,g+p}$	optical thickness of the gas solid dispersion for absorption (–)

K5 Heat Radiation in Furnaces

Wolfgang Richter[1,†] · *Klaus Görner*[2]
[1]Essen, Germany
[2]Universität Duisburg-Essen, Essen, Germany

1 Introduction

The exchange of energy by radiation in a flame or a furnace is the result of a complex radiation interaction in the furnace or combustion chamber including emission, absorption, reflection, and scattering within the suspension (flue gas) and between this and the walls of the combustion chamber. For simplifying nomenclature, subsequently the expressions "flue gas suspension" and "furnace" are used.

A calculation of this radiation energy transport presumes knowledge of the optical properties of the flue gas suspension and of the walls, as well as of the local temperature distribution in the calculation space and at the embracing walls. The optical properties depend on the composition of the flue gas suspension taking into account both gaseous and particulate species.

The temperature distribution depends on the interaction of flow, reaction, and burn-out processes. These variables are described by the flow (velocity) field and the concentration fields of the single species, resulting in an interaction as pointed out schematically in Fig. 1 [1].

Referring to the temperature distribution, it has to be taken into account additionally that gas and the particles could show differences in temperatures and in concentration distributions too, caused by locally high rates of heat release.

From the mathematical point of view, this is a system with distributed parameters which, due to the above-described dependencies, shows a strong coupling within and between the subsystems.

The spatial distribution of radiation heat fluxes inside the furnace and the net heat flow to the walls of the furnace are obtained from (radiation) energy balance equations for finite volume and surface regions of the furnace.

Often, it is not possible to predict the temperature distribution within the flue gas suspension or at the walls of the furnace. It is rather for the determination of these temperature distributions that the calculation of heat transfer is carried out. In this case, it is necessary to specify at first the flow field of flow and the location of energy release in the furnace as well as the convective heat exchange coefficients, then one has to compute the balance equations for radiation energies and also the total energy balance for finite volume and surface regions. A combined solution of total and radiation energy balance equations then leads to the wanted temperature field and simultaneously to total and radiation heat profiles corresponding to this temperature distribution.

On one hand, the knowledge of the local properties of the components contributing to the radiation in the furnace is usually incomplete. On the other hand, the calculation of the radiation energy exchange for furnaces with a geometry even close to reality is already insolvable in a straight forward mathematical way even for a homogeneous distribution of radiating components. Therefore, procedures for the computation of heat transfer in furnaces are mainly based on simplifications. These procedures are so-called mathematical furnace models.

Radiation models are mainly divided into flux and zone models (Fig. 2). Zone models include the so-called Monte Carlo models by which the radiation energy emitted per zone is divided into discrete single beams and the direction of which is determined by random numbers [2].

2 Radiation Properties of the Flue Gas Suspension and their Simplified Mathematical Modelling

The main thermal radiation emitting and absorbing components within a flame or a furnace fuelled by fossil fuels are the

K5. Fig. 2. Classification of radiation models.

gaseous components steam (H_2O) and carbon dioxide (CO_2) – to a smaller extent also methane (CH_4) and carbon monoxide (CO) – and suspended particulate matter, e.g., soot, char (carbon), and ash particles. Triatomic gas phase species, like CO_2 and H_2O, show in single spectral areas large absorption coefficients. At other frequencies, no absorption/emission interaction with thermal radiation is observed, they are spectral diatherm (or diabate) in these areas. With respect to this overall behavior, this type of thermal radiator is called a narrow band radiator. Otherwise, the spectral degree of absorption of particulate flue gas components and of the embracing walls shows small or no frequency dependence, they are the so-called gray radiators. Both types of radiators contribute in the flue gas suspension to the total radiation.

With the exception of soot particles, particulate matter causes a not negligible scattering of the radiation. Their selective radiation of the gas components and the continuous radiation of the particulate matter in the furnace is superimposed by the gray radiation of hot areas of the walls of the furnace. Subsequently, based on and supplementary to Chaps. K3 and K4 treating physical principles of radiation of gases and dust particles, basic mathematical approaches are presented describing the properties and the interaction of the above-mentioned radiation sources in furnaces. Thereby, it is favorable to formulate the radiation properties of the suspension additively from those of the pure gas and the particulate phase.

2.1 Radiation Properties of Gaseous Combustion Room Components

For simplified calculations of radiation energy exchanges in a furnace including gas radiation, it is usually sufficient assuming contributions to thermal radiation only by H_2O and CO_2, and that each of these components shows uniform partial pressures within the whole combustion space. The partial pressures p_{H_2O} and p_{CO_2} are determined by stoichiometric calculation based on the fuel composition and on the air fuel ratio λ for fixed values of burn-out (common assumption: complete burn-out).

In Table 1, columns 10 and 11, CO_2 and H_2O partial pressures of the combustion gases of some solid fuels types are given for a total pressure of 1 bar in the furnace. The stoichiometric calculation is presented for complete burn-out and 30% air surplus. The small SO_2 partial pressures of the combustion gases of the solid fuels are covered by the CO_2 partial pressures.

Columns 12 and 14 in Table 1 show the degree of emission ε_G, for the combustion gases of each fuel, as determined from data and diagrams of Chap. K3 exemplarily for a uniform furnace temperature of 1,600 K and for two different equivalent layer thicknesses of s_{eq} = 0.6 m and 3.86 m. According to the approximate equation (9) given in Chap. K3, s_{eq} = 0.6 m is the equivalent layer thickness of a cubic gas volume with an edge length of 1 m; s_{eq} = 3.86 m is the equivalent layer thickness of a parallelepiped with the dimensions of 5 m × 5 m × 15 m. Calculating the exchange of radiation within a furnace for which gas radiation plays a role equivalent to that of the radiation of suspended particles or of wall radiation, it has been proved to be advantageous to approach the degree of emission of a radiating gas component depending on p_G s_{eq} by the following sum formula [4]:

$$\begin{aligned}\varepsilon_G &= \sum_{i=1}^{3} a_j\left(1 - e^{-k_{Gi} p_G s_{eq}}\right)\\ &= \sum_{i=1}^{3} a_j \varepsilon_{Gi}.\end{aligned} \tag{1}$$

With

$$\varepsilon_{Gi} = \left(1 - e^{-k_{Gi} p_G s_{eq}}\right).$$

ε_{Gi} has to be considered a fictitious variable. The coefficients a_i and k_{Gi} of Eq. (1) have to be adapted so that ε_G values calculated by Eq. (1) are in best agreement with the measured results presented in Chap. K3. It emerges that each of the three weighting factors a_i may be described by

$$a_i = b_{0i} + b_{1i} T_G \tag{2}$$

with the auxiliary condition

$$\sum_{1}^{3} a_i = 1. \tag{3}$$

The volumetric absorption coefficients k_{Gi} are not considered to be temperature dependent.

Eq. (1) is also applicable to gas radiation emitted from gas mixtures. Coefficients b_{0i}, b_{1i}, and k_{Gi} calculated by Johnson and Beér [3] for overlapping CO_2- and H_2O radiation and their validity limits are presented in Table 2. The conditions are in fair agreement with those of real furnaces. Eq. (1) has to be modified to

$$p_g = p_{H_2O} + p_{CO_2}.$$

K5. Table 1. Properties of coals: Composition of coals, concentration of the radiating gas phase species CO_2 and H_2O and degrees of emission for $s_{eq} = 0.6$ m and $s_{eq} = 3.86$ m at $T_G = 1{,}600$ K and 1 bar total pressure (30% air surplus; air half-saturated with water vapor at 289 K; SO_2 concentration taken into account by surplus CO_2; according to Sarofim and Hottel [3])

K5. Table 2. Constants for the degree of emission of the pure gas phase for Eq. (1), according to Johnson and Beér [5] with the validity limits $p_{Ges} = 1$ bar and $0.5 < p_{H_2O}/p_{CO_2} < 2$

i	b_{oi} (–)	b_{1i} (1/K)	k_{Gi} (1/(m bar))
1	0.130	+0.000265	0.0
2	0.595	–0.000150	0.824
3	0.275	–0.000115	25.907

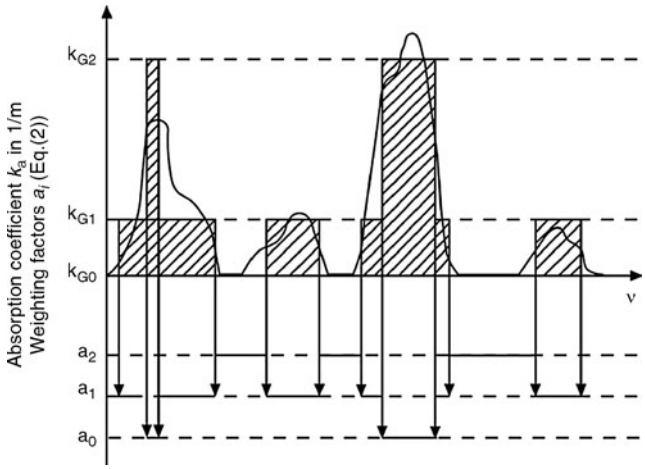
A comparison with the data of columns 12 and 13 in Table 1 demonstrates that degrees of emission calculated by the methods given by Chap. K3 are in good agreement with that determined by Eq. (1).

As described for the degree of emission, the degree of absorption may be approximated in a similar way by a sum of exponential functions using absorption diagrams (Fig. 3):

$$A_v = \sum_{i=1}^{3} a_{Wi}\,(1 - e^{-k_{Gi} p_G s_{eq}}). \tag{4}$$

In this case, the weighting factors a_{Wi} are functions of the temperature T_W of the radiation source and to a smaller extent of the gas temperature T_G. For further simplification of calculations of the radiation exchange, it is recommended to determine A_v from Eq. (1) instead of Eq. (4). Then the degree of absorption A_v of the gas layer is equal to the layer's degree of emission ε_G at the radiation source's temperature T_W, i.e.,

$$a_{Wi}\,(T_W) \approx a_i\,(T_W) \tag{5a}$$



K5. Fig. 3. Basic spectral emissivity curve of a band radiator and its approximation by Eq. (1).

with

$$a_i\,(T_W) = b_{0i} + b_{1i} T_W \tag{5b}$$

and b_{0i} and b_{1i} are according to Table 2.

The given approximations for ε_G and A_v are in no way thought to substitute the exact emission diagrams or their interpolation formulas (Chap. K3, Eqs. (23)–(26b)). However, Eqs. (1) and (4) exhibit the advantage of using temperature-independent absorption coefficients $k_{Gi}\,p_G$, which correspond to gray radiation. This allows the application of precalculated irradiation numbers for the calculation of radiation exchange between the absorbing volume of the furnace and the furnace

walls. These irradiation numbers are given, for instance in [4] for various values of absorption coefficients and different geometric shapes and arrays of surface and volume radiators in diagrams and tables. Hence, during computation or progress of iterations, the matrix of irradiation numbers remains constant and needs not to be recalculated for each step.

Equations (1) and (4) are especially adapted to (cf. Fig. 2) zone procedures by which the radiation exchange in furnaces with inhomogeneous temperature distributions can be calculated. Further on, by means of the sum approaches it is easier to approximate the superposition of selective (discrete) gas radiation and continuous radiation of solids. Finally, the volumetric absorption of reflected radiation can better be taken into account. This could be of importance for the accuracy of radiation exchange calculations for stronger reflecting furnace walls. The degrees of emission and absorption calculated by Eqs. (1), (4), and (5) may be directly inserted into Eq. (18), Chap. K3, to calculate the radiation exchange between an isothermal furnace volume and the surrounding walls. A more realistic approach, however, is achieved, especially for stronger reflecting walls, if Eq. (18) of Chap. K3 is modified accordingly to

$$\dot{Q}_{GW} = A\sigma \sum_{i=1}^{3} \frac{\varepsilon_W \varepsilon_{Gi}}{1 - (1 - \varepsilon_W)(1 - \varepsilon_{Gi})} \cdot [a_i (T_G) T_G^4 - a_i (T_W) T_W^4] \tag{6a}$$

with

$$\varepsilon_{Gi} = (1 - e^{-k_{Gi} p_G s_{eq}}) \tag{6b}$$

in agreement with Eq. (1). For the special case of only one gray gas with $a_i = 1$, and $\varepsilon_G = A_v$, Eq. (6) turns into Eq. (18), Chap. K3.

2.2 Radiation Properties of Suspended Particulate Matter

Disregarding previous loads with particulate matter of the incoming fuel and the combustion air during the combustion of gaseous fuels, usually no particulate matter has to be taken into account. Soot formation can then be neglected for normal operating conditions.

The fuel from oil combustion is already charged with unburnable matter (ash). Because of the usually low absolute concentrations (below 20 mg/m^3 at standard temperature and pressure (STP) conditions), its contribution can be neglected. For insufficient spray atomization, for quenching processes, or for low-NO_x-operation with strongly understoichiometric conditions in sub-areas of the flame or the furnace, reasonable concentrations of soot or char may occur. This problem may also arise with light gas oil fuel (gas oil type L) and may become more severe with heavy gas oil fuel H or oils of even poorer quality (e.g., vacuum residual fuel oils) with high concentrations of asphaltenes. With respect to coal combustion, besides crude coal, coke or coal residues and ash have to be taken into account as optical relevant constituents. Always, if several gray-body-radiators have to be considered, it is necessary to aim at an approximation also for the particulate matter phase for the radiation properties to be as simple as possible by summation of the degrees of emission without considering possible overlapping effects.

This leads to the simplest possible approximation for the absorption coefficients $k_{a,S}$ of the flue gas suspension [1]:

$$k_{a,S} = k_{a,G} + k_{a,P}, \tag{7}$$

where $k_{a,G}$ describes the approximated absorption coefficient of the gas phase, while $k_{a,P}$ represents the summary influence of the particulate matter, such as soot, char, coal, or coke particles resulting in the simplified expression:

$$k_{a,P} = k_{a,R} + k_{a,C} + k_{a,A}, \tag{8}$$

where the indices S, R, C, and A represent suspension, soot, coal/char, and ash.

2.2.1 Radiation by Soot Particles

Soot particles are understood as particulate matter consisting mainly of carbon particles originated from the gas phase combustion of hydrocarbons. The mean diameter of the spherical nonagglomerated soot particles is between $30 \cdot 10^{-9}$ and $65 \cdot 10^{-9}$ m [3]. The soot particles cause the yellow shining of flames; they contribute especially to the energy exchange by radiation in the infrared spectrum. A determination of the spectral and total degree of emission of homogeneous layers of suspended soot particles is possible by means of theoretical approaches if the mass loading B_R of the layers (e.g., in kg/m^3), the density ρ_R, and the optical constants of the soot particulate matter are known [3, 5–7].

An approximate solution of the theoretical approaches for the wavelength-dependent soot radiation leads to the frequently used relation

$$\varepsilon_R = 1 - e^{-k_{a,R} \cdot B_R \cdot s_{eq}}, \tag{9a}$$

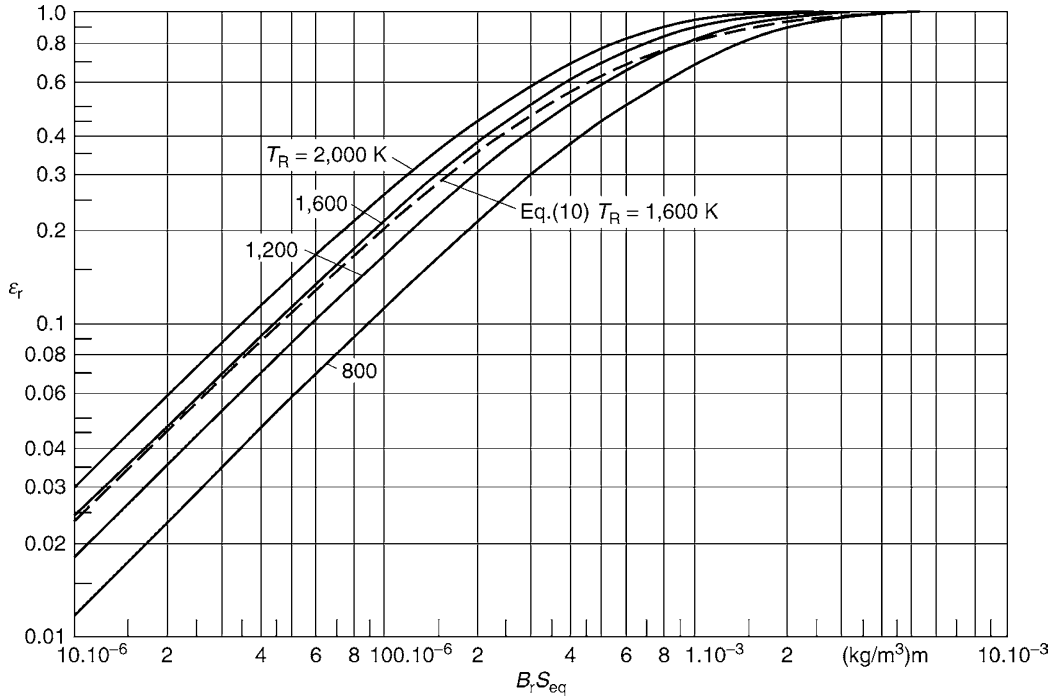
with

$$k_{a,R} = a_R \cdot T_R \text{ in m}^2/\text{kg}. \tag{9b}$$

ε_R is independent of the soot particles' diameter. Data in literature for the factor a_R (in m^2/kg K) for gas oil fuel L vary between 0.47 and 2.09 [8]. This fluctuation range is partially explained by the fact that a_R includes both ρ_R and other optical constants. These factors depend as well on the type of fuel as on the conditions at which the particles are formed (combustion regime). Based on work by Johnson and Beér [5] and by Tietze [8], a_R = 1.49 m^2/kg K appears to be a suitable value for oil flames. Figure 4 shows the emission diagram $\varepsilon_R = f(B_R\, s_{eq})$ with the temperature T_R of the radiating soot particles as a parameter calculated by means of this factor together with Eq. (9).

A possible relationship of $\varepsilon_R = f(B_R\, s_{eq})$ to Eq. (1) has been given by Johnson and Beér [5] in the form of the weighted sum of exponential functions:

$$\varepsilon_R = \sum_{i=1}^{3} a_i (1 - e^{k_{R,i} \cdot B_R \cdot s_{eq}}). \tag{10}$$



K5. Fig. 4. Degree of emission ε_R for suspensions of soot particles, according to Eq. (9) with a_R = 1.49 m^2/(kg K) as a function of B_R s_{eq} and in comparison with the approach following Eq. (10).

K5. Table 3. Constants for the degree of emission by soot, according to Eq. (10) [5]

i	b_{oi} (–)	b_{li} (1/K)	k_{Ri} (m^2/kg)
1	0.130	+0.000265	3,460
2	0.595	–0.000150	960
3	0.275	–0.000115	960

The specific absorption coefficients, which were temperature independent in opposition to Eq. (9a), have been determined by the authors in such a manner, that it was possible to use for the weighting factors $a_i = f(T_R)$ the same coefficients as computed in Table 2 for a H_2O/CO_2 mixture. The constants for the soot radiation result from Table 3.

If ε_R is approximated by Eq. (10), the radiation exchange between an isothermal, soot radiation emitting volume and the surrounding walls may best be formulated by Eq. (6). When calculating the net heat transfer due to soot emission, by far the greatest uncertainty is because of the unknown soot concentration in the furnace volume. A quantitative theory that would allow for the prediction of the formation of soot depending on the kind of fuel, temperature and pressure, air/fuel ratio, and mixing behavior [3] is not known. The problem is still increased by the effect that usually soot loading within a furnace is extremely inhomogeneous. Maxima of soot loading are to be found in flames themselves, and usually in the flame core at areas near to the burner.

In areas of the furnace with oxygen surplus, soot can burn off again at sufficiently high temperatures and adequate residence times. For low-NO_x operation mode, usually one of these conditions is not fulfilled.

Table 4 compiles some experimental results of soot concentrations averaged over flame cross sections. Related mean flame temperatures T_F and diameters D_F have been used to determine by Eq. (9) the degree of emission ε_R of the soot layers (without gas radiation). For these calculations, s_{eq} has been equated to the mean flame diameter. Because of the many influencing factors and the special flame conditions, which have not been taken into account, an uncritical transfer of the results from Table 4 may lead to considerable errors.

The small soot concentrations in natural gas flames are of no importance for the calculation of radiation exchange in small furnaces, although they may cause noticeable shining.

Approximate values for mean soot concentrations in heavy gas oil flames may be (with some caution) 500–1,000 mg/m^3 (at STP conditions), according to 100–200 mg/m^3 at 1,400 K. Local concentration maxima are at 7,000 mg/m^3 (at STP), according to about 1,350 mg/m^3 at 1,400 K.

Frequently, the CO concentration is used as an indicator and as an indirect measured quantity, instead of the soot concentration, because CO is also applied as a characteristic measure for incomplete burn-out (e.g., hydrocarbons). For a first coarse orientation, Tietze [8] presents a relation between local CO concentration and soot loading developed by him accordingly to Fig. 5 for a place downstream from the place of highest radiation density for heavy oil flames with air atomiser at STP. Also, the data given by Fig. 5 are only correct for the specific case. Generalizations may lead to major errors.

The volume of gas oil flames, i.e., the area in which shining soot radiation is emitted, can be calculated approximately by

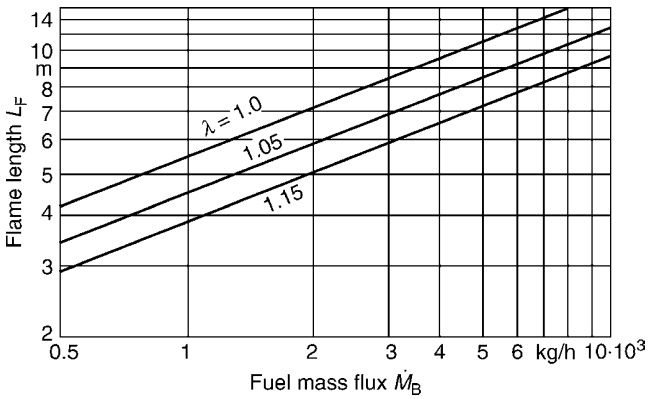
K5. Fig. 5. Basic relation between soot loading B_R and CO concentration in heavy oil flames (jet burner [8]).



K5. Fig. 6. Flame length L_F as a function of fuel throughput $\dot{M}_B$ for each burner (gas oil fuel L) and of the air-ratio number λ (empirical approach [9]).

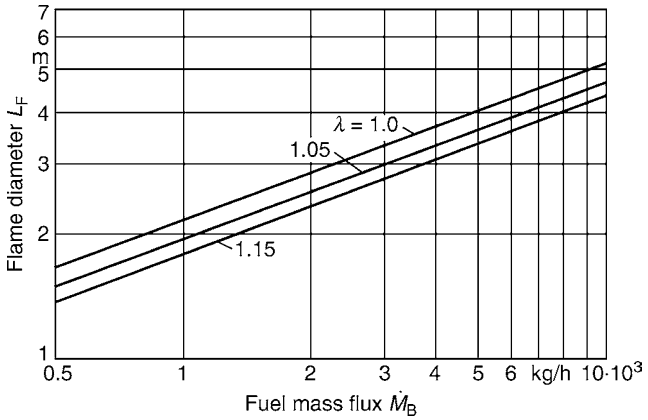
means of the empirical relations (11) and (12) or with the related diagrams in Figs. 6 and 7 [9]:

$$L_F = 1.5\dot{M}_B^{0.379}\left[0.36 + 0.128\ (e^{-16(\lambda-1)} - 1)\right]\ (\text{m}), \qquad (11)$$

$$D_F = \dot{M}_B^{0.387}\left[0.147 + 0.025\ (e^{-22(\lambda-1)} - 1)\right]\ (\text{m}). \qquad (12)$$

These are solely equations for numerical values in which the fuel throughput $\dot{M}_B$ has to be inserted in units of kg/h. In these equations and diagrams, the flame length L_F and the flame diameter D_F are empirically correlated with fuel throughput $\dot{M}_B$ for each burner with the air ratio number λ as a parameter. The approaches have been generated from data by various burner manufacturers [9]. The data refer to flames of swirl burners in which gas oil is usually atomized by atomizer steam or pressurized air.

Depending on degree of swirling and atomizer construction, deviations ±30% are to be expected. Eqs. (11) and (12) are not applicable to flames with smaller fuel throughput. Flames without swirling are by a factor of 2–3 longer than swirling flames



K5. Fig. 7. Flame diameter D_F as a function of fuel throughput $\dot{M}_B$ for each burner (gas oil fuel L) and of the air-ratio number λ (empirical approach [9]).

and accordingly slimmer. Also, low-NO_x flames (gas and oil) are about 20% longer, due to the softer combustion aimed at.

2.2.2 Radiation of Coal and Char Particles

In contrast to the emission of a layer of a soot particle suspension, the emission of clouds of coal and char particles, like that of clouds of ash, which is discussed subsequently, depends on the diameter of the single particles. While larger particles (>20 µm) may be treated at least approximately by the fundamentals of geometric optics, this is no longer the case for smaller particles. As is the case for soot, not-gray radiation behavior is dominant here.

For a common grinding of hard coal dust with a mean weight diameter of about 50 µm or an R 0.09 of 10% (i.e., the residue on the 90 µm sieve is 10 or 90% of the particles show diameters below 90 µm), the assumption of gray radiation for coal and char particles can be accepted as sufficiently exact.

For the degree of emission is also influenced by the particle size distribution [3], which is usually not known, and which is shifted to smaller diameters during the combustion process, in this section the degree of emission ε_K is given for constant particle diameters only

$$\varepsilon_K = 1 - \exp\left(-\bar{Q}_{abs,K} \cdot \frac{3}{2\rho_K \bar{x}_K} \cdot B_K \cdot s_{eq}\right) \qquad (13)$$

and ε_K for the Rosin–Rammler distribution

$$\varepsilon_K = 1 - \exp\left(-\bar{Q}_{abs,K} \cdot \frac{3}{2\rho_K \bar{x}_K} \cdot \frac{\pi}{n \sin(\pi/n)} \cdot B_K \cdot s_{eq}\right) \qquad (14)$$

with

$\bar{x}_K$	mean weighted diameter of the Rosin–Rammler distribution [3]
$\bar{Q}_{abs,K}$	mean relative effective cross section for the absorption of coal/char particles (constant, due to the assumption of a gray radiator)
	$0.8 \leq \bar{Q}_{abs,K} \leq 1.0$ for larger coal/char particles [3, 6, 8]
ρ_K	apparent density of coal/char particles 1,200 to 1,400 kg/m³ for coal
	600 to 1,000 kg/m³ for char
B_K	particle loading
s_{eq}	equivalent layer thickness
n	scattering parameter of Rosin–Rammler distribution

It may be noticed that Eq. (13) is identical with Eq. (1) of Chap. K4. The dependency of the degree of emission ε_K of the product of particle loading and layer thickness, according to Eq. (14) is given for various values of the parameter n from Fig. 8. The correlations have been determined based on $\bar{Q}_{abs,K} = 0.85$, $\rho_K = 1{,}000$ kg/m³, and $\bar{x}_K = 50 \cdot 10^{-6}$ m. In practical applications, Fig. 8 can be used only for estimations because the calculation is based on a pure Rosin–Rammler distribution between $x_K = 0$ and ∞. With such a distribution, for $n \to 1$ the influence of the smallest particle fractions for which Eq. (14) is not valid, will be overestimated.

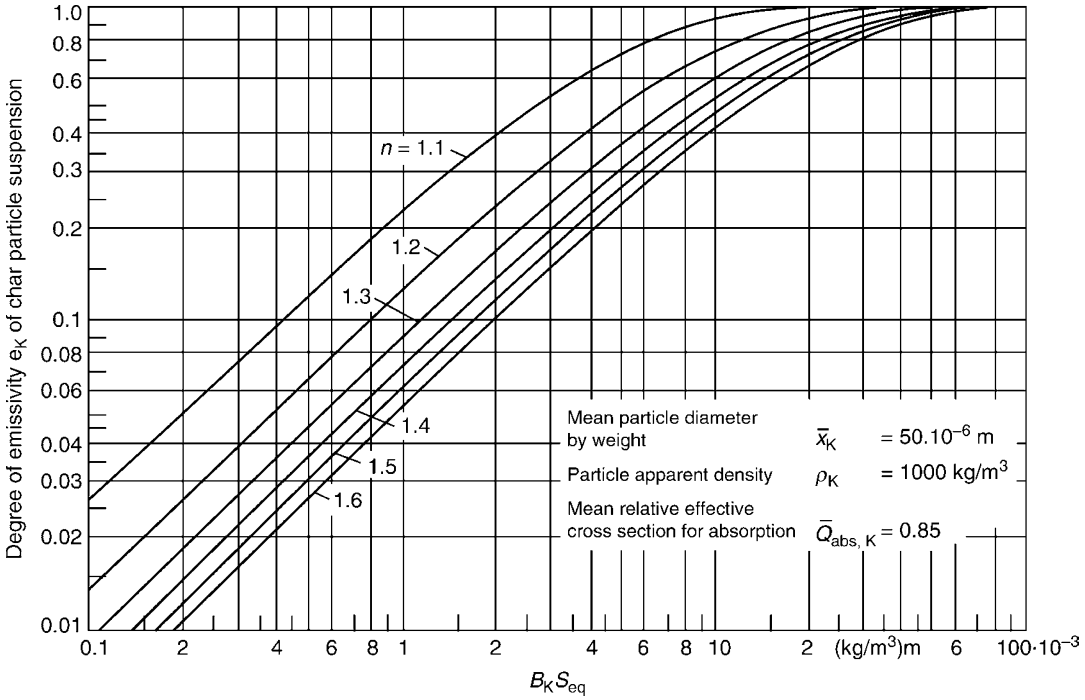
It is not possible to present absolute values for the loading of furnaces with coal and char particles because these data depend much on the kind of coal and combustion and also on the combustion processing. A basic, very rough estimation can be made if a homogeneous mass distribution over the combustion room and flame zones is assumed, accordingly to the added mass flows, and if a certain burnout is anticipated. It has to be taken into consideration that the density ρ_K and usually also the particle size distribution may change depending on degassing and on burnout of the particles' cloud [6, 10].

Burnout calculations for coal and char particle clouds with a finer zone division can be found in the works of Field et al. [7]. From calculations of this type, which, however, would exceed the scope of the presented section, it is possible to derive local distributions of absorption coefficients in particle clouds with an accuracy sufficiently for radiation exchange calculations [11].

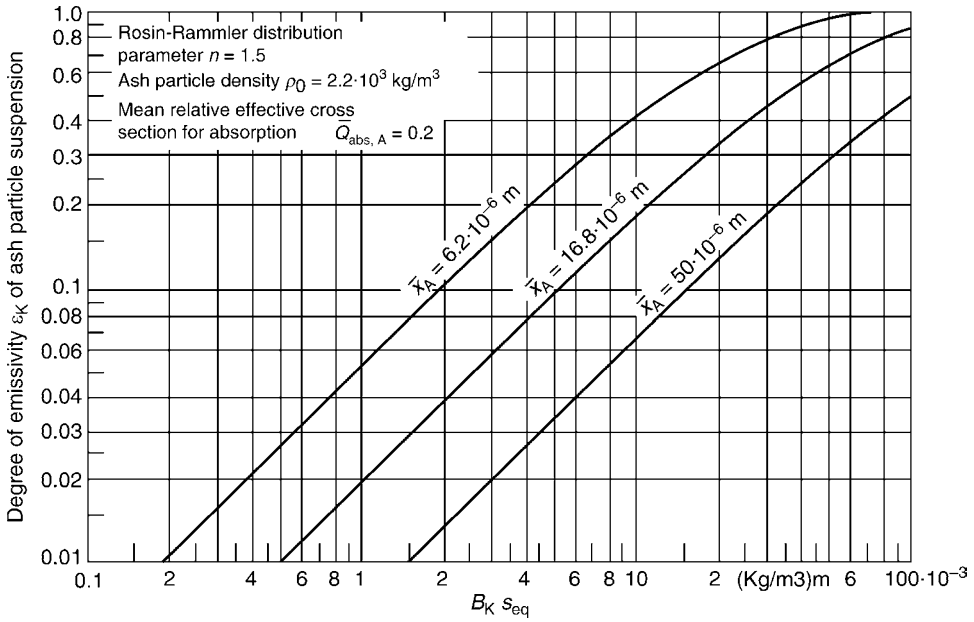
2.2.3 Radiation of Ash Particles

The relations in Eqs. (13) and (14) are similarly valid for the rough calculation of the degree of emission ε_A for ash particles. Problems with the description of radiation from ash particles are especially connected with the determination of the representative mean relative efficiency cross sections $\bar{Q}_{abs,A}$ for the absorption and in the estimation of the particle size distribution (see also Chap. K4, Table 1). Absorption indices of particulate matter of ash may be depending on the kind of combustion eventually strongly influenced by wavelengths [3, 12]. Further on, a considerable amount of ash particles is very small (<10 µm), so that the parameter $\bar{Q}_{abs,A}$ depends on particle diameters. For these reasons, the assumption of gray radiation of the ash particle cloud is only roughly justified. A systematic calculation of $\bar{Q}_{abs,A}$ depending on the kind of coal and combustion processing is not possible until now, it is suggested to consider the radiation of ash particles also as gray and to calculate with either one of the two relations in Eqs. (13) and (14). In agreement with the work of Sarofim and Hottel [3] and Table 1 of Chap. K4 values of $\bar{Q}_{abs,A} = 0.2$ and $\rho_A = 2{,}200$ kg/m³ may be used as representative. For more, differentiated calculations may be referred to Fig. 3 of Chap. K4.

For a Rosin–Rammler distribution with $n = 1{,}5$, ε_A values have been calculated for three different mean diameters of ash



K5. Fig. 8. Degree of emission ε_K of char particle suspensions, according to Eq. (14) as a function of $B_K\, s_{eq}$ and the scattering parameter n of Rosin–Rammler distribution of the char particle size.



K5. Fig. 9. Emission degree ε_A of suspensions of ash particles as a function of $B_A\, s_{eq}$ for three mean ash particle diameters $\bar{x}_A$.

particles according to Eq. (14). Figure 9 shows the dependency of these values of $B_A\, s_{eq}$.

In Fig. 9, the distributions of the weighted diameters of ash particles for the upper and the lower curve may be regarded as limiting cases. Therefore, it is recommended to choose the curve $\varepsilon_A = f(B_A\, s_{eq})$ calculated with $\bar{x}_A = 16.8 \cdot 10^{-6}$ m for fly-ashes with an unknown particle size distribution.

As already mentioned in connection with coal and char particles, the influence of extremely small particles on ε_A is overestimated using the ideal Rosin–Rammler distribution for $n \to 1$.

As a first approximation for calculating the ash loading B_A, it can be assumed that the mass distribution of ash in the combustion room is constant neglecting agglomeration, segregation, and inhomogeneities in the flame zones.

It may be noticed that ash particles (to a minor part also coal and char particles) could influence the radiation exchange by scattering [13, 14]. This scattering of radiation causes minor furnace radiation and hence counteracts the influence of higher absorption coefficients in hot particle loaded layers. The effect of scattering increases with ash loading, with the size of the equivalent layer thickness, with the part of ash particles with diameters between 1 and 15 µm, and with decreasing absorption indices of the ash material. Taking into account these scattering effects, degrees of emission for ash particles can be approximated by Eqs. (5)–(8) in Chap. K4.

However, the simplest approximation is the assumption of a constant absorption coefficient neglecting the spectral dependency completely with

$$k_{a,A} = K_{a,A} \cdot B_A, \tag{15}$$

where the factor $K_{a,A}$ (m^2/kg) takes values between 10 and 50 for hard coal ashes and von 9–25 for lignite ashes [1]. B_A is the loading of the flue gas suspension with ash (continuum density, [kg/m^3]).

2.3 Radiation Properties of the Flue Gas Suspension

If the radiation of all particles is considered as gray, the degree of emission ε_S of the suspension can be expressed similarly to Eq. (9), Chap. K4, by

$$\varepsilon_S = 1 - (1 - \varepsilon_G)(1 - \varepsilon_R)(1 - \varepsilon_K)(1 - \varepsilon_A). \tag{16}$$

ε_R can be calculated accordingly to Eq. (9), ε_K and ε_A accordingly to Eqs. (13) or (14). The absorption ratio for the superimposed real gas and as gray assumed particle radiation can be approximated accordingly to Eq. (10) in Chap. K4, due to the relation

$$\alpha_S = 1 - (1 - A_v)(1 - \varepsilon_R)(1 - \varepsilon_R)(1 - \varepsilon_K)(1 - \varepsilon_A). \tag{17}$$

The advantage of formulating the degree of emission of a flue gas suspension, in which the single components show different radiation characteristics, by a weighted sum of exponential functions similar to Eqs. (1) and (10) has already been pointed out. ε_S is described in this case, e.g., by

$$\varepsilon_S = \sum_{i=1}^{3} a_i \left(1 - \exp\{-[K_{Gi}(p_{H_2O} + p_{co_2}) + k_{Ri} B_R + k_K B_K + k_K B_A] S_{eq}\}\right). \tag{18}$$

The coefficients for the calculation of a_i as well as k_{Gi} and k_{Ri} are given by Tables 2 and 3. Because coal or char and ash particles are considered as gray, their specific absorption coefficients k_K or k_A show the same values for each of the three additive terms of the right-hand side of Eq. (18).

These can be determined for constant particle diameters analogous to Eq. (13) by means of the relation

$$k_K = \bar{Q}_{abs,K} \frac{3}{2\rho_K x_K} \tag{19}$$

or

$$k_A = \bar{Q}_{abs,A} \frac{3}{2\rho_K x_K}. \tag{20}$$

With a known Rosin–Rammler distribution, the relations for k_K and k_A according to Eq. (14) are given by

$$k_K = \bar{Q}_{abs,K} \frac{3}{2\rho_K \bar{x}_K} \frac{\pi}{n \sin(\pi/n)} \tag{21}$$

and

$$k_A = \bar{Q}_{abs,A} \frac{3}{2\rho_A \bar{x}_A} \frac{\pi}{n \sin(\pi/n)}. \tag{22}$$

Similar to the soot radiation, the above-mentioned approach has possibly to be extended for the not gray character of the ash radiation.

Using the sum approach in Eq. (18), the radiation exchange between an isothermal furnace volume and the surrounding walls has to be calculated according to Eq. (6).

3 Calculation Examples

3.1 Basic Procedure

The use of the data presented in the two previous sections will be explained by two examples for typical calculations. For reasons of simplicity and clarity, these are based on the model of the stationary ideally stirred reactor. This model, that can by no ways substitute the more accurate multidimensional models, allows only a rough calculation of the total heat output $\dot{Q}_{GW}$ of a firing system, the efficiency η_F of the furnace, and the calculation of the furnace exit temperature T_G, which depends on these aforementioned values.

It is assumed that the combustion gases are mixed and that partial pressures, mass concentrations, and temperatures are distributed homogeneously all over the furnace and each is characterized by the corresponding values of p_j or m_j and T_G (system with concentrated parameters). The outlet values of the combustion room are identical with these mean values:

$$p_{j,ex} = p_j, \tag{23a}$$

$$m_{j,ex} = m_j, \tag{23b}$$

$$T_{ex} = T_G. \tag{23c}$$

For the easiest case, it is assumed further on that the furnace walls with the surface area A have a given constant surface temperature T_W on the furnace side and a known homogeneous degree of emission ε_W.

The partial pressures p_j or concentrations m_j of the combustion gases in the furnace are determined by means of the supplied mass streams and by the properties of fuel and air by a combustion calculation (not further explained here, see for e.g. [14]). It is convenient to assume complete burnout. The assumption of ideal mixing does implicitly mean that the fuel's chemically bound energy $\dot{Q}_c$ is homogeneously released in the flame or the furnace.

To determine T_G (=T_{ex}), a total energy balance for the combustion volume is necessary.

For stationary conditions, the balance equation reads:

$$f(T_G) = \dot{Q}_F + \dot{Q}_{K,GW} + \dot{Q}_{S,GW} - \dot{Q}_c = 0. \tag{24}$$

$\dot{Q}_F$ is the difference between added and removed convective enthalpy stream, $\dot{Q}_{K,GW}$ and $\dot{Q}_{S,GW}$ are the heat fluxes transferred to the walls by convection and radiation.

The terms in Eq. (24) can be calculated as follows:

$$\dot{Q}_F = \dot{M}_{VG}\left[\bar{c}_P\Big|_{T_U}^{T_G}(T_G - T_U) - \bar{c}_P\Big|_{T_U}^{T_0}(T_0 - T_U)\right], \quad (25)$$

$$\dot{Q}_{K,GW} = A\alpha(T_G - T_W). \quad (26)$$

$\dot{Q}_{S,GW}$ has to be determined accordingly to Eq. (18) of Chap. K3 or Eq. (11), Chap. K4 or accordingly to Eq. (6), Chap. K5. Further on, the chemical energy released by the fuel is

$$\dot{Q}_c = \dot{M}_B H_u. \quad (27)$$

The variables used are:

$\dot{M}_{VG}$	mass flow of the combustion gases in kg/s,
$\dot{M}_B$	mass flow of the fuel in kg/s,
$\bar{c}_P$	mean specific heat capacity of the combustion gas mixture at constant pressure in kJ/(kg K),
T_0	temperature of the incoming mass flows in K,
T_U	surrounding temperature in K,
T_G	temperature of the combustion room in K.

3.1.1 Solution of the Total Energy Balance for T_G

In Eq. (24), the absolute temperature T_G appears linear and also to the fourth order. Hence, the following iteration procedure is suggested to solve for T_G:

$$T_{G,n} = T_{G,n-1} - \frac{f(T_{G,n-1})}{f'(T_{G,n-1})} \quad (28a)$$

with

$$\dot{Q}_F + \dot{Q}_{K,GW} + \dot{Q}_{S,GW} - \dot{Q}_c = f(T_G). \quad (28b)$$

Here the index n refers to the nth iteration step. For incomplete convergence: $f(T_{G,n-1}) \neq 0$ and $T_{G,n} \neq T_{G,n-1}$. When the term for the radiation exchange in Eq. (21) has been determined accordingly to Eq. (18) in Chap. K3, the derivative of the energy in Eq. (24) with respect to T_G becomes approximately

$$f'(T_G) = \frac{df}{dT_G} \approx \dot{M}_{VG}\bar{c}_P\Big|_{T_U}^{T_G} + A\alpha + 4Ac_1\varepsilon_G\sigma T_G^3, \quad (29a)$$

with

$$c_1 = \frac{\varepsilon_W}{1-(1-\varepsilon_W)(1-A_v)}. \quad (29b)$$

If the dependencies $\bar{c}_P(T_G)$, $\varepsilon_G(T_G)$, or $A_v(T_G)$ are taken into account and if analytical descriptions are used therefore, the corresponding derivatives in Eq. (29a) may be used additionally to accelerate convergence.

3.1.2 Combustion or Firing Efficiency

The combustion or firing efficiency η_F is understood as the ratio of the sum of the heat flows delivered to the heat sinks related to the sum of incoming fuel energy and sensible heat energy:

$$\eta_F = \frac{\Sigma\dot{Q}_W}{\dot{Q}_c + \dot{Q}_{Fo}} = 1 - \frac{\dot{M}_{VG}\bar{c}_P\Big|_{T_U}^{T_G}(T_G - T_U)}{\dot{Q}_c + \dot{Q}_{Fo}}, \quad (30a)$$

with

$$\dot{Q}_{Fo} = \dot{M}_{VG}\bar{c}_P\Big|_{T_U}^{T_0}(T_0 - T_U). \quad (30b)$$

The heat totally transferred to the walls $\Sigma\dot{Q}_W$ may be divided into useful heat $\dot{Q}_n$ and heat losses dissipated outside $\dot{Q}_v$. The furnace efficiency, according to Günther [15] then results in

$$\eta_{Often} = \frac{\dot{Q}_n}{\dot{Q}_n + \dot{Q}_v} = \frac{\dot{Q}_n}{\Sigma\dot{Q}_W} \quad (31)$$

and the total efficiency (gross) η_{ges} is

$$\eta_{ges} = \frac{\dot{Q}_n}{\dot{Q}_c + \dot{Q}_{Fo}} = \eta_F\eta_{Often}. \quad (32)$$

3.2 Calculation Example 1: Gas Combustion

The example deals with a gas-fuelled steam generator combustion system, for which the furnace is approximated by an ideally stirred reactor (system with concentrated parameters). The following data are assumed as boundary conditions:

Furnace geometry	5 m × 5 m × 15 m,
Fuel	methane,
Lower heating value	H_u = 50,409 kJ/kg,
Heat introduced by the fuel	$\dot{Q}_c$ = 117,000 kW,
Combustion conditions	30% air surplus, no soot formation,[1])
Temperatures of the incoming mass flows	T_0 = 298.15 K,
Surrounding ambient temperature	T_U = 298.15 K,
Wall temperature	T_W = 700.00 K,
Degree of emission of the walls	ε_W = 0.8,
Convective heat transfer coefficient	$\alpha = 5.8 \cdot 10^{-3}$ kW/(m^2 K),
Stefan–Boltzmann constant	$\sigma = 5.67 \cdot 10^{-11}$ kW/(m^2 K^4).

3.2.1 Looking for the Furnace Exit Temperature T_G and Combustion Efficiency η_F

The calculation of radiation exchange is to be carried out according to the instructions of Chap. K3; ε_G and A_v are

then to be determined at T_G = 1,600 K. Further on, the specific heat capacity c_p of the combustion products is needed. This may be calculated by using temperature dependent values for the mixture, if available, or by the approximation given below:

$$\bar{c}_P \Big|_{T_U}^{T_G} = 1.2603\,\text{kJ/(kg K)} \text{ (at } 1,600 \text{ K)}$$

A combustion calculation, not further described here, gives the following partial pressures for the mentioned combustion conditions:

$$p_{CO_2} = 0.074\,\text{bar}, \quad p_{N_2} = 0.724\,\text{bar},$$
$$p_{H_2O} = 0.158\,\text{bar}, \quad p_{O_2} = 0.044\,\text{bar}$$

and the mass flow of the combustion gases $\dot{M}_{VG}$ = 54,319 kg/s. The mean thickness of the layer of the combustion volume is according to Eq. (9), Chap. K3

$$s_{eq} = 0.9\frac{4V}{A} = 0.9 \cdot \frac{4 \cdot 375}{350}\ \text{m} = 3.86\ \text{m}.$$

With T_G = 1,600 K and the data given for p_{CO_2}, p_{H_2O}, and s_{eq} for the degree of emission or absorption values of ε_G = 0.291 and A_v = 0.543 are obtained accordingly to the explanations in Chap. K3.

The energy balance equation (24) for T_G is solved by iteration by means of Eq. (28).

In the case of convergence, the calculation shows the following results:

$$\dot{Q}_F = 86,862\ \text{kW}; \quad \dot{Q}_{K,GW} = 1,760\ \text{kW};$$
$$\dot{Q}_{S,GW} = 28,378\ \text{kW}; \quad T_G = 1,567\ \text{K}.$$

For the combustion efficiency η_F, the result is, according to Eq. (30),

$$\eta_F = \frac{1,760 + 28,378}{117,000} = 0.2576.$$

3.3 Calculation Example 2: Coal Dust Firing

The example deals with a coal dust fuelled steam generator combustion, for which the furnace is approximated by an ideally stirred reactor (system with concentrated parameters). The boundary conditions are assumed to be the same as for Example 1, with the following exceptions:

Fuel	highly volatile hard coal dust,
Composition of fuel	according to Table 1, No. 3,
Lower heating value	H_u = 31,506 kJ/kg$_{wf}$,
Combustion conditions	according to Table 1, No. 3.

Looking for the furnace exit temperature T_G and for combustion efficiency η_F for the case

(a) that only gaseous combustion products of the coal dust are radiating, and for the case
(b) that this radiation is superimposed by the radiation of ash, coal, and soot particles.

The calculation of radiation exchange is to be carried out in both cases by means of the approach of the weighted three gray gases, according to Eqs. (6) and (6a) or Eq. (18). The specific heat capacity of the mixture of the combustion products should have in both cases a constant value of [1]).

$$\bar{c}_P \Big|_{T_U}^{T_G} = 1.18\,\text{kJ/(kg K)} \text{ (at } 1,500\,\text{K)}$$

For (b) the following, additional assumptions are made:

density of the mixture of the combustion products[2])	ρ_{VG} = 0.241 kg/m^3(at 1,500 K)
density of the ash particulate matter	ρ_A = 2,200 kg/m^3
mean weighted diameter of the ash particles	$\bar{x}_A = 16.8 \cdot 10^{-6}$ m
scattering parameter of the Rosin–Rammler distribution of the ash particles	n = 1.5
mean relative effective cross section for absorption of ash particle radiation	$\bar{Q}_{abs,A}$ = 0.2
effective mass concentration of char particles	one tenth of the mixed, but not reacted coal particles
density of char particulate matter	ρ_K = 850 kg/m^3
mean weighted diameter of the char particles	$\bar{x}_K = 65 \cdot 10^{-6}$ m
scattering parameter of the distribution of the char particles	n = 1.5
mean relative effective cross section for absorption of char particle radiation	$\bar{Q}_{abs,K}$ = 0.85
effective soot loading (at STP conditions)	B_R = 163.5 10^{-6} kg/m^3

A combustion calculation, not further described here, gives the following partial pressures for the mentioned combustion conditions:

$$p_{CO_2} = 0.133\,\text{bar}^3, \quad p_{O_2} = 0.046\,\text{bar},$$
$$p_{H_2O} = 0,062\,\text{bar}, \quad p_{N_2} = 0.759\,\text{bar}.$$

The mass flow of the combustion products results from this combustion calculation as $\dot{M}_{VG}$ = 55.50 kg/s.

To (a): *Pure gas radiation:* Based on the determined partial pressures, on the equivalent layer thickness of the combustion suspension s_{eq} = 3.86 m, and on the coefficients given in Table 2, the following expressions can be summarized for the calculation of the gas–wall radiation exchange according to Eqs. (6) and (6a):

$$\sum_{i=1}^{3} \frac{a_i(T_G)\varepsilon_W\varepsilon_{Gi}}{1-(1-\varepsilon_W)(1-\varepsilon_{Gi})} = 0.4664 - 0.000154\,T_G/\text{K}$$
$$\sum_{i=1}^{3} \frac{a_i(T_W)\varepsilon_W\varepsilon_{Gi}}{1-(1-\varepsilon_W)(1-\varepsilon_{Gi})} = 0.4664 - 0.000154\,T_W/\text{K}$$
$$= 0.3586.$$

The iterative computation of the total energy balance in Eq. (24)

of the combustion room carried out according to Example 1, however, by including the above-given temperature dependencies leads to the following convergent solution:

$$T_G = 1{,}625\ \text{K}; \qquad \dot{Q}_F = 86{,}909\ \text{kW};$$
$$\dot{Q}_{K,GW} = 1{,}878\ \text{kW}; \qquad \dot{Q}_{S,GW} = 28{,}213\ \text{kW}.$$

From this, the combustion efficiency can be determined to be

$$\eta_F = \frac{1,878 + 28,213}{117,000} = 0.2572.$$

To (b): Inclusion of radiation by ash, char, and soot particles: At first, for ideal mixing and for the other already mentioned assumptions, mass concentrations m_j of the particles in the combustion room are calculated.

Ash particles: The fuel stream is given by $\dot{M}_B = \dot{Q}_c/H_u = 3{,}714\ \text{kg}_{wf}/\text{s}$. With the portion of ash from Table 1 and the total mass flow $\dot{M}_{VG}$, it is obtained

$$m_A = 0.065\,\dot{M}_B/\dot{M}_{VG} = 0.00435\ \text{kg/kg}.$$

Char particles:

$$m_K = 0.1\frac{1}{1-0.014}\dot{M}_B/\dot{M}_{VG} = 0.00679\,\text{kg/kg}.$$

The loading with particles is calculated from the given density ρ_{VG}[4]) of the combustion products:

$$B_A = m_A\rho_{VG} = 0.00435 \cdot 0.241\text{kg/m}^3 = 1{,}048 \cdot 10^{-3}\text{kg/m}^3,$$
$$B_K = m_K\rho_{VG} = 0.00679 \cdot 0.241\ \text{kg/m}^3 = 1{,}636 \cdot 10^{-3}\ \text{kg/m}^3.$$

The soot loading at 1,500 K is

$$B_R = 163.5 \cdot 10^{-6} \cdot (273/1{,}500)\ \text{kg/m}^3 = 29.76 \cdot 10^{-6}\ \text{kg/m}^3.$$

The radiation exchange between furnace volume and wall is calculated accordingly to Eq. (6); the degrees of emission ε_{Si} for the three gray parts of the proposed sum approach for the radiation of the suspension are calculated by Eq. (18).

With the exception of k_K and k_A, the coefficients can be taken from Tables 2 and 3. The values of k_K and k_A are determined by means of Eqs. (21) and (22):

$$k_K = 0.85 \cdot \frac{3}{2} \cdot \frac{2.42}{850 \cdot 65 \cdot 10^{-6}}/(\text{kg/m}^3) = 55{,}846/(\text{kg/m}^3)\ \text{m},$$
$$k_A = 0.2 \cdot \frac{3}{2} \cdot \frac{2.42}{2{,}200 \cdot 16.8 \cdot 10^{-6}}/(\text{kg/m}^3)\,\text{m} = 19{,}643/(\text{kg/m}^3)\,\text{m}.$$

The temperature dependence of the radiation exchange coefficients can be summarized accordingly to the pure gas radiation (case (a)) and Eq. (6), as follows:

$$\sum_{i=1}^{3}\frac{a_i(T_G)\varepsilon_W\varepsilon_{Gi}}{1-(1-\varepsilon_W)(1-\varepsilon_{Si})} = 0.6331 - 0.00004905\,T_G/\text{K},$$
$$\sum_{i=1}^{3}\frac{a_i(T_W)\varepsilon_W\varepsilon_{Gi}}{1-(1-\varepsilon_W)(1-\varepsilon_{Si})} = 0.6331 - 0.00004905\,T_W/\text{K} = 0.5988.$$

The solution of the total energy balance in Eq. (24) for the flue gas suspension corresponds – accordingly to the assumptions of the task – with the following temperatures and heat flows:

$$T_G = 1{,}417\ \text{K}; \qquad \dot{Q}_F = 73{,}284\ \text{kW};$$
$$\dot{Q}_{K,GW} = 1{,}456\ \text{kW}; \qquad \dot{Q}_{S,GW} = 42{,}260\ \text{kW}.$$

The combustion efficiency is

$$\eta_F = \frac{1,456 + 42,260}{117,000} = 0.3736.$$

For the case of coal dust combustion, the presence of particles leads to a 45% increase of heat release in comparison to case (a), which neglects particle radiation. Evidently, this value depends on the assumptions about concentrations and sizes of particles. However, it has to be noticed that relevant differences for the heat release by flames with and without solid particles occur only in boiler (steam generator) firings, as these are the only ones, which are surrounded by relatively cold surfaces.

K6 Superinsulations

Harald Reiss
Julius-Maximilians-Universität Würzburg, Würzburg, Germany

1 Introduction

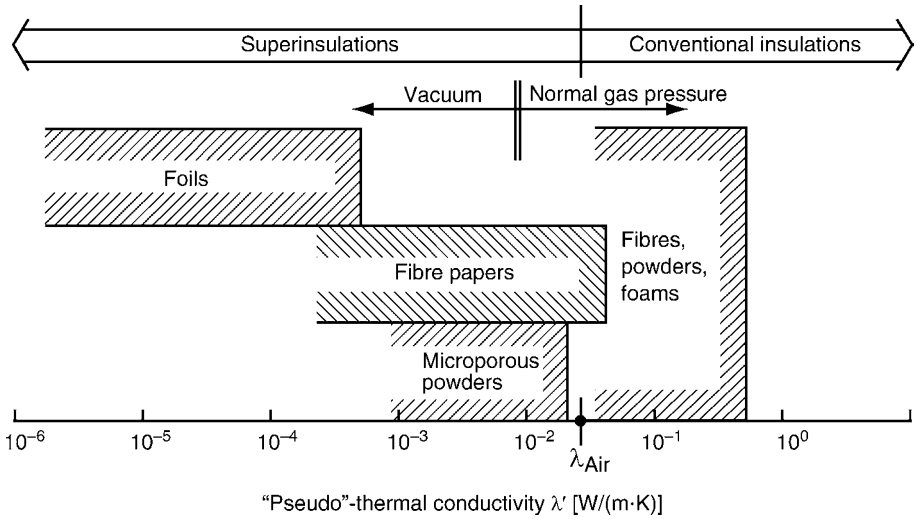
This chapter describes theoretical and experimental methods for determining heat transport through superinsulations, that is, thermal insulations with a permeability to heat significantly less than that of motionless air. One means of satisfying this condition is to evacuate beds of finely divided solids. Considerably less heat flows through evacuated, highly specular metal foils that are available either as rolls or blankets. This type also referenced as "multilayer superinsulations" with a discontinuous structure, includes Dewar (thermos) flasks and locally supported insulations. Thermal transport through multilayer insulations will be described in the first part of this chapter. The second part concerns superinsulations with a continuous structure, for example, evacuated powders and fibers, like in panel superinsulations.

Figure 1 compares the thermal "pseudo"-conductivity of different types on superinsulations, with approximately same thickness. "Pseudo" thermal conductivity, λ', is provisionally used in Fig. 1 to compare continuous with discontinuous, or non-transparent with transparent types of superinsulations, respectively. For the latter, total heat flow, $\dot{Q}_{Total}$, includes radiative contributions that cannot be described by the conduction law, $\dot{Q} = \lambda\ A\ \Delta T/D$. Thickness, D, of the insulations by which λ' was derived from $\dot{Q}$ must be specified in these cases, or comparison made for samples of the same thickness (cf. Appendix A1). Classification is made with respect to discontinuous and continuous superinsulations.

This chapter is focussed on *nontransparent*, industrial-scale (i.e., not miniature) superinsulations used in energy technology, cryostats, superconducting magnets, or transformers. This also includes evacuated panels. Heat transfer in transparent insulations will be considered at the end of this chapter.

Reviews on the thermal properties and the flow of heat through superinsulations that exceed the scope of this chapter have been published by Kaganer [1], with a very large variety of experimental data and analysis, and Tien [2], both for cryogenic temperature, and by Glaser [3] for both low and high temperatures. These traditional (not necessarily old-fashioned) references may be consulted in case the reader is not familiar with superinsulations. A large variety of publications that shows measured total heat flow or total thermal conductivity of insulations is available, but only a minority of them report separation of heat flow and conductivity into gaseous, solid–solid contact and radiation components.

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_45,



K6. Fig. 1. Thermal conductivity attainable by superinsulations at low temperatures; for explanation of the "Pseudo"-conductivity, λ′, compare footnote 1 and Appendix A1.

2 Superinsulations of Discontinuous Structures (Multilayers)

The purpose of this type of insulation is to minimize total heat flow losses $\dot{Q}_{Total}$ by reducing its components $\dot{Q}_{Gas}$, $\dot{Q}_{sc}$, and $\dot{Q}_{Rad}$, i.e.,

- To prevent heat flow, $\dot{Q}_{Gas}$, that otherwise would occur as a result of gases or ambient air by evacuating the insulated space to a residual gas pressure of less than 1 Pa.
- To avoid solid heat bridges as much as possible (solid–solid contacts between neighbouring metal foils or spacer materials, or through supports) and therefore heat flow losses, $\dot{Q}_{sc}$.
- To counteract radiation losses, $\dot{Q}_{Rad}$, by mirror coating the walls of a container (Dewar flasks) or by installing highly reflective metal foils (multilayer insulations).

If all these measures are adopted together and eventually additional actions taken such as reduction of the temperature of the warm wall by enclosing a vessel containing LH_2 or LH_e with a sheath cooled by LN_2, or by installation of intermediate vapour cooled, radiation shields, the total heat flow losses at all temperatures can be reduced to the minimum feasible in the light of the current state of the art. To increase the standby period of containers or pipings operating at low or medium temperature, application of phase change materials (latent heat storage) can be another option.

Methods for the separate determination, or at least estimates, of the heat loss currents $\dot{Q}_{Gas}$. $\dot{Q}_{sc}$, and $\dot{Q}_{Rad}$ are presented in the following section. Under *optimum* operating conditions in evacuated multilayer insulations the $\dot{Q}_{Gas}$ and $\dot{Q}_{sc}$-components are negligibly small as compared to $\dot{Q}_{Rad}$. However, heat leakages in multilayers by solid–solid contacts, the influence of disturbances such as gaps, or uncontrolled wrapping of the foils, play an important role on their thermal performance.

K6. Table 1. Constants C_1 and C_2 (data are from [5]) for calculation of mean free path, l_{Gas}, between two molecule/molecule collisions, by Eq. (1)

Gas	C_1 (p_0) [μm]	C_2 [K]
H_2	105.6	76
N_2	61	112
O_2	68.7	132
He	160	79
Ne	111.9	56
Ar	70.3	169
Kr	59.6	143
Xe	48.7	252
H_2O	95	600
CO	60.2	100
CO_2	57	273

C_1 applies for a gas pressure p_0 = 133 Pa. For a given value, $p_{Gas} \neq p_0$, the relationship that applies is $C_1(p_{Gas}) = (p_0/p_{Gas})\ C_1(p_0)$

2.1 Determination of $\dot{Q}_{Gas}$

The first step is to determine the mean free path, l_{Gas}, of the gas molecules between collisions, at a given residual gas pressure p_{Gas}, in the insulations. According to Sutherland [4], l_{Gas} is given by

$$l_{Gas} = \frac{C_1(p_{Gas})}{1 + C_2/T}\,[\mathrm{m}] \qquad (1)$$

where T is the absolute temperature in Kelvin, and C_1 and C_2 are constants for specific gases, some values for which are presented in Table 1. Example 1 for the determination of l_{Gas}. is given in Sect. 3.1. For air at atmospheric pressure and room temperature, $l_{Gas} \approx 0.06$ μm.

The next step is to estimate the average foil spacing δ. As a rule, $l_{Gas} >> \delta$, for this type of insulations. In other words, the

mean free path l_{Gas} is restricted not so much by intermolecular collisions as by the average foil spacing δ, i.e., by interactions with the solid components of the insulations.

The thermal conductivity of the residual gas λ_{Gas} is given by Kaganer [1], p. 6:

$$\lambda_{Gas}(p_{Gas}) = \frac{\lambda_0}{1 + 2 \times \beta \times Kn} [W/(m \cdot K)] \quad (2a)$$

where λ_0 is the thermal conductivity of the gas at atmospheric pressure (see Tables in Chap. D1, Subchap. D3.1), and Kn is the Knudsen number. The term β is a weighting factor that contains a correction, k, for the specific heat of the gas (figures are listed in Table 2), the well-known specific heat ratio $\kappa = c_p/c_v$ at constant pressure and volume, and the accommodation coefficient α, that is,

$$\beta = \frac{2 \times k}{\kappa + 1} \times \frac{2 - \alpha}{\alpha} \quad (3)$$

The figure for air is $\beta \approx 1.63$.

Accurate figures for the accommodation coefficient are not always available: $\alpha \approx 0.3$ for light gases (hydrogen and helium), and α is very close to unity for heavy gases, e.g., nitrogen (cf. [6]).

The Knudsen number in Eq. (2a) is given by

$$Kn = \frac{l_{Gas}}{\delta} \quad (4)$$

It is evident from Eq. (2a) that λ_{Gas} is small if

- λ_0 is as small as possible (in some special technical applications, inert gases would be suitable candidates for filling the space between the foils, after previous evacuation)
- The Knudsen number, Kn, is as large as possible, by reducing the foil clearance, δ, and by evacuation. However, a too high density of foils and/or spacers, per unit length, could lead to undesirable solid–solid contact conduction, and extend evacuation periods.

The lower the pressure, the greater the Knudsen number, Kn, or the less the value for λ_{Gas} simply because evacuation increases l_{Gas}. It follows from Eq. (4) that high Knudsen numbers can also be achieved in beds of very finely divided solids and very fine pore diameters, δ. The thermal conductivity component λ_{Gas} can then be completely eliminated, on an industrial scale, by evacuation and selection of small values for δ. A specimen calculation for λ_{Gas} is presented in Sect. 3.1.

The heat flow losses $\dot{Q}_{Gas}$ are obtained from the usual rule for heat conduction, i.e., $\dot{Q} = \lambda\ A\ \Delta T/D$ (Fourier's empirical law). Combining with Eq. (2a) gives

$$\dot{Q}_{Gas}(p_{Gas}) = \lambda_{Gas}(p_{Gas}) A \Delta T / D \quad (5)$$

where A is the area of the insulations, ΔT is the difference between the temperature of the heated wall and that of the cold wall, and D is the wall spacing. Note that Eq. (5) does not take into account coupling between the different heat transfer modes. Accordingly, Eq. (5) is an approximation that is the better fulfilled the lower the gas pressure.

If the residual gas pressure p_{Gas} is very low, λ_{Gas} as given in Eq. (2a) is converted into an expression for the free molecular thermal conductivity, that is, without intermolecular collisions, which is directly proportional to p_{Gas}.

2.2 Estimation of $\dot{Q}_{sc}$

There is no mathematical expression of general validity that allows heat transfer by solid–solid contacts, $\dot{Q}_{SC}$, in foil insulations to be estimated. Benefit of finite differences or finite element numerical methods in this case is comparatively small. The absolute number, or the density, of punctiform, or of line-wise or area-like solid–solid contacts between neighboring foils or spacers, is largely subject to the wrapping procedure and depends on the compressive load or, in case of cylindrical geometry, on the wrapping force (and the own weight of the foils plus spacers) under which the multilayer structure (foils plus spacers) is prepared. While in some cases an *overall* compressive load on the multifoil structure can be estimated, it is hardly possible to specify *local* compressive load distribution, which would be needed to estimate contact radii under local elastic or inelastic deformation of foils and spacers.

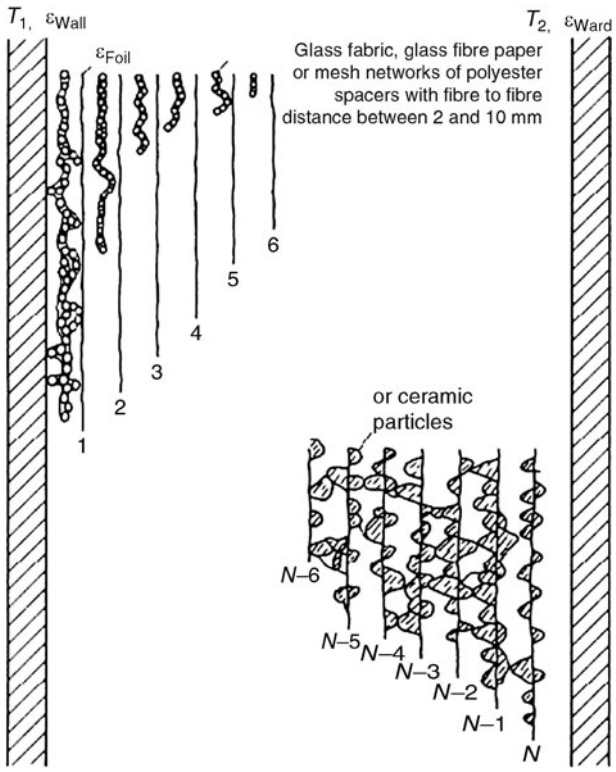
Metallic contacts between radiation foils are frequently obviated by layers of woven glass fabrics, nettings of polyester materials, thin fiber-glass paper spacers, or even punctiform ceramic coatings on metal foils, the latter for high temperature applications (Fig. 2). Modern spacers are produced in net form (tulle), with high porosity and with filament diameter in the order of 50 μm. Another means is to apply dimpled or crinkled metallic foils (Fig. 3b, c) that make spacers superfluous and avoid or reduce area-like solid–solid metallic contacts.

The same purpose is served by vacuum-metallized plastic films, e.g., Terepthalate (Mylar), with a thickness of polymer film and metallization of 6 μm and at least 40 nm, respectively. Compared to massive Al-foils, with thickness in the order of 10 μm, this not only reduces compressive loads, under their own weight, but also reduces conductive or radiative heat flow parallel to the foil surface; this aspect is important, for example, concerning the insulations of the neck or other feed-throughs of a cryostat.



K6. Fig. 2. Structure (not to scale) of a multilayer superinsulation. Depending on the specific application (temperature), foil materials, for use at cryogenic to high temperatures, comprise either thin (in the order of 10 μm thickness), massive, flat (with appropriate spacers), crinkled or dimpled (to avoid area-like solid–solid contacts between neighboring foils, then without spacers) or perforated (to speed up evacuation) Al-foils, or, preferentially (because of low specific weight), very thin, smooth (to optical surface quality) polymer (Mylar, Kapton, PTFE) foils (6–12 μm thickness, for cryogenic applications) that are aluminized on one or on both sides, with Al-coating thickness per foil between 25 and 80 nm (one side coatings should have thickness of at least 40 nm), with spacers (mostly nettings, but sometimes also using very thin glass fiber paper). Both kind of foils (massive Al, aluminized polymer foils) are available from rolls or, concerning aluminized polymer foils, in form of mats (blankets) of 10–40 single polymer layers. Mechanical stabilization of foils and spacers is made by punctiform thermo-fixation and/or adhesive strips again composed of aluminized polyester foils with adhesives suitable for use at cryogenic temperatures.

If the number of foils increases, the radiation transmittance of the superinsulations decreases, but there would be more solid–solid contacts and greater heat flow losses Q_{SC}. Consequently, there is an optimum figure for the number per unit length of foils (Fig. 4).

Heat losses through multilayer insulations may increase significantly if the foils are subjected to compressive loads (Fig. 5, see also [8], a comprehensive study of the influence of all sorts of degradations onto the thermal performance of multilayer superinsulations), which could result from their own weight or from the winding procedure. An effective method to avoid compression of multifoils on cylindrical surfaces is spiral winding of foils and spacers, simultaneously from two rolls. More recommendations for the winding of multifoils can be found in Kaganer [1], pp. 121–123.

If atmospheric pressure were to act on flat outer side walls of an evacuated insulation space, locally supported foil insulations has been suggested for avoiding deformation of the walls. Thus the strain may be taken up by thin ceramic pegs, microporous powder insulation supports, or fiberglass paper spacers.

The strength of the usual construction materials for the walls (stainless steel, in many applications) entails that the spacing between supports must be less than 10 cm. Hence many additional thermal bridges, which detract from the insulation efficiency, are formed per unit of area. Foil insulations supported by ceramic pegs could be taken as an example to demonstrate this: Consider a high temperature multifoil superinsulation. If there are 50 highly reflective radiation foils in a completely evacuated space, and the wall temperatures are T_1 = 600 K and T_2 = 300 K, the heat flux will be $\dot{q}_{Total} = \dot{Q}_{Total}/A \approx$ 7–10 W/m^2. Let the diameter of a ceramic support be 3 mm. Then, if the wall spacing is 20 mm and the thermal conductivity of the ceramic is λ_S = 1 [W/(m · K)], the heat losses over this single support will be

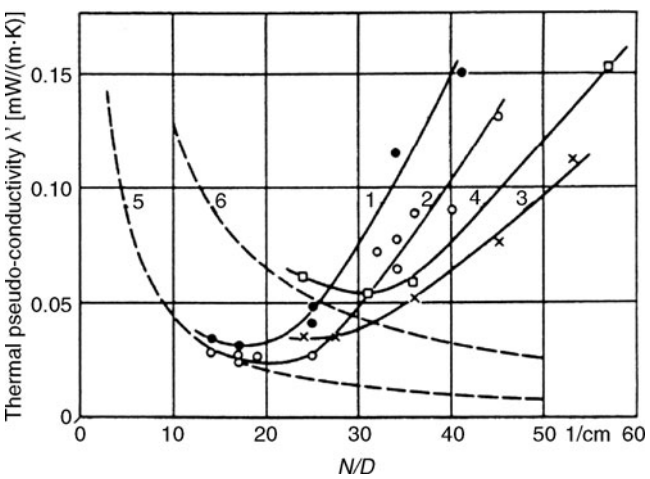
$$\dot{Q}_{SC} = \frac{1 \cdot (0.0015^2 \cdot \pi) \cdot 300}{0.020} \left[\frac{\mathrm{W \cdot m^2 K}}{\mathrm{m \cdot K \cdot m}}\right] = 0.1\,\mathrm{W}.$$

Thus 100 ceramic supports per square meter cause the total heat losses through the peg-supported, high temperature foil insulations to be twice as much of the undisturbed case (in reality, even more supports would have to be installed).

Also, an increase in the thickness of the outer walls would entail considerable increase in mass. Accordingly, application of ceramic pegs, except for special cases, does not seem to be a favorable solution.

Instead, compressive loads on radiation foils can be avoided by fitting them in recesses in microporous insulation panels, as is illustrated in Fig. 6a. However, owing to the comparatively high thermal conductivity of the solid contacts in the microporous supporting material, viz. ca 5 [mW/(m · K)] in vacuum and at low or cryogenic temperatures, the attendant total heat

L., Mormant, France; (**b**) dimpled Al-foil, courtesy Linde AG, Höllriegelskreuth, Germany (sample diameter about 40 mm); (**c**) crinkled metallized Mylar foil (sample size about 40 × 60 mm^2, and (**d**) spacer netting (tulle) using monofilament polyester filaments, surface density about 5–7 g/m^2, mesh size about 2 mm; (**c**) and (**d**) courtesy Jehier S. A., Chemille, France; (**d**) also shows perforation holes of about 2 mm diameter, in-line distance between holes 50 mm, to speed-up evacuation.

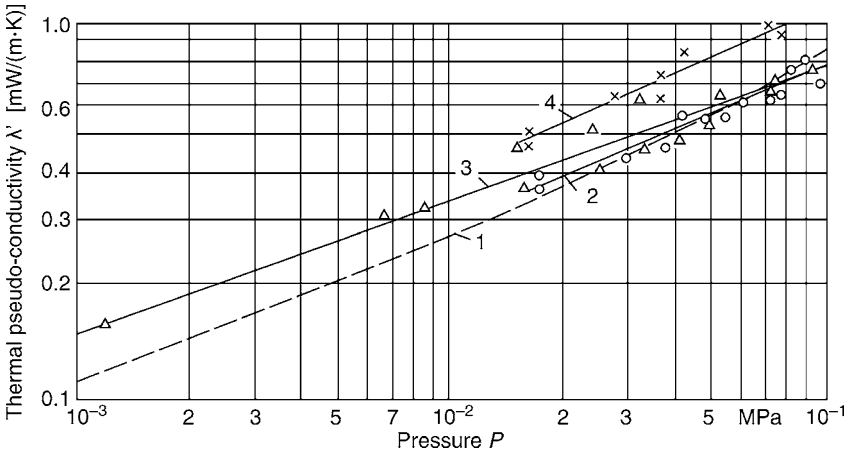


K6. Fig. 4. "Pseudo"- thermal conductivity, λ', of multifoil superinsulations, as a function of the number of foils, N, per unit thickness of insulation, D. The figure is from [1]. Curves 1- 3: aluminum foil with fiberglass paper of various thicknesses; Curve 4: vacuum-aluminized Dracon film with woven glass fabric, Curves 5 and 6: theoretical values (with no allowance for solid-contact conduction) calculated from ε_{Foil} = 0.04 and 0.12. Wall temperatures T_1 = 293 K and T_2 = 90 K.

losses still are at least twice as high as those for purely metallic foil on which there is no compressive load.

A more favorable solution (Figs. 6b and 7a, b) is offered by supports produced from fiberglass paper (conditioned, if necessary, by a thermo-fixation process, under mechanical pressure; this process has successfully been applied also to glass wool or, at high temperatures, to silica fibers). The very low total conductivity of the conditioned fiberglass material (fiberglass boards) hardly increases even under compression of up to 5 bar and especially at high temperatures ([9]). A ratio of 1:5 to 1:10 of the supported area to the total area appears to be realistic. A ratio of 1:10 would restrict the total heat flux losses to 10^{-12} W/m^2 at ΔT = 300 K and D = 20 mm ([10]); in other words, the unsupported, high temperature foil's resistance to heat would hardly be impaired.

As an example, Fig. 7a, b ([11]) shows the "k-value" associated with the total heat losses, i.e., $k = \dot{Q}_{Total}/(A\ \Delta T)$ in [W/(m^2 · K)], for a locally supported superinsulation (Curve 1) that consists of square supports (35 × 35 mm^2, with an average spacing of 70 mm) and ten continuous aluminium foils with intervening fiberglass layers. Curve 2 is obtained if the aluminium foils are left out. The measured values have been plotted against the mean radiation temperature, T^{*3} or T_{Rad}, as defined by Eq. (21) in Sect. 3.3.1. The corresponding k-values for unsegmented



K6. Fig. 5. "Pseudo"- thermal conductivity, λ', of aluminium multifoil superinsulations, as a function of the compressive load, *p*. The figure is from [1]. K6. Fig. 6. (**a**, **b**) Locally supported insulations (not to scale); (**a**) Microporous insulations with non-loadbearing circular recesses to accommodate the foils (or dispersed insulating material of very low density); (**b**) Supports, e.g., fiberglass material.

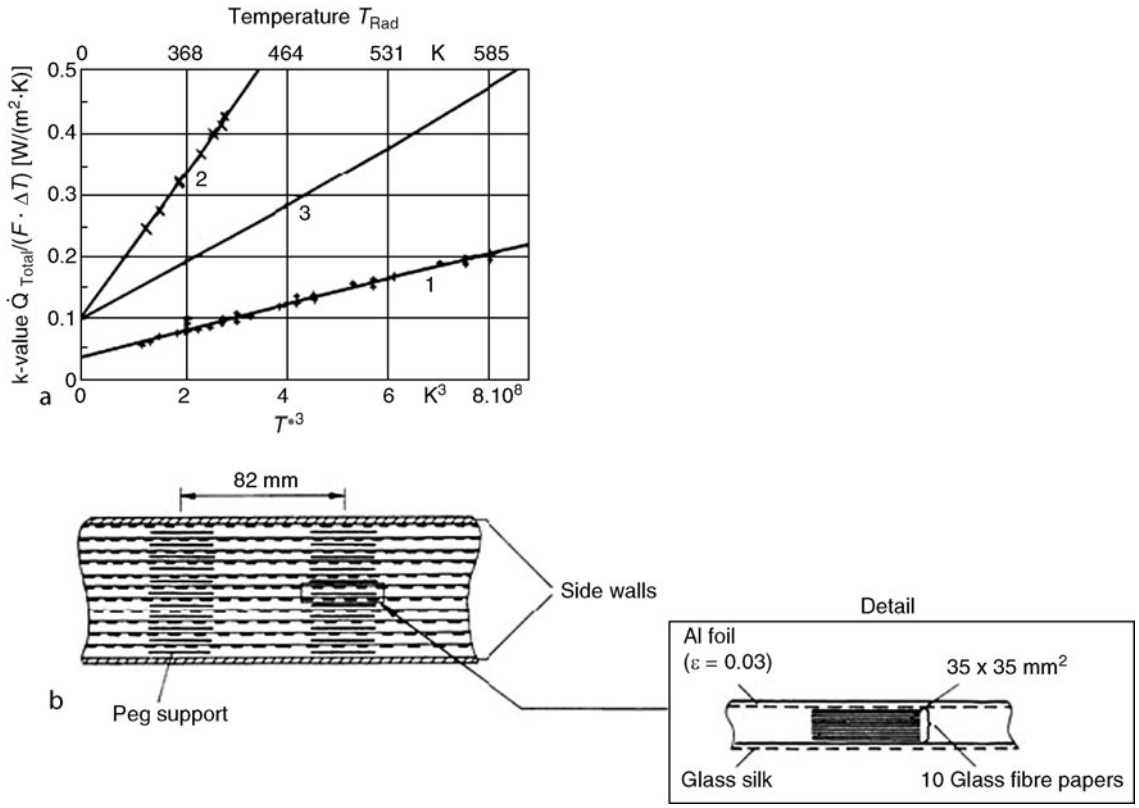
insulations consisting solely of fiberglass (Curve 3) have been included as a comparison. The thermal superiority of the segmented superinsulations can be clearly recognized. All the measured values plotted in this diagram were recorded under a pressure of 1.16 bar.

Heat losses can be considerably increased by direct contact between the warm and the cold sides of the foil assembly (Fig. 8a) by lateral conduction and radiation tunnelling caused by "cold ends" of the film when forming edge jointing. These heat losses can be avoided by staggering the layers of foil (Fig. 8b–d) or by shingled multilayer insulations. In shingled multilayers, one end of each shingle is attached to the inner tank wall and overlaps with a neighboring shingle; this also speeds up evacuation.

A very effective support structure that does not rely on supports (crinkling, nettings, papers) *between* neighboring foils



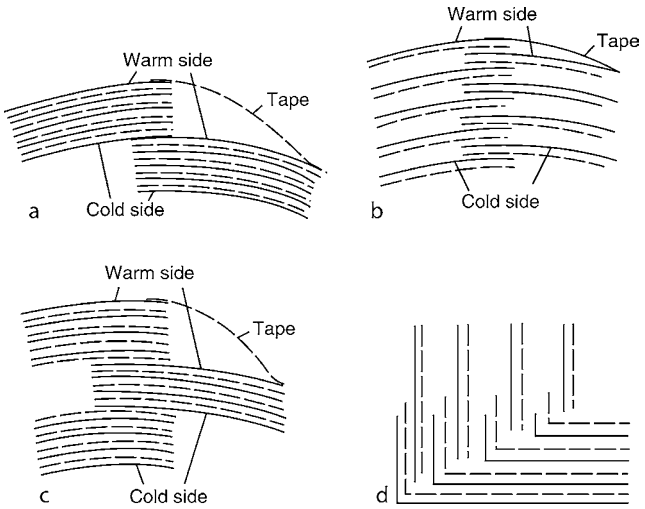
K6. Fig. 7. (**a**) k-Values associated with total heat losses for locally supported and unsegmented, load-bearing superinsulations subjected to compressive load as a function of the average temperature of radiation, T^{*3} {as defined by Eq. (21)}, or of $T_{Rad}{}^3$; the figure is from [11]. Curve 1: superinsulation with local fiberglass paper supports and 10 continuous strips of aluminum foil with intervening layers of woven glass fabric (Fig. 7b); area occupied by the supports as a percentage (18%) of the total area of insulation, average spacing between supports 70 mm; thickness of insulation D = 15.9 mm. Curve 2: same supports but without Al foil; D = 15.2 mm. Curve 3: unsegmented purely fiberglass insulations (fit with measured values, [9]); D = 15 mm. All measured values are determined at a pressure of 1.16 bar exerted by a compressive load. (**b**) Schematic diagram of locally supported superinsulations (Curve 1 in Fig. 7a) with fiberglass paper supports and continuous strips of aluminum foil (10 μm thickness; hemispherical emissivity $\varepsilon \approx 0.03$). Average density of insulations $\rho \approx 90$ kg/m^3 (The figure is from [11]).

but applies inner and outer corrugated tubes, rings, and thin rods (fiber-reinforced material) to support a *stack* of foils, or a blanket, of a multilayer insulation has been reported by Neumann [12], compare Fig. 9. In this concept, radiative exchange between neighboring stacks or blankets will not be increased by the supports, because the radiation exchanging surface of the rods and rings is small (a small percentage of the foil surfaces, contrary to e.g., fiber glass papers), while the non-radiative (solid conduction) paths become rather long due to large distances between neighboring support to blanket contacts. Further, the contacts, either punctiform or as lines, on the upper half-circle are subject to only the small weight of the blankets and on both half-circles only to some tension remaining from winding.

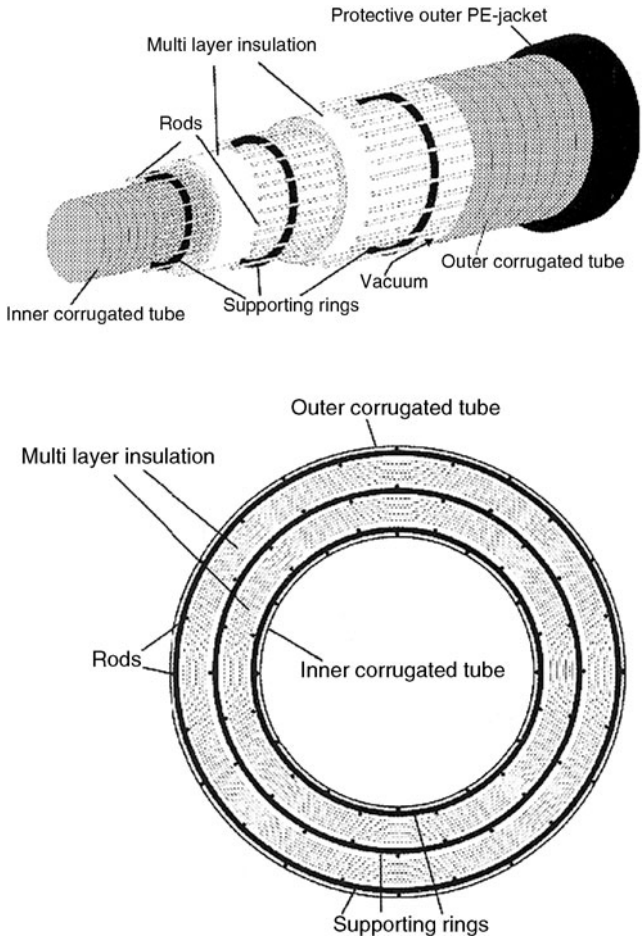
But heat losses over thermal bridges, between inner and outer tank of a container for cryogenic liquids, mostly at the front surfaces, may greatly exceed loss through the foils. This aspect is important also for long, vacuum-insulated tubes for the transport of cryogenic liquids, for superconducting power cables or, as occasionally considered, for medium temperature applications like large diameter pipings in district heating. Long hold times of a LHe cryostat are obtained using vapor-cooled shields for the inner liquid helium tank and a multifoil superinsulation for the outer liquid nitrogen tank. The inner tank can be supported using Kevlar cords, compare, e.g., [13]. Cords, straps, or struts are used in commercially available cryogenic containers. Thermal conductivity, tensile or compressive properties of these materials are critical.

Vapor cooling is applied not only to shields but also to current supply (feed-throughs) into containers housing superconducting magnets [15] or even for bushings in superconducting transformers. An example for calculation of the efficiency of vapor-cooled radiation shields from heat balance conditions is reported in Kaganer ([1], pp. 102–103).

As a completely different concept to support the inner against the outer tank of a container for LH_2, Walter [14] suggests to apply levitation forces between superconductors (melt-textured YBCO or melt-cast BSCCO 2212) and permanent magnets. While in the warm state of the tank, memory-metal actuators serve as supports between both tanks, this concept avoids any solid–solid contacts between both tanks in the cold phase; what remains is the interconnection between inner and outer tank at the neck of a storage unit. When the container is filled, the superconductor is field-cooled which



K6. Fig. 8. Overlap in multifoil superinsulations (schematic, following Langer [17]; (**a**) Simple overlap (greatest heat losses); (**b**) Layer-for-layer overlap; (**c**) Multiple-layer (blanket) overlap; (**d**) Edge joints (indentations). The total losses in a cylindrical tank with layer-for-layer and multiple-layer overlaps are 7% and 2%, respectively, less than those in tanks with simple overlaps [17]. However, these improvements depend on the configuration.



K6. Fig. 9. Mechanical support applied to shields in a multilayer insulation to prevent solid–solid contacts between neighboring shields (The figure is from [12]).

means its position is stabilized ("frozen") against displacements, by means of Lorentz forces between the magnetic field and shielding supercurrents, like in levitation experiments. As reported in [14], the heat loss component, $\dot{Q}_{SC}$, of the LH_2-container was reduced to 0.35 W by this concept, in comparison to the $\dot{Q}_{SC}$ of 2.1 W of a conventional storage unit (total heat losses were reduced from 4.5 to about 2.6 W; certainly, there is potential for further reduction).

2.3 Determination of $\dot{Q}_{Rad}$

Without using multifoils as radiation shields, suppression of radiative heat leakage in Dewar flasks is obtained solely by the extremely small thermal emissivity of mirror-finished glass or metallic walls. Radiative heat leakage in Dewar flasks can be estimated using the relations for multilayers given in the following by simply assuming the number N of foils to $N = 0$.

A standard choice for storage cryostats, cryostats for space missions, or stratospheric balloon experiments is to surround the inner liquid helium tank by an outer liquid nitrogen tank, with an intermediate temperature shield in-between. The shield is convectively cooled by evaporated helium. The radiative load on the liquid nitrogen tank is reduced by means of a multilayer insulation. Metallic walls of the inner tank, shield and outer tank that face each other can be designed simply as a Dewar flask provided they can be given a very small emissivity.

Consider the case of N highly specular foils, e.g., aluminum, nickel, or other metals of very low emissivity, between infinitely extended, *plane* parallel walls of temperatures T_1 and T_2 at right angles to the temperature gradient in an evacuated insulated space. Assume that ε_W is the hemispherical thermal emissivity of the two walls of area A and that it is independent of temperature and wavelength. It is also assumed that ε_{Foil} is the corresponding emissivity of the foils. Also let $\eta_W = \varepsilon_W/(2 - \varepsilon_W)$ and $\eta_{Foil} = \varepsilon_{Foil}/(2 - \varepsilon_{Foil})$ be the corresponding reduced emissivities. The radiant flux $\dot{q}_{Rad} = \dot{Q}_{Rad}/A$ (cf. [1], pp. 33–35) will then be given by

$$\dot{q}_{Rad} = \frac{\dot{q}_{Rad,0}}{1 + N \times \frac{\eta_W}{\eta_{Foil}}} \left[W/m^2\right]. \tag{6}$$

It is assumed that ε is the same for all the foils. The term $\dot{q}_{Rad,0}$ in Eq. (6) is the radiant flux without the foils and is defined by

$$\dot{q}_{Rad,0} = \varepsilon_{eff} \times \sigma \times (T_1^4 - T_2^4)\,[W/m^2] \tag{7a}$$

where T_1 and T_2 are absolute temperatures in Kelvin and

$$\varepsilon_{eff} = \frac{1}{2/\varepsilon_W - 1} = \eta_W \tag{8}$$

The term σ is the Stefan-Boltzmann constant, σ = 5.67040 10^{-8} [W /(m^2 K^4)]. Numerical values for the thermal emissivity, ε, can be found on pages from Chap. K1 or in the traditional literature and in some examples reported in Appendix A2 of this chapter.

It should be noted that the expression for $\dot{q}_{Rad,0}$ in Eq. (7a), and thus that for $\dot{q}_{Rad}$ in Eq. (6), are not in accordance with the structure of the normal thermal conductivity relationship $\dot{Q} = \lambda\ A\ \Delta T/D$, in which the thermal conductivity applies exclusively to specific substances. Thus it is not always possible to report a "radiation conductivity" λ_{Rad} (cf. Sect. 3.3 and Appendix A1).

If the inner surfaces of the walls are mirror-finished, e.g., by electro-polishing, $\varepsilon_W \approx \varepsilon_F$. In this case, the relationship for infinitely extended, *plane* parallel walls is

$$\dot{q}_{Rad} = \frac{\dot{q}_{Rad,0}}{1+N} = \frac{1}{1+N} \times \frac{\sigma \times (T_1^4 - T_2^4)}{2/\varepsilon - 1}\ [W/m^2]. \quad (9)$$

If there are no foils, i.e., if $N = 0$, Eq. (9) becomes

$$\dot{q}_{Rad} = \frac{\sigma \times (T_1^4 - T_2^4)}{2/\varepsilon - 1}\ [W/m^2] \quad (7b)$$

This expression is also valid (approximately, because it was assumed the walls are infinitely extended in length) for the side walls of cylindrical Dewar flasks if the two inner surfaces are mirror-finished to the same extent. However, if the reflection from the second wall is diffuse, regardless of that of the first wall, Eq. (7b) is transformed into Eqs. (12–14) of Chap. K1, Sect. 2.1.

The case of infinitely extended, concentric *cylindrical* walls is considered in Appendix A1 of this chapter, Eqs. (A1) and (A4).

2.4 Total Heat Losses in Evacuated Foil Insulations

A good, though not rigorous expression for the total heat losses is given by

$$\dot{Q}_{Total} = \dot{Q}_{Gas} + \dot{Q}_{SC} + \dot{Q}_{Rad} \quad (10)$$

if $\dot{Q}_{Gas}$ is obtained from Eqs. (2a) and (5); and $\dot{Q}_{Rad}$ from Eqs. (6–9). $\dot{Q}_{SC}$ is estimated as described in Sect. 3. The likelihood of free convection losses can be excluded if the foil insulation is evacuated (and if the foil spacing is not too large). In cases of doubt, the Rayleigh number must be estimated as described in Part. F.

The approximation to $\dot{Q}_{Total}$ given in Eq. (10) is based on the assumption that the individual components of heat flow $\dot{Q}_{Gas}$, $\dot{Q}_{SC}$, and $\dot{Q}_{Rad}$ can be determined separately from one another, as has been described here, and then simply be added. If the residual gas pressures are very low and the number of foils is large (conditions that are usually realized in foil insulations), the approximation is justified. However, the following reservations must be observed:

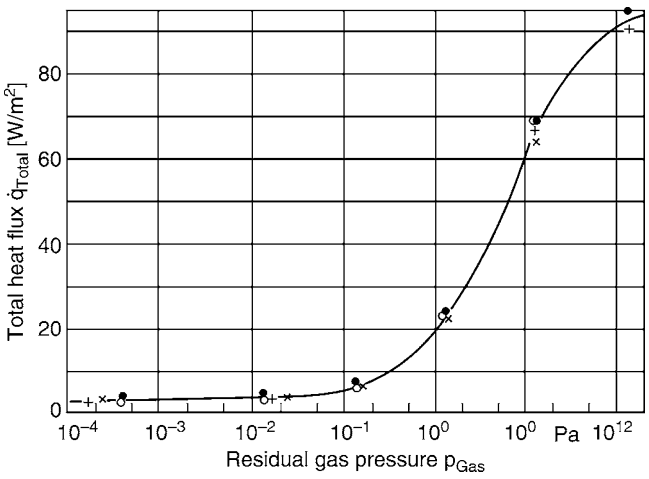
(a) If the residual gas pressures are significant, the heat currents caused by solid contacts may be greater than estimated, as has been observed by Fricke [16]. This can be interpreted as an apparent enlargement of the contact surfaces.

(b) Rigorously, the law of conservation of energy couples all the components of heat flow by means of the temperature profile in the superinsulations, in accordance with their respective relationships to temperature. Consequently, coupling between the different, temperature-dependent heat transport mechanisms must be observed in very accurate analyses. Nevertheless, the approximation obtained by Eq. (10) suffices for the description of regular superinsulations in the majority of applications.

In Sect. 3, a method for experimental separation of heat flow components, $\dot{Q}_{SC}$ and $\dot{Q}_{Rad}$, in *continuous* insulations will be outlined. The question is whether this is also possible in multilayers.

First, a plot of $\dot{Q}_{Total}$ against the residual gas pressure, p_{Gas} (Fig. 10, from [17]), yields the S-curves observed in multifoil insulations; curves of this type are typical also of dispersed insulations (or of any dispersed medium exposed to heat flow, if $\dot{Q}_{Total}$ is measured as a function of residual gas pressure). This can be explained by the fact that $\dot{Q}_{Gas}$ is the dominant component at high gas pressures, in which range λ_{Gas} is constant, i.e., independent of p_{Gas} (if there is no convection that would transfer λ_{Gas} into increased, "effective" values). Hence $\dot{Q}_{Gas}$ and thus $\dot{Q}_{Total}$ are also independent of p_{gas} at high gas pressures. At very low gas pressures, on the other hand, $\dot{Q}_{Gas}$ is negligibly small, and all that remains to be measured is the sum of $\dot{Q}_{SC}$ and $\dot{Q}_{Rad}$ which then does not depend on the residual gas pressure. As can be seen from Fig. 10, $\dot{q}_{Total}$ is reduced to values below 10 W/m^2 in this region. Between these two ranges of pressure, the $\dot{Q}_{Gas}$ component decreases with p_{Gas}, as is described in Sect. 2.1. A separation of $\dot{Q}_{Gas}$ from $\dot{Q}_{SC} + \dot{Q}_{Rad}$ in this intermediate range of p_{Gas}, and of $\dot{Q}_{SC}$ from $\dot{Q}_{Rad}$ in the whole range of pressure, is not possible from the diagram $\dot{Q}_{Total}$ versus residual gas pressure.

An experimental method to separate $\dot{Q}_{SC}$ (thermal bridges between foils and by other solid–solid contacts) from $\dot{Q}_{Rad}$ (solely radiation heat flow through the foils) in multilayer superinsulations has been suggested by Kaganer [1] (pp.164–167). It is based on transient measurements of heat losses, $\dot{Q}_{Total}$,



K6. Fig. 10. Total heat losses $\dot{q}_{Total} = \dot{Q}_{Total}/A$ in foil insulations as a function of the residual gas pressure p_{Gas} (data are from [17]); solid circles: 9 μm aluminium foil and glass tissue, crosses x: 0.25 μm aluminum on both sides of 12 μm polyester film and glass tissue, crosses + : 0.25 μm aluminum on both sides of 6 μm polyester film and polyester nonwoven, open circles: 0.25 μm aluminum on both sides of 12.5 μm polyimide film and polyester nonwoven.

during cool-down of a cryostat. Since this requires measurement of evaporation rates of a completely filled cryostat, there are hardly experimental values available other than those reported by Kaganer. Instead, the author has performed a numerical experiment (see Appendix A3) to check the suggested method.

Note that the components of $\dot{Q}_{\text{Total}}$ in Eq. (10) are calculated with given temperatures of warm and cold walls, at coordinates $x = \text{D}$ and $x = 0$, respectively. Conversely, if heat flux, $\dot{q}$, is given as boundary condition, i.e., not $T(\text{D})$ and $T(0)$, but $\lambda\, \text{d}T/\text{d}x$, on either wall plus the temperature of one wall, either $T(\text{D})$ or $T(0)$, the other temperature, $T(0)$ or $T(\text{D})$, respectively, can be calculated, from conservation of energy (see below). This means that temperature profiles can be calculated, which subsequently allows calculation also of the heat flux components.

Application of the second boundary conditions option (heat flux, plus one wall temperature) allows to account for coupling between radiation and conduction heat transfer (for an application of the following, see, e.g., [18]). Assume N concentric radiation shields of wrapped around an inner container of infinite length. Heat flow parallel to the cylindrical surfaces is neglected. This assumption can be justified if clearance between the shields and cross section of each shield is very small. Heat exchange between neighboring shields is by radiation and, because of some mechanical contacts, by conduction. Under stationary conditions, the energy balance for each of the $1 \le \text{j} \le \text{N}$ shields, with respect to its neighbours, $1 \le k \le N$, $j \ne k$, reads

$$\dot{Q}_{\text{j,k}} = (T_{\text{j}} - T_{\text{k}})/R_{\text{Cond (j,k)}} + (T_{\text{j}}^4 - T_{\text{k}}^4)/R_{\text{Rad(j,k)}} \qquad (11)$$

In Eq. (11), the first and second terms describe conduction and radiation contributions, respectively. The $R_{\text{Cond(j,k)}}$ and $R_{\text{Rad(j,k)}}$ are the corresponding thermal resistances to conduction and radiation between shields j and k. Assume that the shields $j = 1$ and $j = \text{N}$ are surrounded by outer and inner concentric walls, $j = 0$ and $j = \text{N} + 1$ (index a), respectively. The temperature of the outer wall, T_{a}, roughly equals ambient temperature $T_{\text{a}} > T_{\text{j=1}}$, while the temperature of the inner wall, T_0, equals temperature of a stored cryogenic liquid, T_2. Thus two additional equations like Eq. (11) take into account boundary conditions, either

$$\dot{Q}_{\text{1,a}} = (T_{\text{a}}^4 - T_1^4)/R_{\text{Rad(1,a)}} \qquad (12a)$$

or

$$\dot{Q}_{\text{N,0}} = (T_{\text{N}}^4 - T_0^4)/R_{\text{Rad(N,0)}} \qquad (12b)$$

For definition of the conductive and radiative resistances in Eqs. (11), (12a), and (12b), see Sect. 2.5 dealing with resistance networks. If using for radiative resistances between neighboring foils the relation $R_{\text{Rad}} = \Delta T/\dot{Q}_{\text{Rad}}$ with $\dot{Q}_{\text{Rad}}$ from Eq. (7b), that describes concentric cylinders of *infinite* length, a correction with respect to finite length of the container has to be introduced. If all materials parameters (conductivities and emissivities of shields and walls) are considered as independent of temperature, and the emissivities of all (mirror-finished) shields and walls identical, the resistances incorporate only geometry (size of the N + 1 surfaces).

Since all $\dot{Q}$ in Eqs. (11), (12a), and (12b) are equal, by conservation of energy we have a system of N + 1 interdependent, algebraic equations that can easily be solved. A check of this method can be made using thermal resistance networks (see Sect. 2.5). It is also possible to consider temperature-dependent conductivities and emissivities, but then solutions of the system of equations have to be found in iterations.

Values determined by experiment for the total heat losses $\dot{q}_{\text{Total}} = \dot{Q}_{\text{Total}}/A$ in foil insulations are listed in Tables 3 and 4. They are valid for various materials for foils and spacers in cryogenic and high-temperature insulations, various grades of perforations of the foils (to reduce the time required for gas removal), and winding forces. The tables have been extracted from Langer's comprehensive documentation [17], again a traditional source of data.

The recently published, detailed compilation ([8], Sects. 3–5) investigates experimentally the influence of the whole catalogue of degradations on thermal performance of multifoil superinsulations. The study includes interruptions like flanges, turns, gaps, fissures and edge jointing, the increase of heat transmission by mechanical pressure on multilayers, and longitudinal (parallel to foils) thermal conduction, all for a variety of materials and in the cryogenic range of temperatures including LHe. Advantages of winding versus mat technology is discussed also, and best results obtained so far for $\dot{Q}_{\text{Total}}$ of large cryogenic installations are reported in Sect. 6 of this reference.

2.5 Thermal Network Calculations Applied to Multilayer Superinsulations

Estimation of $\dot{Q}_{\text{SC}}$ in Sect. 2.2 and of $\dot{Q}_{\text{Rad}}$ using Eq. (6) and determination of $\dot{Q}_{\text{Total}}$ using Eq. (10) or Eqs. (11) and (12a, b), are restricted to heat flow components *perpendicular* to surfaces of foils and spacers. Lateral heat flow is not taken into account by these methods. However, lateral heat flow can be important at cryogenic and high-temperature multilayer insulations with respect to heat leakage through the neck of cryostats, through mechanical supports, or other penetrations (insulated evacuation channels or current feed-through). Further, the methods presented in the previous sections, except for Eqs. (11) and (12a, b), do not consider coupling between the different heat transfer mechanisms (gaseous or solid–solid contact conduction, radiation); this is because they do not take into account the temperature profiles, and accordingly, the temperature dependence of the conductivities or corresponding thermal resistances.

A practical method that allows to take into account not only heat flow of any origin and in *any* direction and coupling between conduction and radiation, by temperature-dependent material's properties like thermal conductivity (at least in intervals), is available from thermal network calculations.

Thermal networks are a generalization of electrical networks. The method is similar to Finite Element calculations using 1D-elements (differences occur in the applied solution schemes of the corresponding conduction and load matrices). Thermal networks have been applied successfully to power electronics, pipings for transport of hot fluids, motors and generators, power electronics, and superconducting transformers.

K6. Table 3. Total heat losses, $\dot{q}_{Total}$, through multilayer superinsulations; residual gas pressure $\leq 10^{-3}$ Pa, at cryogenic temperatures (Data are from [17]). The figures for the winding forces apply to foil of 70 cm width

Foil material	Spacer material	Thickness of insulations [mm]	ΔT [K]	$\dot{q}_{Total}$ [W/m^2]

To outline the principle, consider a cylindrical storage unit as indicated schematically in Fig. 11. It consists of a super-insulated inner tank and an outer container (shield to ambient) and a super-insulated neck. A thin-walled bellow is used as the inner tube of the neck, to reduce axial conductive heat losses to the surroundings. Assume N radiation shields are wrapped around the inner container, over its entire length and on its upper and lower front sides, with spacer materials in-between.

The method applies a suitable division of the solid components of the cryostat into length or volume sections, and the center of each section is denoted by a "node." In Fig. 11, in total M = 46 nodes have been defined. Finer divisions of the wall or shields volumes would significantly increase the number of nodes and thus calculation efforts, without substantially improving the accuracy needed for an overall analysis of the thermal performance of the cryostat. The thermal network could perhaps be a first step taken before detailed finite differences or finite element calculations are performed; actually, they could be made superfluous by results from a suitably designed thermal network.

2.5.1 Stationary Conditions

Consider in Fig. 11 a particular node, j. Thermal resistances, R_{jk}, are located between this and each of its neighboring nodes, k. Heat flow between each node (conduction, radiation, and even convection between solid components and stored liquid) follows the law $\dot{Q}_{jk} = \Delta T_{jk}/R_{jk}$ with ΔT_{jk} denoting the temperature difference between nodes j and k; the thermal resistances, R_{jk}, are explained below. Under stationary conditions, summation over all incoming and outgoing heat flow components at any of the nodes, j, equals zero, for stationary conditions (compare Kirchhoff's law in electrical circuits). A corresponding algebraic equation thus can be written for each node.

Consider as an example the node $j = 3$ located on the wall of the inner tank. Temperature at node 3 is T_3, and T_{Fluid} denotes

K6. Table 4. Total heat losses, $\dot{q}_{Total}$, through multilayer superinsulations at medium and high temperatures. The figures for the winding forces apply to foil of 70 cm width. Measured values A + to C from [17]

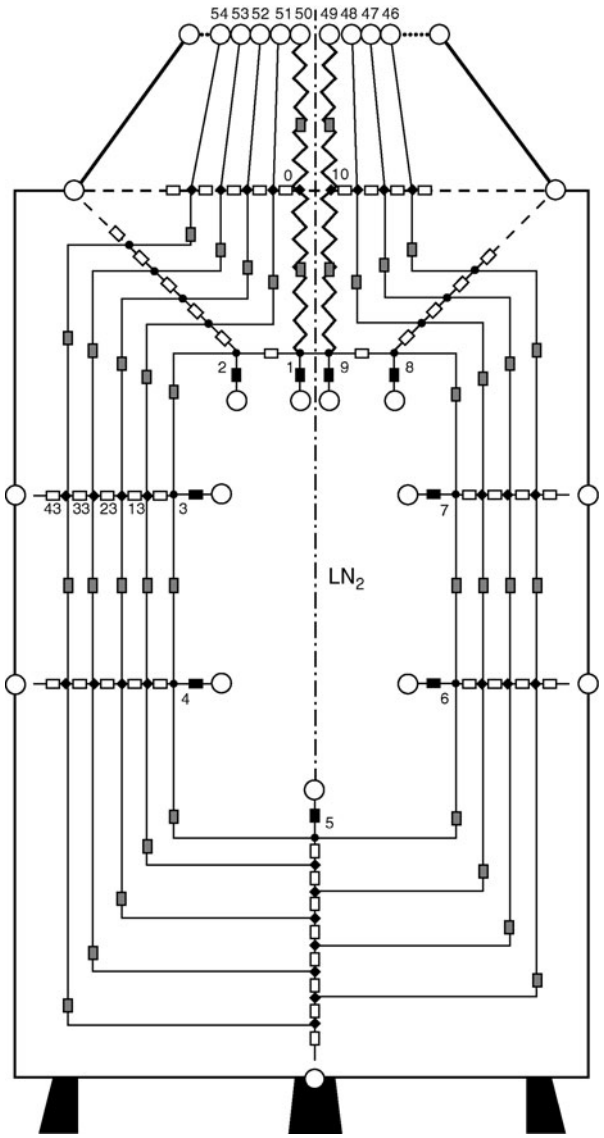
The measured values marked by an asterisk can serve solely as a guide for estimating $\dot{q}_{Total}$



K6. Fig. 11. Thermal network of a cryogenic storage tank (the figure is from [19]; schematic, strongly simplified tank geometry, Klöpper design at top and bottom of inner and outer containers and filling pipe not indicated, dimensions at the neck enlarged). Dashed-dotted line: symmetry axis, thick solid lines: walls of containers and neck, thin solid lines: radiation shields and spacers (the solid lines thus also represent heat flow paths between nodes). Small solid circles: positions where temperatures are calculated in the network, large open circles: positions where boundary conditions are given; open, dotted, or full rectangles: thermal resistances concerning radiation, conduction and boiling, or convection, respectively.

the temperature of the stored liquid. With respect to the immediate neighbors of node 3, we have the equation

$$(T_2 - T_3)/R_{2,3} + (T_{13} - T_3)/R_{13,3} = (T_3 - T_4)/R_{3,4} + (T_3 - T_{Fluid})/R_{3,Fluid} \quad (13a)$$

Resistances $R_{2,3}$ and $R_{3,4}$ describe solid thermal conduction while $R_{13,3}$ is the radiative resistance between the innermost foil and the wall of the inner tank; $R_{3,Fluid}$ denotes heat transfer, by free convection or boiling, from the wall to the liquid.

Accordingly, $R_{2,3}$ takes the form

$$R_{2,3} = D_{2,3}/(\lambda_S A_{2,3})\ [\mathrm{K/W}] \quad (14a)$$

with $D_{2,3}$ the distance between nodes 2 and 3, λ_S the thermal conductivity of the stainless steel wall of the inner tank, and $A_{2,3}$ the cross section of the heat flow path between both nodes.

The radiative resistance, $R_{13,3}$ is given by

$$R_{13,3} = (T_{13} - T_3)/\dot{Q}_{Rad(13,3)}\ [\mathrm{K/W}] \quad (14b)$$

using Eq. (6) for determination of the radiative heat flow $\dot{Q}_{Rad(13,3)}$. For simplicity, Eq. (6) that describes radiative

exchange between parallel walls and shields has been taken for $\dot{Q}_{\mathrm{Rad}(13,3)}$; for the cylindrical case see [1], pp. 33–35. Because of the strong dependence on temperature of $\dot{Q}_{\mathrm{Rad}(13,3)}$, the temperatures T_{13} and T_3 have to be iteratively determined from solutions of the algebraic system of equations, see below.

The radiative resistance $R_{13,3}$ can be re-formulated to also integrate resistances parallel to radiation, that is, a resistance to solid–solid contact heat flow or to thermal conduction by the residual gas between foils and spacers.

For the convective thermal resistance, $R_{3,\mathrm{Fluid}}$, we have

$$R_{3,\mathrm{Fluid}} = 1/(\alpha F)[K/W] \tag{14c}$$

using α for the heat transfer coefficient and F the wetted surface of the inner container.

Assuming M nodes means we have a set of M interdependent, algebraic equations of the type Eq. (13a), for determination of the temperatures T_j $(1 \le j \le M)$. Thermal conductances, that is, the inverse of thermal resistances, constitute the coefficients in the conduction matrix. The calculated T_j have to be interpreted as mean values averaged over corresponding volumes (the above-mentioned sections) of the walls of inner container, of the bellow, and of the shields. Temperatures of the outer container and of the outer wall of the neck are given as boundary conditions (or if convection on the outer surface shall be modeled, ambient temperature and a corresponding heat transfer coefficient must be taken into account).

Solutions are easily found using standard methods to solve systems of algebraic equations (Kramer's scheme, or matrix methods). For more details of the network, of the resistances and the solution, see [19].

With the obtained temperature distribution T_j $(1 \le j \le M)$, the heat flow, $\dot{Q}_{jk}$, between any two nodes j and k, and the total heat loss, $\dot{Q}_{\mathrm{Total}}$, of the container accordingly is calculated using

$$\dot{Q}_{jk} = (T_j - T_k)/R_{jk} \tag{15a}$$

$$\dot{Q}_{\mathrm{Total}} = \sum \dot{Q}_{jk} \tag{15b}$$

The summation taken between the nodes of the inner wall $(1 \le j \le 9$ in Fig. 11) and the fixed node, k, indicated by an open circle, the fluid.

Total heat losses, $\dot{Q}_{\mathrm{Total}}$, and total conductive losses, $\dot{Q}_{\mathrm{Cond}}$ can be determined only at appropriate boundaries of the network. In Fig. 11, we have two boundaries: the first with the nodes $1 \le j \le 9$ separates the inner container from the stored liquid, and the second is identified between nodes $46 \le j \le 54$ located near the upper end of the bellow, and ambient. $\dot{Q}_{\mathrm{Cond}}$ is the heat that is delivered only by conduction from the ambient to the insulations material, to walls of the storage unit, and to the bellow before it is distributed in the insulations by radiation and solid–solid contact conductivity. Accordingly, separation of radiative and conductive losses is possible from network calculations.

2.5.2 Unsteady-State Conditions

Extension of the thermal resistance method to transient problems can be useful to analyze cool-down of a superinsulated container. For this purpose, terms $C_j\ \mathrm{d}T_j/\mathrm{d}t$, again for each node, j, have to be introduced into Eq. (13a); C_j denotes the heat capacity of the corresponding section of walls or foils. For node $j = 3$ (Fig. 11), we have

$$(T_2 - T_3)/R_{2,3} + (T_{13} - T_3)/R_{13,3} + (T_4 - T_3)/R_{4,3} + (T_{\mathrm{liq}} - T_3)/R_{\mathrm{Liq},3} = C_3 \mathrm{d}T_3/\mathrm{d}t \tag{13b}$$

This changes the calculation scheme from a system of interdependent, algebraic to a corresponding system of interdependent differential equations. If we take also into account temperature-dependent material properties, after elementary transformations, Eq. (13b) and the corresponding other $M - 1$ heat balances together yield the set

$$T_j(t) \times \sum k_{jk}(T) + \sum k_{jk}(T) \times T_k(t) - \dot{Q}_j(t) = C_j \times \mathrm{d}T_j(t)/\mathrm{d}t \qquad 0 \le j, k \le M, \text{ with } j \ne k. \tag{13c}$$

In Eq. (13c), the symbols $\sum k_{jk}(T)$ denote summations over temperature-dependent coefficients, the inverse of the corresponding thermal resistances, $R_{jk}(T)$, and $C_j(T) = \rho_j \times c_{p,j}(T) \times V_j$ the heat capacities, with density, specific heat, and volume, ρ_j, $c_{p,j}(T)$, and V_j, respectively, at the nodes, j; we further have source terms, $\dot{Q}_j(t)$, that in this simulation contain summations over constant temperatures (the boundary conditions) and inverse of heat resistances.

In the closed form, analytical integration would be possible with constant k_{jk}, C_j, and $\dot{Q}_j$, the solution scheme to Eq. (13c) has to apply numerical integration. The procedure is similar to solution steps in finite element problems.

The set Eq. (13c) can be rewritten in matrix form as $[\mathrm{k}] \times \{\mathrm{T}\} - \{\dot{\mathrm{Q}}\} = [\mathrm{C}] \times \{\mathrm{d}T/\mathrm{d}t\}$, with the conduction (or "stiffness") matrix, [k], the temperature column vector, {T}, the source column vector, $\{\dot{\mathrm{Q}}\}$, the heat capacity matrix, [C], and the temperature derivatives column vector, $\{\mathrm{d}T/\mathrm{d}t\}$. The elements of all these matrices and column vectors are functions of time, t. [k] and [C] are $M \times M$ matrices, and the column vectors have M rows. For each t, the matrix [k] equals its transposed matrix. The matrix [C] has only diagonal elements. Calculation of the inverse, $[\mathrm{C}^{-1}]$ of [C], and multiplication of the left side of Eq. (13c) by $[\mathrm{C}^{-1}]$ and by finite time steps, Δt, yields the column vector $\{\Delta T\}$ that has to be added to $\{T\}$ to yield the node temperatures, $\{T_k(t + \Delta t)\}$, obtained after one time step. The new T_k then are applied to recalculate the elements of the matrices [k], $[\dot{\mathrm{Q}}]$, and [C], to continue with the stepwise procedure. For an example, compare [20].

The method can be generalized to fluid networks, for calculation of stationary or transient distributions of residual gas pressures between foils and spacers, e.g., for modeling evacuation periods. Nodes have to be positioned in evacuation channels established by the open spaces between foils, spacers, and walls. In the system of algebraic or differential equations, respectively, temperatures, T_j, at the nodes, j, accordingly have to be replaced by residual gas pressures, p_j, likewise, thermal resistances, R_{jk}, by resistances to fluid flow, Z_{jk}, under *molecular* gas flow. While restriction to molecular gas flow conditions seems to be a drawback of the method, this flow condition is reached very quickly, usually after a few seconds during evacuation of multifoil superinsulations. Evacuation to final residual gas pressure, in the order

of 10^{-6} mbar, on the other hand, usually takes hours so that the missing initial degassing period does not play a big role.

For estimation of the fluid flow resistances, Z_{jk}, consult standard literature of vacuum technology, like [21] or [22], or the examples in [19] and [23].

Residual gas pressures in evacuated insulations are frequently measured at singular points only, mostly with closed valves. After individual waiting periods, it is assumed that the detected residual gas pressure is the same for all sections of the insulations. However, this is not fulfilled if sources like desorption of gas molecules from wall, foil or spacer surfaces, or permeation of gas molecules from ambient or from stored liquids, in particular hydrogen, through the outer or inner walls of the container, and/or sinks like getters in the evacuated space contribute to local variations of the residual gas pressure; this is the case in particular if the width of the evacuation channels (described by corresponding hydraulic diameters) is small. Such local variations can be modeled with the fluid networks like in [23].

3 Superinsulations of Continuous Structure (Powders, Fibers, Panels)

Heat transport through beds of dispersed solids in which the particle diameter is decidedly greater than the wavelength of thermal radiation has been described in Subchap. D6.3. The following concerns heat transport through media of considerably smaller particle size, e.g., evacuated powder and fiber insulations. Foamed material falls outside the scope of this study.

If the diameter of the particles or their interstices is, at the most, equal to the wavelength of radiant heat that is emitted by the source to be insulated, i.e., 1–500 µm, the insulating substance can be regarded as a continuum with respect to the propagation of radiation (cf. Sect. 3.3). As was the case in Sect. 1, the total heat losses are determined as the sum of individually estimated components, again in an approximation the validity of which has to be checked carefully.

3.1 Determination of $\dot{Q}_{Gas}$

$\dot{Q}_{Gas}$ is calculated by the same methods as those described in Sect. 2.1. After the mean free path l_{Gas} has been obtained from Eq. (1), the average pore diameter δ, that is, the mean diameter of the interstices between particles, is determined. Values of δ should be taken that have been verified by experiment, e.g., from measurements of capillary depression with a non-wetting liquid, BET adsorption isotherms, capillary condensation, or by light scattering experiments. If these are not available, a very rough estimate of δ can be made, for spherical particles or for fibers, using the following (traditional) equation ([24]) or Kaganer [1], p. 75,

$$\delta = C_3\, d/(1-\Pi)[\mathrm{m}] \qquad (16a)$$

where C_3 is a constant ($C_3 = 2/3$ for spherical particles and $C_3 = \pi/4$ for fibers), d is the particle diameter [m] and Π is the porosity of the insulations. But for spherical particles, Kaganer [1], p. 14, also reports

$$\delta = (2/3)\, d\,\Pi/(1-\Pi)\ [\mathrm{m}] \qquad (16b)$$

Equation (16a) applies only in an intermediate range of porosities, Π, while Eq. (16b) at least reproduces the case $\Pi = 0$ but also fails for $\Pi \to 1$. Neither formula is very convincing, so that experimental values of δ should be preferred; in case these are given as a function of the Knudsen number, it should be checked how the pore diameter was determined.

Example 1

Determine λ_{Gas} for nitrogen at 1/100th atmospheric pressure and $T = 300$ K in a bed of spherical particles (particle diameter 1 µm; powder density $\rho_P = 300$ kg/m^3; density of solid material $\rho_S = 5000$ kg/m^3).

Solution

Since $p_{Gas} = 10^3$ Pa, it follows from Table 1 that

$$\begin{aligned} C_1(p_{Gas}) &= (133\times 10^{-3})61\ \mu\mathrm{m} \\ &= 8.1\ \mu\mathrm{m}. \\ \text{Also } C_2 &= 112\ \mathrm{K}. \\ \text{Hence } l_{Gas} &= 8.1/(1+112/300)\ \mu\mathrm{m} \\ &= 5.9\ \mu\mathrm{m}. \end{aligned}$$

The porosity is $\Pi = 1 - \rho_P/\rho_S = 1 - 300/5000 = 0.94$. Inserting $C_3 = 0.667$, $d = 10^{-6}$, and $\Pi = 0.94$ in Eq. (16a) gives $\delta = 0.667 \times 10^{-6}/(1-0.94) = 1.11 \times 10^{-5} = 11.1$ µm. The Knudsen number is therefore Kn = 5.9/11.1 = 0.53.

The correction obtained from Table 2 for nitrogen at 300 K is $k = 1.95$. The ratio $\kappa = c_p/c_v$ for the bi-atomic gas molecule N_2 with $f = 5$ degrees of freedom is $(f+2)/f = 1.4$.

Therefore, if $\alpha = 1$, $\beta = (2 \times 1.95/(1.4+1) = 1.63$.

From the tables (e.g., in Subchap. D2.3), λ_0 for nitrogen at $T = 300$ K is $\lambda_0 = 0.026$ [W/(m · K)]. Equation (2a) then gives

$$\begin{aligned} \lambda_{Gas} &= \lambda_0/(1+2\times 1.63\times 0.53) \\ &= 0.026/2.73 \\ &= 0.0095\ [\mathrm{W/(m\cdot K)}]. \end{aligned}$$

The term Π in Eq. (16a, b), the porosity, is due to the interstices between particles. This is the only form of porosity that exists in beds of mono-dispersed particles and in fiber insulations (the intergrain porosity). However, if the particles themselves are micro-porous, for example, silica aerogel, corresponding allowance must be made by introducing a second porosity term Π' in Eq. (2a) (cf. [1], pp. 67, 68 and 71–75, Eq. (125)). In this case, Eq. (2a) transforms into

$$\lambda_{Gas} = C_{IGP}/(1+2\beta\,\mathrm{Kn}_{IGP}) + C_{MPP}/(1+2\,\beta\,\mathrm{Kn}_{MPP}) \qquad (2b)$$

with constants C_{IGP} and C_{MPP} and Kn_{IGP} and Kn_{MPP} the Knudsen numbers for the intergranular (index IGP) and microporous porosities (MPP), respectively. Addition of the gaseous conductivity components in Eq. (2b) indicates that the corresponding thermal conduction resistances are parallel.

As was the case in Sect. 2.1, $\dot{Q}_{Gas} = \lambda_{Gas}\, A\, \Delta T/D$ Eq. (5).

3.2 Determination of $\dot{Q}_{SC}$

Since the particles applied in thermal superinsulations are of much smaller diameter than those considered in Subchap. D6.3, the resistance to contact heat flow is an important factor in heat transfer. The following expressions for thermal conductivity by contact, λ_{SC}, have been derived by relating the conductivity of the solid material, λ_S, to the contact radii calculated from elasticity theory. The equation for λ_{SC} also includes the number of contacts between the particles in the bed of insulating material.

Let λ_S [W/(m · K)] be the thermal conductivity of the solid material from which the particles of insulations have been produced, and let p (Pa = N/m^2) be the mechanical pressure that acts on the insulations. Then, if the surfaces of the particles undergo elastic deformation in the zones of contact, the thermal conductivity by solid contact, λ_{SC}, for a bed of spherical particles (index "Spheres") will be given by Eq. (17) ([1], pp. 18–21), and for a regular network of fibers (index "Fibers"), compare Fig. 12a (another idealization), by Eq. (18) ([1], pp. 22–25):

$$\lambda_{SC,Spheres} = 3.44\,(1-\Pi)^{4/3}[(1-\gamma^2)/Y]^{1/3}\,\lambda_S\,p^{1/3}[W/(m\cdot K)] \tag{17}$$

$$\lambda_{SC,Fibers} = [16(1-\Pi)^2/\pi^2]\,\lambda_S\{[1/(1.86\,a\,p^{1/3})] + 1/[4(1-\Pi)]\}^{-1}[W/(m\cdot K)] \tag{18}$$

where γ is Poisson's ratio (about 0.22 for ceramic particles or glass fibers), Y is Young's modulus of elasticity for the solid material, and $a = \{(1-\gamma^2)/Y(1-\Pi)^2\}^{1/3}$.

Fiberglass paper (Fig. 12b) has a somewhat similar structure to that of the ideal network (Fig. 12a).

Values of λ_{SC} determined by Eqs. (17) and (18) for spherical particles and glass fibers have been plotted against temperature in Fig. 13. It is evident from these equations that λ_{SC} is independent of the particle diameter. See also [1], pp. 15–18 for more (traditional) expressions to estimate simultaneous gaseous and solid–solid contact heat flow through beds.

Example 2

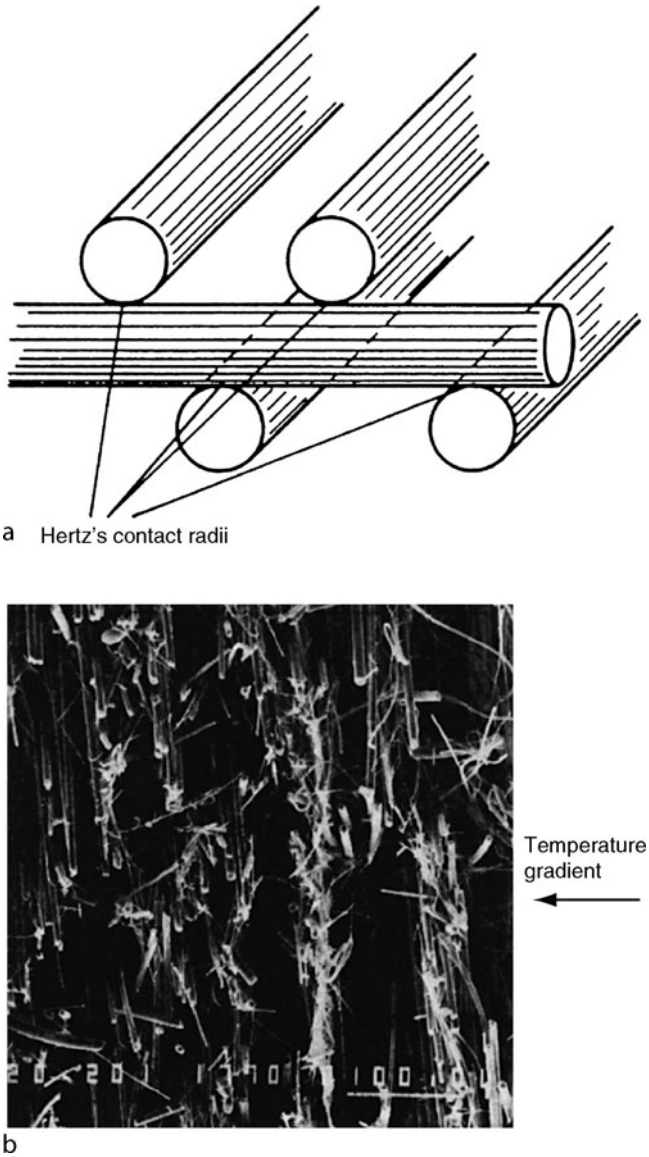
Determine λ_{SC} for the bed of spherical particles described in Example 1 in Sect. 3.1 under the assumption that $\gamma = 0.22$, $Y = 6.7\times 10^{10}$ Pa (the value for boron silicate glass at $T = 300$ K), $\lambda_S = 1$ [W/(m · K)] and $p = 10^5$ Pa.

Solution

Inserting the above values in Eq. (17) yields

$$\lambda_{SC} = 3.44(1-0.94)^{4/3}\{[(1-0.22^2)/6.7\times 10^{10}]\,10^5\}^{1/3} = 9.1\times 10^{-4}[W/(m\cdot K)].$$

It is evident from Eqs. (17) and (18) that λ_{SC} for spherical and fibrous particles subjected to elastic deformation is related to the cube root of the applied pressure, p [Pa]. The relationship has been confirmed by experiments performed on insulations that was produced from evacuated fiberglass paper and subjected to low compressive loads (Fig. 14, from [9]). If the deformation is inelastic, λ_{SC} is more likely to be related to the square root of the applied pressure, *p*.



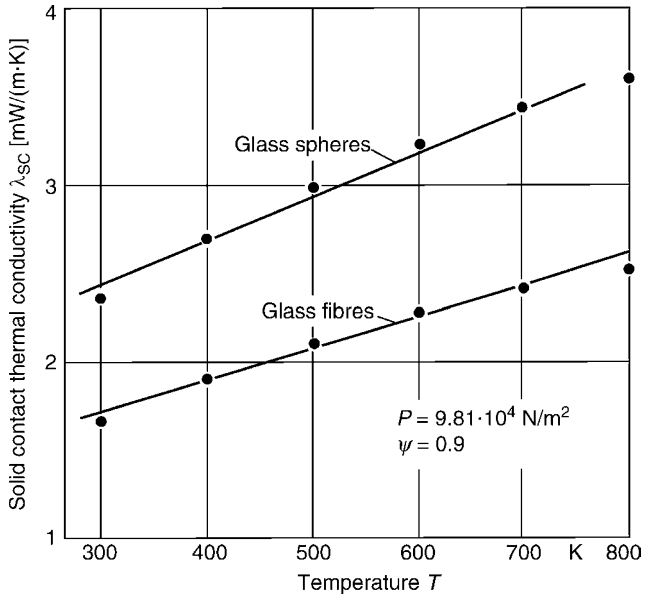
K6. Fig. 12. (**a**) Regular fiber network (schematic), for calculation of solid conduction conductivity assuming ideal orientation of fibers in a fiberglass insulations, (**b**) Scanning electron micrograph of a fiberglass paper (side view). The horizontal bar in the right corner below represents a length of 100 μm.

Calculation of λ_{SC} for expanded materials (foams) lies outside the scope of this chapter.

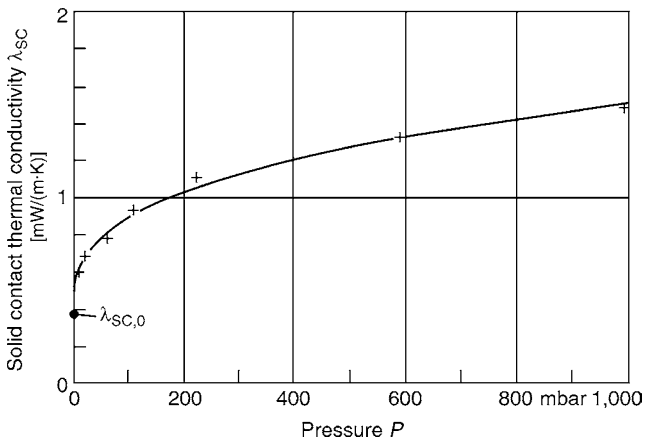
$\dot{Q}_{SC}$ is obtained from λ_{SC} by applying the normal rule for heat conduction, like in Eq. (5).

3.3 Determination of $\dot{Q}_{Rad}$

The method presented here differs significantly from that given for dispersed beds (cf. Part D). In the latter, radiation was expressed in terms of properties at the *surface*, i.e., the emissivity ε and the effective radiation path X_R, and was described as energy *exchange*. Here, instead, the small grain size entails that the penetration of radiation *into* the particles must also be taken into consideration, i.e., radiation energy *transport* is involved.



K6. Fig. 13. Thermal conductivity by solid contact, λ_{SC} (calculated values), as a function of temperature T, in a bed of spherical particles and in a regular network of fibers. Determined from Eqs. (17) and (18) for $\Pi = 0.9$, $\gamma = 0.22$, $p = 9.81 \times 10^4$ Pa, and temperature-dependent values of Y and λ_S.



K6. Fig. 14. Thermal conductivity by solid contact, λ_{SC} (measured values), as a function of low values of the pressure p applied by a compressive load. Plotted from values determined by experiment (the figure is from [9]). The curve fits the relationship $\lambda_{SC} = \lambda_{SC,0} + a\, p^{1/3}$ by the method of least squares; $\lambda_{SC,0} = 0.37$ [mW/(m · K)] and $a = 0.11$ [mW/(m · K mbar$^{1/3}$)].

In the perfectly nontransparent case, the transport mechanism may even be regarded as diffusion. Therefore, the main parameters for the determination of heat flux by radiation are not restricted to the exchange of energy between surfaces but must also embrace the entire effect exerted by the particles on the extinction of radiation along a mean free path, l_{Rad}.

Radiative flow, $\dot{Q}_{Rad}$, as a transport process, is considerably more difficult to determine than the other components. Thus, it must first of all be determined whether or not the fine-grained insulating material is transparent or nontransparent in the range of wavelengths that is important for a heat balance within the thermal spectrum. If it is nontransparent, the heat losses can be expressed as a thermal conductivity in the form of λ_{Rad}, from a diffusion model (cf. Sect. 3.3.1 and Appendix A1). If the material is transparent (cf. Sect. 3.3.2), using an expression of this nature would involve a considerable error.

A substance of continuous structure is *nontransparent* if its optical thickness τ_0 is much larger than unity, i.e., $\tau_0 \geq 15$ (an explanation for this limit is given in Appendix A1). The optical thickness, $\tau_0(\Lambda\}$ at a given wave length, Λ, is defined by

$$\tau_0(\Lambda) = \int_0^D E(\Lambda) \times \mathrm{d}s \qquad (19)$$

where D [m] is the thickness of the insulations, which is to be considered constant in this case, and $E(\Lambda)$ [1/m] is the spectral linear extinction coefficient.

As a first approximation, it may be assumed that the dispersed insulating material scatters radiation isotropically, i.e., equally in all directions. This is usually assumed for the linear extinction coefficient, E, in the Lambert-Beer law. *Anisotropic* scattering, however, which is displayed by many real insulating materials, can be allowed for by converting E into an effective coefficient E^* (cf. Example 5).

In homogeneous media, the linear extinction coefficient is independent of position, i.e., $\tau_0(\Lambda\} = E(\Lambda)\, D$. If it is also independent of wavelength, i.e., in "gray" bodies, the optical thickness can simply be given by $\tau_0 = E\, D$, for all wavelengths. However, media of this nature represent, at the most, exceptions to the spectral behavior of the overwhelming majority of real substances.

Experience has shown that the mathematical method outlined in Sect. 3.3.1 yields values that agree weIl with those obtained in experiments, provided that $\tau_0(\Lambda\}$ is at least about 15 for *all* wavelengths, Λ.

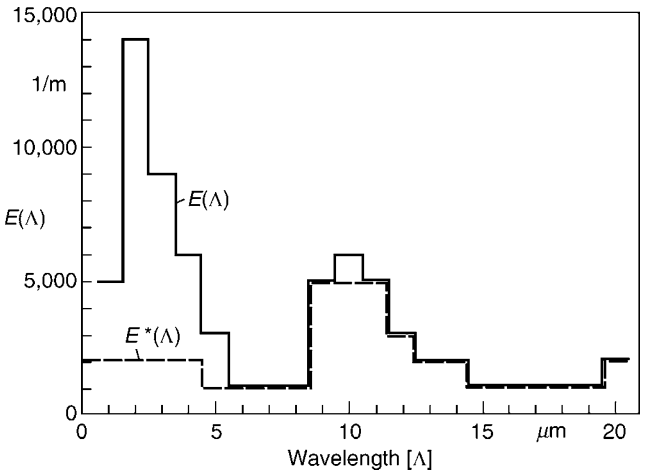
Example 3

The extinction spectrum $E(\Lambda\}$ for glass fiber insulations with a continuous homogeneous structure is presented, in a very rough approximation in the form of a bar diagram in Fig. 15 (specialists are kindly asked to tolerate this for the moment). Calculate how thick the insulations must be if $\tau_0(\Lambda)$ is to be at least 100 at all wavelengths within the $1 \leq \Lambda \leq 20$ µm range.

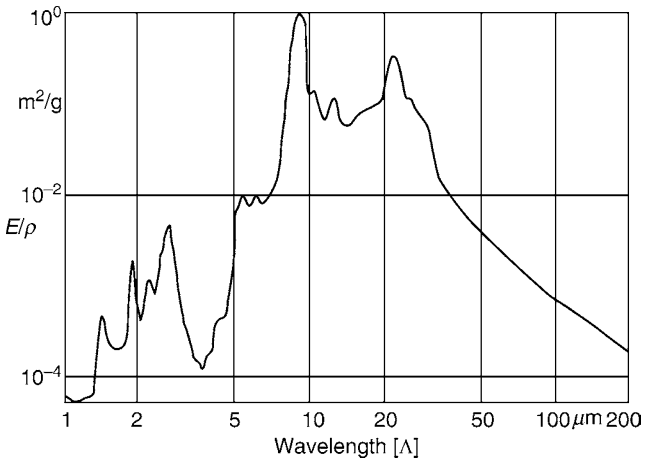
Solution

The lowest values, $E(\Lambda) = 10^3$ m^{-1}, occur in the $6 \leq \Lambda \leq 8$ µm and $15 \leq \Lambda \leq 19$ µm ranges. Since $\tau_0(\Lambda) = E(\Lambda)\, D$, the minimum required thickness of the insulations is $D = \tau_0(\Lambda)/E(\Lambda) = 10^1/10^3$ m^{-1} = 0.1 m. This value obviously is too large for many practical applications. Accordingly, "opacifiers" have to be used to close the radiative "windows" of this material, see below.

In many cases, there will be no empirically determined extinction spectra available on which decisions of this nature can be based. It may be possible to find out whether at least a transmission spectrum for the substance concerned exists in the literature, compare e.g., in Nyquist [25]. Ranges of wavelengths in which the linear extinction coefficient is small or the



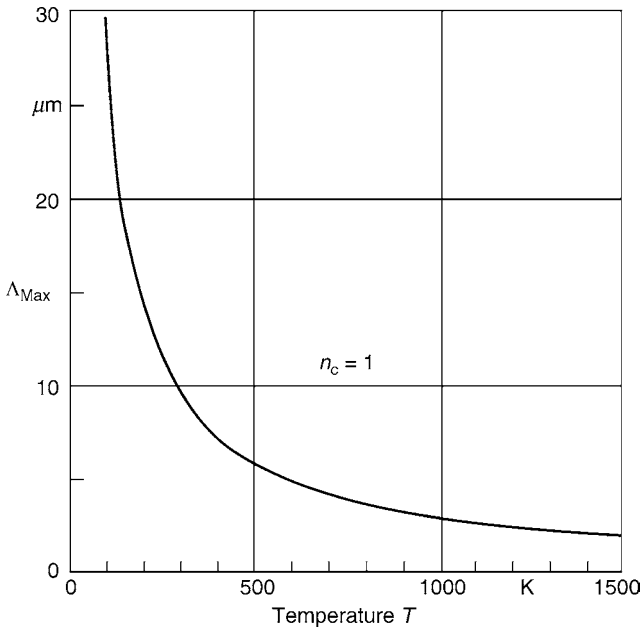
K6. Fig. 15. Extinction spectra (roughly corresponding to spectra of glass fibers) $E(\Lambda)$ and $E^*(\Lambda)$, as functions of wavelength, Λ. Presented in the form of a bar diagram to simplify calculation of minimum required optical thickness in the Examples 3, 5, and 6.



K6. Fig. 16. Linear extinction coefficient per unit density E/ρ, for silica aerogel as a function of wavelength, Λ (the figure is from [26]). ρ denotes density of the insulations.

transmission coefficient is correspondingly large, can be immediately recognized as transmission "windows" in the spectra. Examples are the $6 \leq \Lambda \leq 8$ μm range in the extinction spectrum in Fig. 15 and the $1 \leq \Lambda \leq 5$ and $\Lambda \geq 30$ μm ranges in the extinction spectrum for silica aerogel in Fig. 16 (from [26]; note the logarithmic scales). These windows account for particularly great radiant heat losses, and it must be determined whether components of black body radiation fall within them.

For this purpose, the spectral position, Λ_{max}, at a given temperature, at which the Planck radiation curve culminates, is determined from Fig. 17. If Λ_{max} lies within a window that cannot be closed by an opacifier (cf. Sect. 4, for selection of opacifiers), or by increasing the thickness of the insulations



K6. Fig. 17. Wavelength Λ_{max} corresponding to the maximum on the Planck radiation curve at the given temperature T (Wien's displacement law). Determined for emission in vacuo (refractive index in a vacuum $n_c = 1$).

(see above example), great reserve must be shown in applying the expressions for λ_{Rad} given in Sect. 3.3.1. Conversely, values of λ_{Rad} calculated for nontransparent insulations always agree well with those obtained by measurement.

3.3.1 $\dot{Q}_{Rad}$ for Nontransparent Insulations

The solution of the classical Rosseland radiation diffusion model [28] can be adopted to calculate λ_{Rad} if the optical thickness $\tau_0(\Lambda) \geq 15$ for all the wavelengths that are of importance, i.e.,

$$\lambda_{Rad} = \frac{16 \times \sigma \times n^2}{3 \times E} \times T_{Rad}^3 [\mathrm{W/(m \cdot K)}] \qquad (20)$$

where σ the Stefan-Boltzmann constant, $\sigma = 5.67040 \times 10^{-8}$ $[\mathrm{W/(m^2 \cdot K)}]$, n the real part of the complex (effective) refractive index for the dispersed insulating structure, which is always close to unity if the porosity is high, and T_{Rad} is an (average) radiation temperature that is given by

$$\begin{aligned} T_{Rad}^3 &= \frac{T_1^4 - T_2^4}{4 \times (T_1 - T_2)} \\ &= \left(T_1^2 + T_2^2\right) \times (T_1 + T_2)/4 \\ &= \frac{T^{*3}}{4} \left[\mathrm{K^3}\right]. \end{aligned} \qquad (21)$$

where T_1 and T_2 are again the wall temperatures. Corresponding terms for the average radiation temperature found in the literature are T_{Rad}^3 or T^{*3}.

If the linear extinction coefficient, E, is known to be within sufficient accuracy, Eq. (20) together with Eq. (21) yields reliable results in the $120 \leq T_1 \leq 700$ K and $1 \leq T_2 \leq 300$ K ranges.

In a gray body, E is simply a constant that is independent of radiation temperature (but there may be materials properties of the corresponding material other than extinction coefficient of radiation that depend on temperature). If the medium is not a gray body radiator, the requisite value of $E(\Lambda)$ is $E_R(T)$, which is the average over the range of wavelengths concerned and is thus dependent on radiation temperature. Values calculated for this average, referred to as the Rosseland average, per unit density ρ, for some insulating materials have been plotted against the particle diameter d and the radiation temperature T in Fig. 18a–d.

In Fig. 18a–d, the asterisk in the Rosseland mean per unit density, E_R^*/ρ, indicates that allowance has been made for anisotropic scattering (cf. Example 5). The values plotted for E_R^*/ρ remain valid without major corrections (up to a maximum of 20%) within the $\Pi \geq 0.8$ porosity range ([26]). However, as compaction increases, "dependent scattering" and thus a reduction in E_R^*/ρ become evident.

The values for $E_R^*(T)$ are read off from these diagrams against $T = T_{Rad}$.

Example 4

A thermal insulations of continuous structure consists of glass fibers of $d = 4$ µm diameter, and the density is $\rho = 200$ kg/m^3. The temperatures at the walls are $T_1 = 485.6$ K and $T_2 = 300$ K. Determine T_{Rad}, and thus $E_R^*(T_{Rad})$ from Fig. 18a, and consequently calculate $\lambda_{Rad}\,(T_{Rad})$.

Solution

The first step is to determine T_{Rad} from Eq. (21). Thus T_{Rad}, $= [(485.6^2 + 300^2)\,(485.6 + 300)/4]^{1/3} = 400.0$ K.

$E_R^*(T_{Rad}) \approx 1.6 \times 10^4$ m^{-1} can then be read off against $d = 4$µm and $\rho = 200$ kg/m^3 in Fig. 18a.

If the extinction spectrum is fairly smooth, the Rosseland average does not depend very much on radiation temperature.

When the desired average linear extinction coefficient cannot be found from Fig. 18a–d, it may be obtained as follows from any spectral values of $E^*(\Lambda)$ that might be available ([34], p. 474):

$$\frac{1}{E_R^*(T)} = \frac{\sum_{\Delta\Lambda} \frac{1}{E^*(\Lambda)} \times f_\Lambda(T) \times \Delta\Lambda}{\sum_{\Delta\Lambda} f_\Lambda(T) \times \Delta\Lambda}\,[\mathrm{m}] \qquad (22)$$

This entails adding all the values in the wavelength intervals $\Delta\Lambda$ in which known figures for the spectral linear extinction coefficients are available, e.g., from spectroscopic measurements. The weighting functions, $f_\Lambda(T)$, are given by the same reference as

$$f_\Lambda(T) = \frac{\pi \times C_4 \times C_5}{2 \times \Lambda^6} \times \frac{1}{\sigma \times T^5} \times \frac{\exp\left(\frac{C_5}{\Lambda \times T}\right)}{\left[\exp\left(\frac{C_5}{\Lambda \times T}\right) - 1\right]^2}\,[1/\mathrm{m}] \quad (23)$$

where $C_4 = 5.9544 \times 10^{-17}$ W m^2 and $C_5 = 1.4388 \times 10^{-2}$ m K.

The relationship between the weighting factor $f_\Lambda(T)$ and the wavelength, Λ, at various temperatures is shown in Fig. 19.

Example 5

By means of Eqs. (22) and (23) or Fig. 19, determine $E_R(T_{Rad})$ and $\lambda_{Rad}(T_{Rad})$, one after the other, in the $1 \leq \Lambda \leq 20$ µm range of wavelengths. The wall temperatures are the same as in Example 4, and the extinction spectrum is that denoted by $E(\Lambda)$ in Fig. 15. Note: $E(\Lambda)$ {*without* asterisk} in this example implies the *erroneous* assumption of isotropic scattering by glass fibers.

Solution

$T_{Rad} = 400.0$ K and Eq. (22) give

$$\frac{1}{E_R(T_{Rad})}$$

$$= \frac{\frac{1}{5\cdot10^3} \cdot 5.54 \cdot 10^{-4} + \frac{1}{1.4\cdot10^4} \cdot 5.6 \cdot 10^2 + \cdots \frac{1}{2\cdot10^3} 8.611 \cdot 10^3}{5.54 \cdot 10^{-4} + 5.6 \cdot 10^2 + \cdots + 8.611 \cdot 10^3},$$

from which $E_R(T_{Rad}) = 1.679\ 10^3$ [1/m]

Using this value, and with $n^2 = 1$ (usually fulfilled in dispersed media) we have

$$\lambda_{Rad} = \frac{16 \cdot 5.669 \cdot 10^{-8}}{3 \cdot 1.679 \cdot 10^3} \cdot 400^3 \left[\frac{\mathrm{W} \cdot \mathrm{K}^3}{\mathrm{m}^2 \cdot \mathrm{K}^4 \cdot 1/\mathrm{m}} = [\mathrm{W/(m \cdot K)}]\right]$$
$$= 0.0115\,[\mathrm{W/(m \cdot K)}].$$

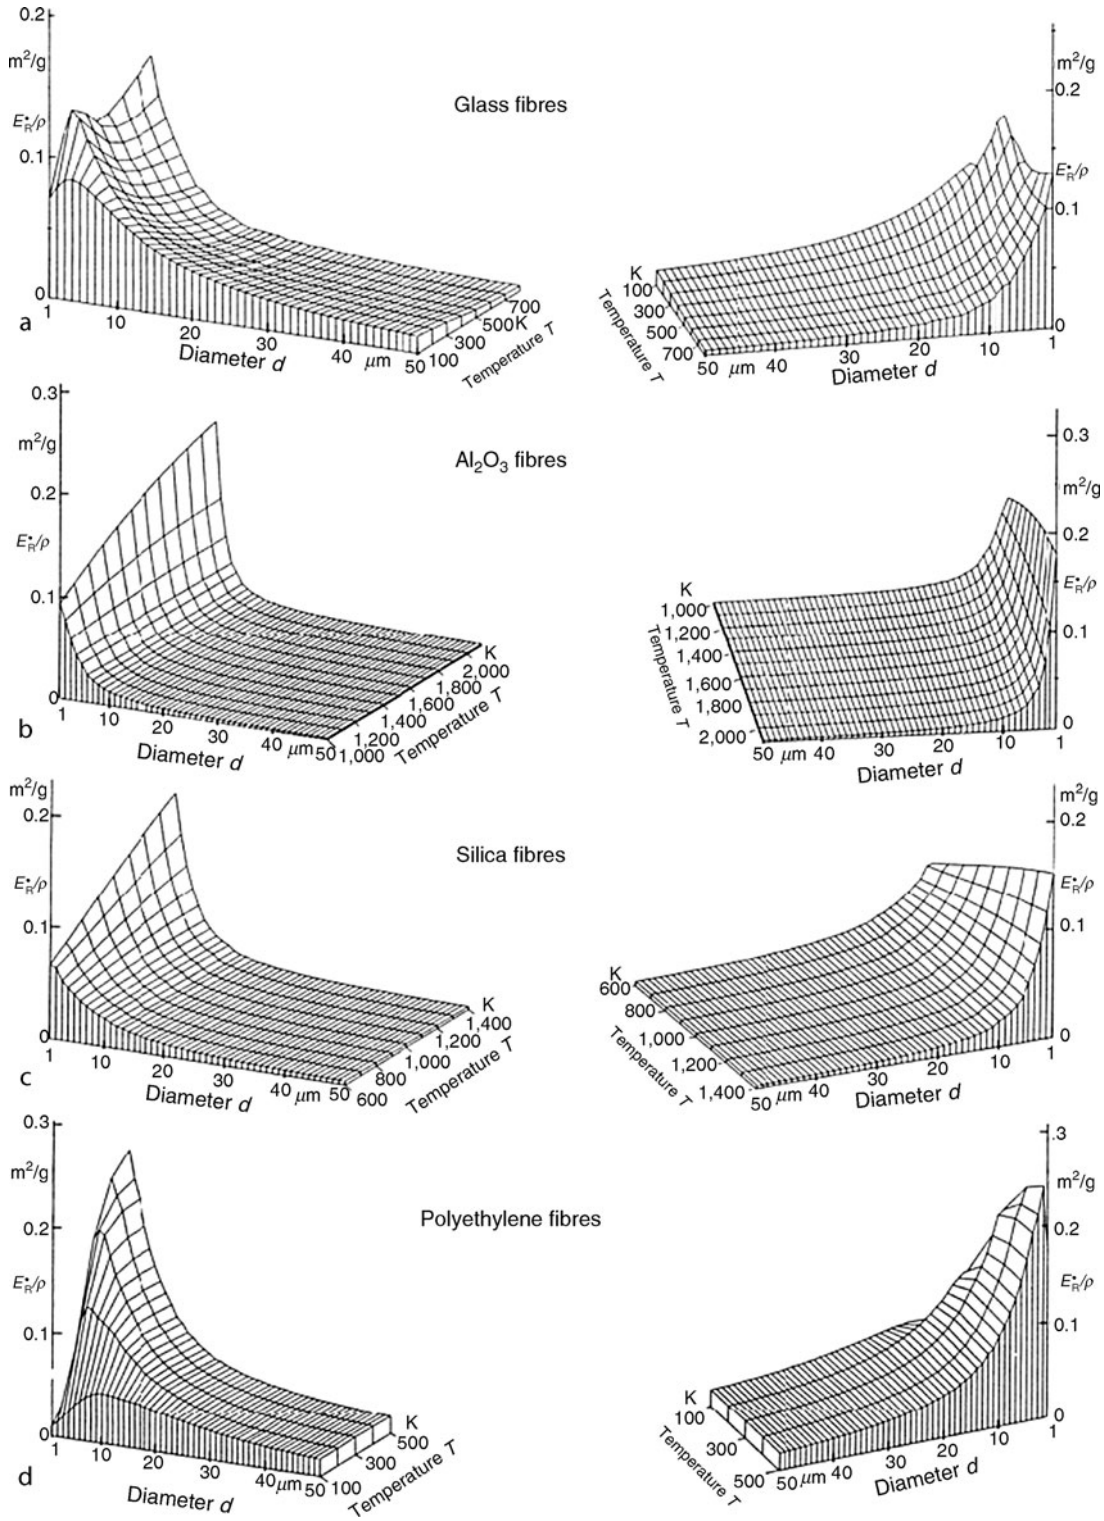
If neither calculated values of $E_R{}^*(T)$ nor $E(\Lambda)$ or $E^*(\Lambda)$ spectra are available, the relevant linear extinction coefficients E^*/ρ listed in Table 6 can be taken as approximations to calculate E in Eq. (20). The coefficients in Table 6 have been compiled from calorimetric or spectroscopic measurements or have been calculated from the Mie theory, which means they can be obtained from three different, independent methods.

Although isotropic scattering has been preferentially treated in older literature, it is the exception rather than the rule and applies only approximately in special cases, e.g., very small dielectric particles. A general rule is that anisotropic forward scattering increases with the particle size and leads to the reduction of $E(\Lambda)$ and thus E_R to effective values $E^*(\Lambda)$ and $E_R{}^*(T)$ respectively (as related to *single* scattering, this is *not* identical with dependent scattering, a phenomenon that goes back to the presence of closely located, neighboring particles). Likewise, backward scattering causes an increase in $E(\Lambda)$ and E_R. Forward scattering is particularly pronounced for glass fibers in the $1 \leq \Lambda \leq 6$ µm range of wavelengths {cf. $E(\Lambda)$ and $E^*(\Lambda)$ in Fig. 15). The effect of scattering on the linear extinction coefficient depends on the orientation of the fibers relative to the direction of the temperature gradient within the insulations (cf. caption to Fig. 18a–d). As opposed to this, scattering by very finely divided primary silica particles is more likely to be isotropic. In this case, therefore, $E^*(\Lambda)$ is equal to the $E(\Lambda)$ in Beer's law, and the same applies to the Rosseland average.

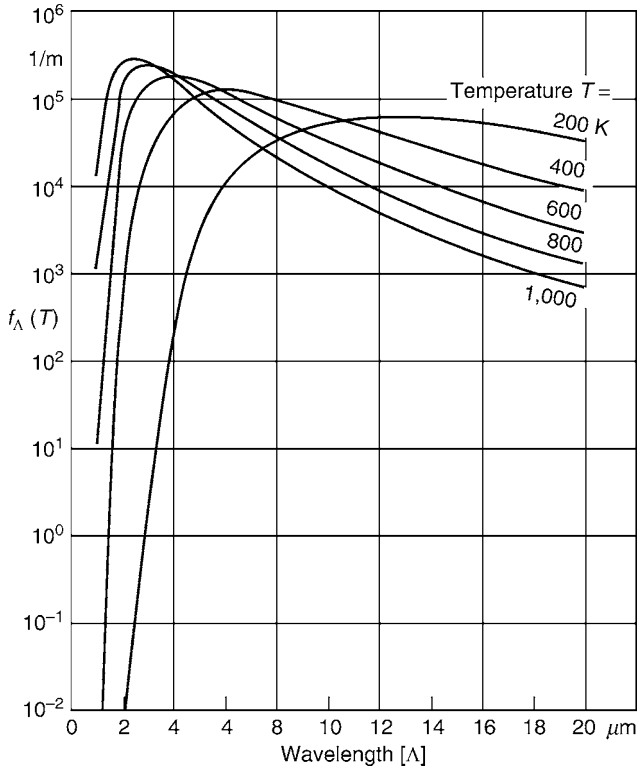
The potential effect of anisotropic scattering on the calculated value for λ_{Rad} is evident from the following example.

Example 6

In analogy to Example 5, calculate $E_{Rad}^*(T_{Rad})$ from the $E^*(A)$ values (with asterisk) in Fig. 15 and thus determine the correct value for $\lambda_{Rad}(T_{Rad})$.



K6. Fig. 18. (**a**–**d**) Wavelength-averaged, effective linear extinction coefficient per unit density, E_R^*/ρ, for fibrous insulations as a function of the particle diameter, d, and the radiation temperature, T_{Rad}; E_R^*/ρ is calculated by the Mie theory using complex refractive indices. Diagrams (**a**) Glass fibers, (**b**) Ceramic fibers, (**c**) Silica fiber, (**d**) Polyethylene fibers. The calculations apply to vertical (non-polarized) radiation incidence, i.e., the axis of the fibers is at right angles to the direction of incident radiation. This condition can be roughly met for fiber papers (cf. Fig. 12b). If instead the insulations consists of glass or rock wool with the fiber axes in a random arrangement, the figures obtained for E_R^*/ρ must be corrected by multiplying with a factor ϕ, which has a numerical value of $\phi = 2/3$ for pure scattering. If the fibers were strongly absorbent, the numerical value would be about $\phi = 4/5$ ([26]) (ϕ also depends on fiber diameter and temperature [27]. The experimental values for the refractive indices originate from the literature: (**a**) [29], (**b**) [30] and [31], (**c**) [32], and (**d**) [33].



K6. Fig. 19. Weighting function $f_\Lambda(T)$ defined by Eq. (23) as a function of wavelength, Λ, with temperature T as parameter.

Solution

$$\frac{1}{E_R^*(T_{Rad})} = \frac{\frac{1}{2\cdot10^3}\cdot 5.54\cdot10^{-4} + \frac{1}{2\cdot10^3}\cdot 5.6\cdot10^{2} + \cdots \frac{1}{2\cdot10^3}\,8.611\cdot10^{3}}{5.54\cdot10^{-4} + 5.6\cdot10^{2} + \cdots + 8.611\cdot10^{3}}$$

Inserting this value in Eq. (20) with $n^2 = 1$ gives

$$\lambda_{Rad} = \frac{16\cdot5.669\cdot10^{-8}}{3\cdot1.413\cdot10^{3}}\cdot 400^3\left[\frac{W\cdot K^3}{m^2\cdot K^4\cdot 1/m} = [W/(m\cdot K)]\right]$$
$$= 0.0137\,[W/(m\cdot K)].$$

Thus the allowance for the importance of forward scattering caused by glass fibers has increased the radiation conductivity, λ_{Rad}, to a value about 20% higher than that obtained in Example 5.

Many of the linear extinction coefficients cited in the literature have been derived on the assumption of isotropic scattering. Hence, in order to avoid serious errors, they must be converted into the corresponding effective values before they are inserted in Eq. (20). Details of this conversion is the subject of specialized publications (e.g., [26]) and would be impossible without a knowledge of the complex refractive indices. The corrections necessary for the individual wavelengths may be as much as 90% of $E(\Lambda)$. However, since an average is taken in the Rosseland mean over a range of wavelengths, the corresponding error in E_R is reduced, and the deviation from E_R^* is thus usually 10–20%.

$\dot{Q}_{Rad}$ using the Rosseland diffusion mean is calculated using the value of λ_{Rad} in the usual rule for heat conduction, compare Eq. (5) (provided it is a nontransparent insulation).

3.3.2 $\dot{Q}_{Rad}$ for Insulations with IR-Transparent Zones

Insulation that is transparent in the visible and, partly, in the infrared spectrum, includes silica aerogels and highly dispersed Silicas. Aerogels are eminently suitable for solar energy systems ([35]) but are responsible for heat losses owing to their IR-transparency. Transparent insulations are also becoming integrated parts of façades of buildings, with the intention to contribute to development of "zero energy houses."

If no extinction spectra $E^*(\Lambda)$ but only average values of E^*/ρ (cf. Table 6) are available, the radiation losses, $\dot{Q}_{Rad}$, can be approximately determined in the same way as that for a homogeneous bed of transparent gray body radiators with small optical thicknesses, $\tau_0^* = E^* D$, between infinitely extended, plane parallel walls ([34], p. 480), i.e.,

$$\dot{q}_{Rad} = \frac{\dot{Q}_{Rad}}{F} = \frac{\sigma\times\left(T_1^4 - T_2^4\right)}{\frac{2}{\varepsilon_W} - 1 + \frac{3}{4}\times\tau_0^*}\,[W/m^2] \qquad (24)$$

where T_1 and T_2 are absolute temperatures in Kelvin. Methods that involve a more accurate description of radiation propagation in aerogels have been suggested by Caps [26].

If IR-transparency is pronounced, i.e., if $\tau_0(\Lambda) \ll 1$, heat transport by radiation cannot be described in terms of thermal conduction. In this case, figures for the total thermal conductivity, sometimes calculated from numerical results for the total heat flux or from its measurement, are not authentic, because they are not constants for the material concerned but depend on the thickness, D, of the layer and/or on the emissivity ε of the wall (compare Appendix A1), i.e., on the measuring instruments. A conductivity determined from Eq. (24) accordingly is a "pseudo"-radiative conductivity, λ'_{Rad}, and if it is summed up with other conductivity components to a total thermal conductivity, e.g., $\lambda_{Total} = \lambda_{Gas} + \lambda_{SC} + \lambda_{Rad}$, the total thermal conductivity, λ_{Total}, is a pseudo-conductivity, λ'_{Total}, too.

3.4 Total Heat Losses in Nontransparent Continuous Superinsulations

The total thermal conductivity, λ_{Total}, in nontransparent insulations is given by

$$\lambda_{Total} = \lambda_{Gas} + \lambda_{SC} + \lambda_{Rad} \qquad (25)$$

The loss components are obtained as follows: Eq. (2a) or (2b) using Eqs. (1) and (16a) or (16b) to determine Kn; Eq. (17) or (18) for λ_{SC}; and Eq. (20) for λ_{Rad}. As was stated in the remarks on Eq. (10), the likelihood of free convection losses can be excluded. Likewise, the restrictions on "additive approximation" appended to these remarks must be correspondingly applied to the thermal conductivity components. In this case, the lower the residual gas pressure and the greater the linear extinction coefficient, the better the approximation. If very accurate analyses are required, the principle of the conservation of energy (divergence of $\dot{q}_{Total} = 0$) must be applied to determine the temperature profile and the temperature-dependent thermal conductivity components.

If the components λ_{Gas} and λ_{SC} are combined to form a constant, a, that is roughly independent of temperature, Eq. (20) is extended to

$$\lambda_{Total} = a + \frac{16 \times \sigma \times n^2}{3 \times E^*} \times T_{Rad}^3 = a + b \times T_{Rad}^3 \qquad (26)$$

in which also b is a constant, and T_{Rad}^3 is given by Eq. (21). The plots of the measured values of λ_{Total} against T_{Rad}^3 are close approximations to straight lines (Fig. 20a–d). The sum of λ_{Gas} and λ_{SC} can be read off against the intersect at $T_{Rad}^3 = 0$, and the linear extinction coefficient for an average temperature and thickness can be obtained from the slope. Calorimetric values λ_{SC} and E^*/ρ listed in Tables 5 and 6, respectively, were determined in this way.

The remarkable agreement between measured λ_{Total} and the linear equation $\lambda_{Total} = a + b\ T_{Rad}^3$, Eq. (26), or using T^{*3} instead of using T_{Rad}^3, Eq. (21), is found not only with evacuated superinsulations (Fig. 20a–d) but also with non-evacuated, microporous powder insulations as demonstrated in Fig. 21. Like the insulations of Fig. 20c and d the non-evacuated insulations in Fig. 21 are also load-bearing ("load-bearing" means the compression of these insulations, under a mechanical pressure of 1 bar, i.e., during evacuation, could be kept below 10% of the original thickness). These insulations provide a thermal conductivity below that of motionless air, even at elevated temperatures. Following the classification made in Fig. 1, these insulations, too, can be considered "superinsulations."

The same applies to organic monolithic aerogels, or to aerogels doped with opacifiers that render these materials non-transparent. They exhibit very small thermal conductivity also under ambient pressure ([38]), with values even below the data reported in Fig. 21 (the samples of Fig. 21 were pressed to load-bearing boards, under high pressures, however).

3.5 Superinsulated Panels

A superinsulated panel consists of a pressure-resistant core (a board) that is prepared from microporous materials (powders, fibers), and vacuum-tight envelopes that encapsulate the core to safely protect its vacuum. The envelopes apply thin polymer foils, for medium to low temperature insulations, or stainless steel foils at elevated temperatures. Superinsulating properties of the panels rely on very small thermal conductivity of the evacuated core material. Heat leakage through the core material can be estimated following the relations given in the foregoing sections.

Thickness of the microporous core and of polymer foils is in the order of 10 mm or 100 µm, respectively. Accordingly, superinsulated panels are composed of materials not only of strongly differing thermal transport and mechanical properties but also of very strongly differing dimensions of its components. As a consequence, prediction of heat flow through, and temperature profiles in the panel and on its surfaces, is difficult. This applies in particular to analysis made by numerical methods (standard finite element codes do not like these conditions), and also to analysis of the mechanical behavior of the thin foils when they are exposed to mechanical load, as is the case during evacuation, or if they are wound around tubes, or under large temperature gradients.

Flat panel geometry presently dominates, but panels may be applied also for superinsulations of pipings and cylindrical vessels.

Thermal leakage through joints between neighboring panels may seriously degrade the thermal resistance of panel insulations, in particular if the foils are metallic or are metallized to provide improved, vacuum-tight barriers. Further, local temperature variations in the envelope materials can be responsible for mechanical load from differential thermo-contraction or expansion.

3.5.1 Flat Panel Geometry

Temperature of the envelopes is critical with regard to materials properties (vacuum thightness) under thermal load and lifetime of the insulations. Temperature distributions in envelope materials in indented panels can approximately be determined as suggested by Caps [48]): Assume a flat plate panel insulation, with two neighboring one-layer panels of thickness, D, that overlap over a distance (indentation length), L_i, (compare Fig. 22a; the case "blunt joins" is approximated by $L_i \to 0$).

To obtain the temperature profile of the foils in the horizontal section, path s_2, of the indentation, $-L_i/2 \le x \le L_i/2$, combine the two parallel foils into one. Heat flux components, $\dot{q}_1(x)$ and $\dot{q}_2(x)$, perpendicular through the surfaces of panels 1 and 2, serve as source and sink terms, respectively, for the divergence of the horizontal, local heat flux, $\dot{q}_{2Foils}(x)$, in the two foils. With constant (temperature-independent and homogeneous) thermal resistances, $R_{1,2}$ [K m^2/W], to the components $\dot{q}_1(x)$ and $\dot{q}_2(x)$ through the core material, we have

$$\dot{q}_1(x) = (1/R_1)[T_1 - T(x)]\left[\mathrm{W/m^2}\right] \qquad (27a)$$

$$\dot{q}_2(x) = (1/R_2)[T(x) - T_2]\left[\mathrm{W/m^2}\right] \qquad (27b)$$

Assuming the panels have a unit length, $L_z = 1$ m, in z-direction, a cross section of the foils of $A = d_{2Foil}\ x\ L_z$, the heat flux, $\dot{q}_{2Foils}(x)$, in the overlap region reads

$$\dot{q}_{2Foils}(x) = -\lambda_{Foil}\, d_{2Foils}\, \mathrm{d}T(x)/\mathrm{d}x\left[\mathrm{W/m^3}\right] \qquad (28)$$

using the solid thermal conductivity, λ_{Foil}, of the foils. Conservation of energy requires

$$[\dot{q}_2(x) - \dot{q}_1(x)]/d_{2Foils} = \mathrm{d}/\mathrm{d}x[\dot{q}_{2Foils}(x)]\left[\mathrm{W/m^3}\right] \qquad (29)$$

This yields a second order, inhomogeneous differential equation defining the temperature profile, T(x), in the foils by

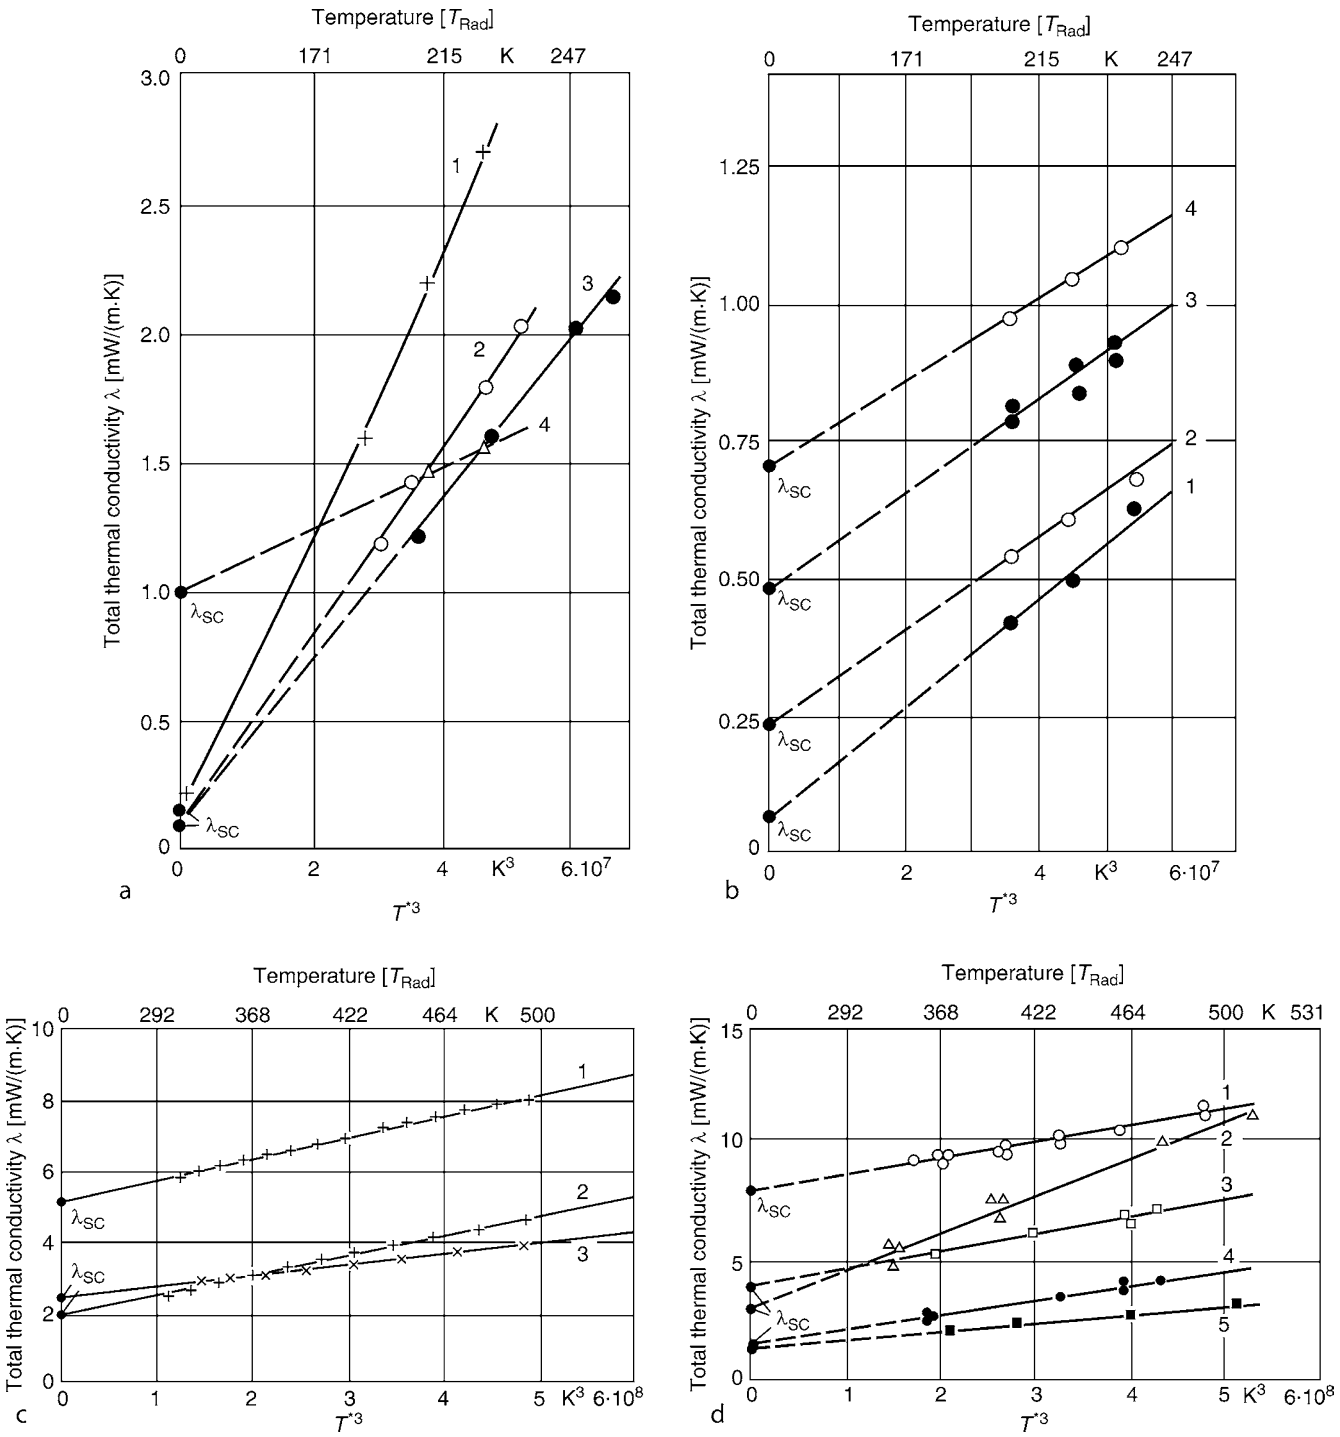
$$\mathrm{d}^2/\mathrm{d}x^2[T(x)] - K_1 T(x) + K_2 = 0 \qquad (30)$$

using the constants $K_1 = \lambda_{Foil}\, d_{2Foils}\, R_m$ and $K_2 = K_1\ T_m$, with $R_m = R_1R_2/(R_1 + R_2)$ and $T_m = (T_1R_2 + T_2R_1)/(R_1 + R_2)$. Boundary conditions are

$$T(x = +L_i/2) = T_1 \qquad (31a)$$

$$T(x = -L_i/2) = T_2 \qquad (31b)$$

Two limiting cases, $\lambda_{Foil} \to \infty$ and $\lambda_{Foil} \to 0$, respectively, can be considered: In the first case, Eq. (30) reduces to



K6. Fig. 20. (**a**) Total thermal conductivity, λ_{Total}, of pure silica aerogel in a vacuum at cryogenic temperatures and various densities, ρ; the figure is from [1]. Curves 1–4: ρ = 70, 105, 125, and 457 kg/m^3. [b] [43]
[c] [44]
[d] [45]
[e] [46]
[f] [36]. The E/ρ values cited lie close to the E^*/ρ values, because absorption preponderates in glass fibers doped with Fe_3O_4
[g] [47]
[h] [1], p. 77; these E^*/ρ values are valid only for low densities and cryogenic temperatures
The authors assumed isotropic scattering in Cases [d] to [f]. In addition, the calorimetric measurements in Cases [d] and [e] were not performed in a vacuum Consequently, these E^*/ρ can serve solely as estimates
All opacifier addition rates are expressed as percentages in terms of the mass fraction

$$d^2/dx^2[T(x)] = 0 \tag{32a}$$

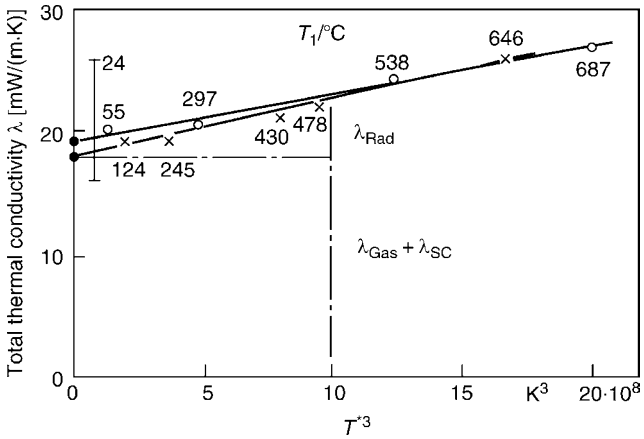
which indicates a linear temperature profile in the foils, $T(x) = K_3\, x + K_4$, with constants K_3 and K_4.

In the second case, the variation $d^2/dx^2\ [T(x)]$ can be neglected in the interval $-L_i/2 < x < L_i/2$, at positions, x, sufficiently distant from the boundaries. This yields

$$K_1[-T(x) + T_m] = 0 \tag{32b}$$

with the solution $T(x) = T_m$, the constant mean foil temperature at these positions.

In-between the two limiting cases, $T(x)$ may be curved, in dependence of conductivity, λ_{Foil}, and thickness, d, of the foils. While integration of Eq. (30) is straightforward, determination



K6. Fig. 21. Total thermal conductivity, λ_{Total}, of two nonevacuated, microporous powder insulations (symbols and linear approximations) and, for comparison, of a sample of polyurethane foam expanded with fluoro-tri-chloro-rmethane (vertical bar), plotted vs. $T^{*3} = 4T_{Rad}{}^3$ [37]. Data for the powders (crosses and open circles) are from Micropore Europe N. V., Stint Niklaas, Belgium, for a density of 254 kg/m^3, and from Wacker Chemie GmbH, Kempten, Germany, for a density of 344 kg/m^3, respectively. Data were reported by Forschungsinstitut für Wärmeschutz e. V., München, Germany. Numbers attached to the data points and to the bar indicate temperature T_1 (in deg C) of the hot wall of the measuring installation. Full circles at $T^{*3} = 0$ indicate $\lambda_{Total} = \lambda_{Gas} + \lambda_{SC}$ obtained from a least squares fit to the data. The length of the vertical bar indicates ageing of the foam material over a 5 year-period [38].

of the integration constants from the boundary conditions is laborious; preference should be given to numerical solutions that also would allow temperature-dependent material properties, or applications of solvers like *Mathematica*.

The approach made in Eq. (30) has some drawbacks:

(a) Thermal conductivity of all solid components of the panels (foils and core material) is assumed constant (independent of temperature) and homogeneous
(b) Boundary conditions Eq. (31a, b) introduce a thermal short-circuit which leads to an overestimate of $\dot{Q}_{Total}$ (in reality, thin polymer foils constitute thermal resistance against heat flow parallel to their surface)
(c) The influence of surface temperature that in turn depends on convection or radiation on the upper and/or lower panel surfaces cannot be taken into account in his scheme because surface temperatures are given as a boundary conditions; contrary to this, thermal resistance networks, or finite element simulations (below) yield also surface temperatures (Fig. 23b and Figs. 26b–31b), because convection is modelled and heat flow, instead of temperature, is given as boundary condition
(d) Joints and gaps (and their filling, to suppress convection) between neighboring panels are neglected; taking joints or gaps into account, or extending the method to more than a single layer panel insulation, would enormously complicate the solution.

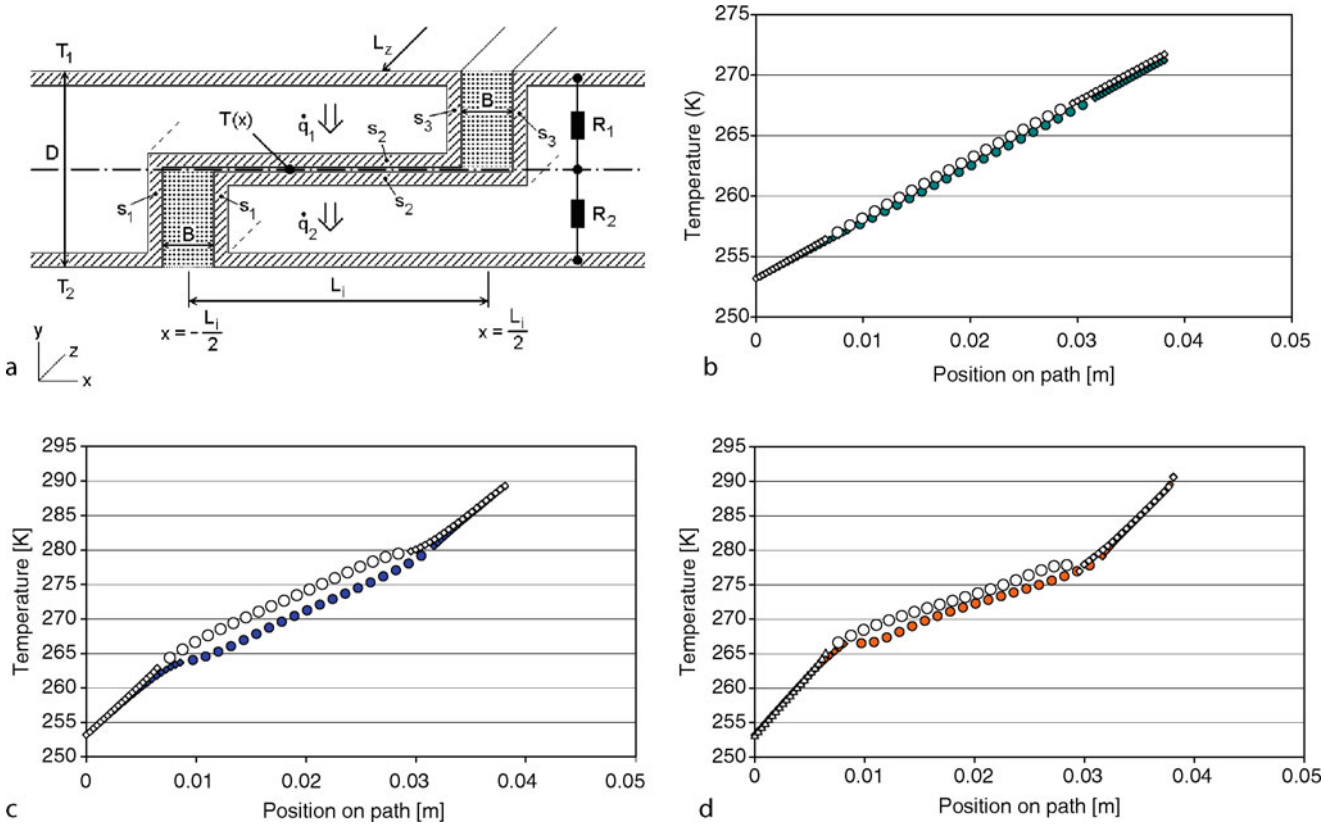
More suitable methods comprise thermal resistance networks (compare Sect. 2.5) and finite element calculations, see below. With reasonable fine divisions of the solid components of panels and joints, thermal resistance networks can take into account temperature dependency of conductivity or inhomogeneous materials properties. The situation for the one-layer panel insulation is comparatively simple, but this method becomes laborious with two or three layers, in particular, if the scheme would also be extended to 3D. In this case, at the latest, the advantage of finite element programs, in comparison to both Eq. (30) and resistance networks, with "top to bottom"-modeling tools and solution strategies becomes obvious.

However, the prediction for the temperature profile on the foils for the first limiting case, $\lambda_{Foil} \to \infty$, of Eq. (30) is nicely confirmed by 2D finite element calculations (Fig. 22b) using Al-foils of 50 µm thickness. On the other hand, the curves in Fig. 22c, d only gradually approach the second limiting case, $\lambda_{Foil} \to 0$, using PE-foils (c) or assuming, as a hypothetical case (d), a foil material with a conductivity identical to the conductivity of the core material (in Fig. 22b–d, identical foil thickness of 50 µm has been assumed to facilitate comparison of the results). Note (1): the case (d), "no foils," is not identical to the case "no joints," see, below, because microporous filling of the gap and of the two joints still remains, (2): the *s-coordinates* (the total path length, abscissa in Fig. 22b–d) of the upper foil (belonging to the left panel) are not identical to the s-coordinates of the lower foil (the right panel), compare Fig. 22a; at the same *x-coordinates*, foil temperature of the upper foil (open symbols in Fig. 22b–d), is always larger than foil temperature of the lower foil, of course. Boundary temperatures are 293.2 and 253.3 K, with convective boundary conditions on the upper surface and with a global temperature gradient of about 40 K over 15 mm panel thickness.

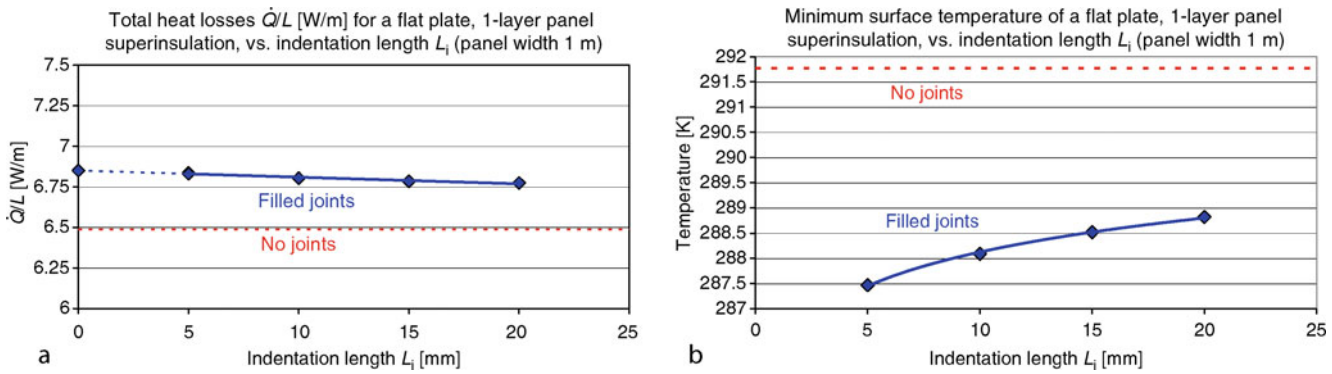
In summary, calculation of temperature profiles in indented panel insulations may be based on Eq. (30) if the conductivity of the foils is large, while for low conductivity envelope materials, it should be based on finite difference or finite element calculations. Once the temperature profiles are determined, they can be used for calculations of thermal contraction or expansion to yield stress in the foils (v. Mises average stress, to be compared with experimental values of maximum allowable stress at the corresponding temperatures). With regard to thermally induced stress, note from Fig. 22b–d that the temperature gradients in path sections s_1 and s_3 increase if the conductivity of the foils decreases.

Total heat loss, $\dot{Q}_{Total,}$ from 2D finite element calculation for indented, flat plate, one layer panel insulation, in dependence of indentation length, L_i, is shown in Fig. 23a using standard polymer foils with total thickness in the order of 100 µm. Such foils comprise one to three aluminized polymer foils as thin barriers against penetration of N_2, O_2, Ne, and H_2O-vapor, adhesive layers and a 50 µm polymer sealing layer that serves for welding the envelope at the joints to a vacuum-tight compound.

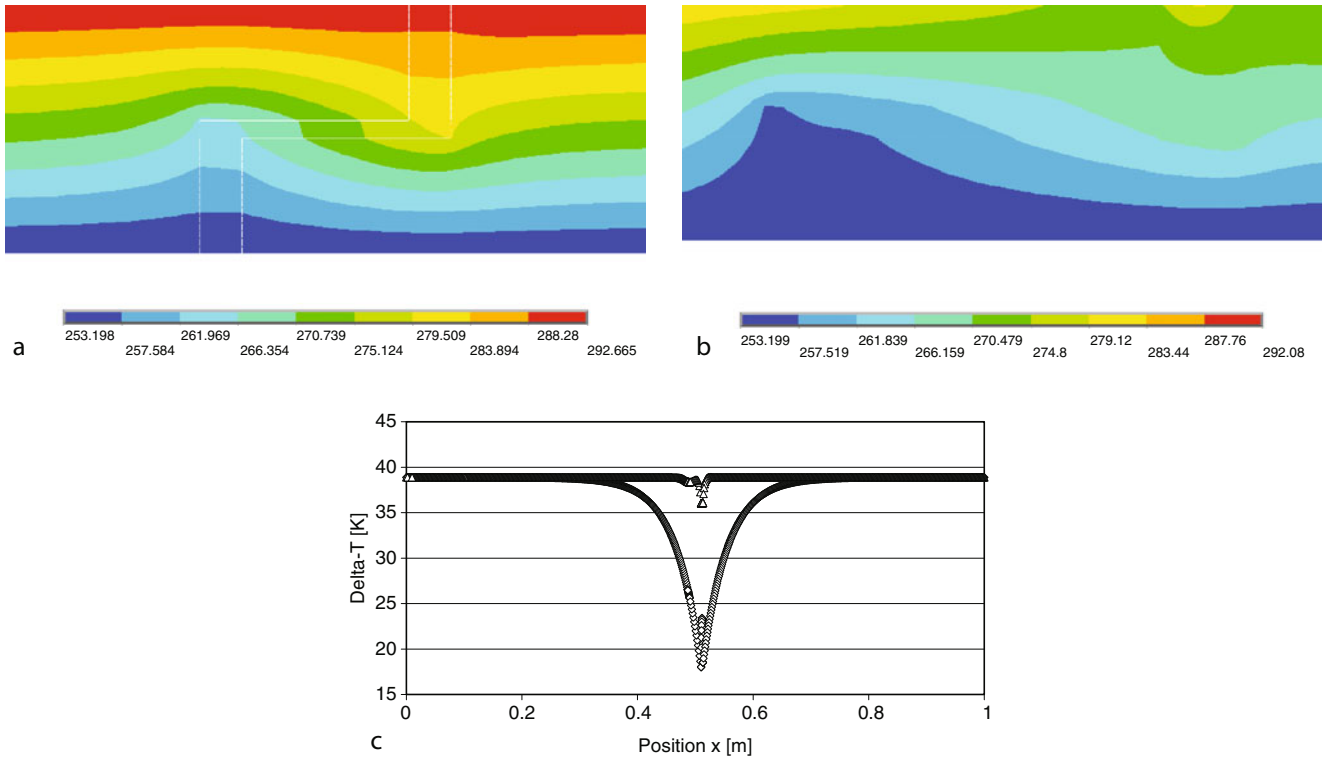
Figure 23a shows that $\dot{Q}_{Total}$ depends only weakly on indentation length. From the same analysis, in dependence of joint width, B, of the indented joints, Fig. 23b shows minimum temperature on the upper surface under convection if $T_1 = T_{ambient}$ and T_2 are 293 and 253 K, respectively (as before, the global temperature gradient is 40 K over a thickness of 15 mm. The insulations should be thick enough to avoid surface temperatures below dew point.



K6. Fig. 22. (**a**–**d**) Heat transfer in a flat plate, single layer panel insulation with indented joints; (**a**) Heat flow paths (schematic, rounded panel edges neglected in the diagram) in the overlap region, with shaded and dotted areas denoting envelope or filling material, respectively; the diagram (**a**) serves for finite element analysis in (**b**), (**c**), and (**d**), in Figs. 23a, b and 24a–c) and for application of Eqs. (27a, b–32a, b). Total path length, *s*, used for presentation of the finite element calculation results, runs from the lower vertical (s_1) over the horizontal (s_2) to the upper vertical sections (s_3) of the foils; in-between is a gap filled with a microporous filling, like in the joint sections; (**b**) and (**c**): Temperature of Al- or polyethylene foils, respectively; (**d**): Temperature if hypothetically assuming thermal conductivity of the foil would be identical to conductivity of the core material (evacuated fiberglass board); foil thickness in (**b**), (**c**), and (**d**) is identical 50 μm, to facilitate comparison with respect to the strongly different thermal transport properties of these materials. Foil temperature is plotted versus total path length, *s*, with solid symbols for the foils of the left, open symbols for the foils of the right panel; compare (**a**) for definition of s: diamonds denote sections s_1 and s_3, circles denote section s_2 of the total *s*. Note that the *total path length, s* (the abscissa in Fig. 22b–d), is not identical for the upper (left panel) and the lower foils (right panel), compare (**a**). For *identical x-coordinates*, foil temperature of the upper foil is always larger than temperature of the lower foil.



K6. Fig. 23. (**a**, **b**) Total heat losses, $\dot{Q}_{Total}$, and minimum surface temperatures, using standard polymer foils (in the order of 100 μm total thickness); (**a**) and (**b**) are plotted versus indentation length, L_i. Panel thickness is 15 mm, temperatures T_1 (293.2 K, of ambient air, for convection boundary condition on the upper insulation surface) and T_2 (253.2 K of bottom, temperature boundary condition), respectively.



K6. Fig. 24. (**a**–**c**) Temperatures profiles, from 2D finite element calculations in the overlap region of an indented, single layer panel insulation; (**a**) and (**b**): Overall temperature profiles in the cross section of both panels using polyethylene (**a**) or Al-foils **(b)**, with identical foil thickness of 50 μm (again to facilitate comparison of the results); the dashed lines in (**a**) schematically identify positions of the overlap region; (**c**) temperature difference, ΔT, between upper and lower panel surfaces, versus x-coordinate of the insulation, when using polyethylene or Al-foils, respectively.

In all finite element calculations of this Subchapter, a thermal conductivity, λ, of the core material of 2.0, 2.25, 2.75, and 3.5 [mW/(m · K)], at temperatures 73, 173, 273, and 373 [K], respectively, has been applied. This conductivity may be considered representative for evacuated, load-bearing glassfiber boards. Results for the contributions to total heat flow by the *joints*, see below, does not depend much on the particular choice for the *core* materials conductivity.

Figure 24a, b show temperature profiles in the cross section of the indented panel insulations of Fig. 22a–c. Without a joint, the temperature profiles would be stratified homogenously over the total width of the panel. But the joint strongly disturbes stratified temperature distribution. This is also seen from Fig. 24c that reports temperature difference, ΔT, between the upper and lower surface. Note the strong variation of ΔT in the overlap region. For this reason, assumption of a homogeneous temperature difference over the total panel surfaces is approximately fulfilled only if the envelope material is of low thermal conductivity.

Using in the following standard polymer foils (thickness in the order of 100 μm), under variation of the width, **B,** of joints filled with a microporous material, and of the indentation length, $\mathbf{L_i}$ heat losses of panel insulations of the indented (and, later, blunt) joints have been condensed into algebraic relationships, see below. Figure 25a schematically describes heat flow paths in a blunt joint, and Fig. 25b illustrates positions of a minimum number of blunt joints in one-, two and three layer panel insulations (the latter diagram serves for identification of the following 2D finite element calculations for flat panel insulations).

For the dependence of $\dot{Q}_{\mathrm{Total}}/L_z$ on joint width, B, we have

$$\begin{aligned}\dot{Q}_{\mathrm{Total}}/L_z(\mathbf{B})\,[\mathrm{W/m}] &= C_{\mathrm{B1}}\{\Delta T[\mathrm{K}]\times L[\mathrm{m}]\times\lambda[\mathrm{W/(m\cdot K)}]/D[\mathrm{m}]\}\times \\ &\quad \mathbf{B}[mm]+C_{\mathrm{B2}}\{\Delta T[\mathrm{K}]\times L[\mathrm{m}]/D[\mathrm{m}]\}+C_{\mathrm{B3}}\end{aligned} \tag{33a}$$

and for the dependence of $\dot{Q}_{\mathrm{Total}}/L_z$ on indentation length, L_i

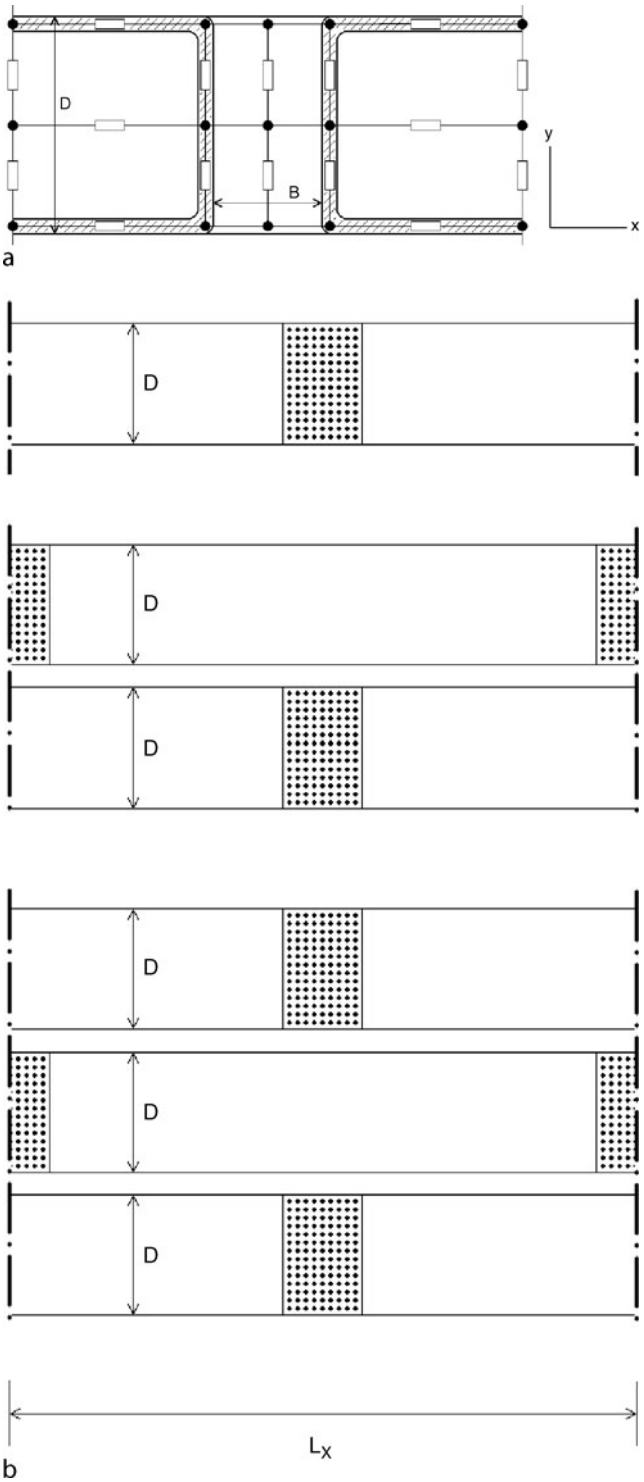
$$\begin{aligned}\dot{Q}_{\mathrm{Total}}/L_z(\mathbf{L_i})[\mathrm{W/m}] &= C_{\mathrm{Li1}}\{\Delta T[\mathrm{K}]\times L[\mathrm{m}]\times\lambda[\mathrm{W/(m\cdot K)}]/D[\mathrm{m}]\} \\ &\quad \times L_i[\mathrm{mm}]+C_{\mathrm{Li2}}\{\Delta T[\mathrm{K}]\times L[\mathrm{m}]/D[\mathrm{m}]\}+C_{\mathrm{Li3}}\end{aligned} \tag{33b}$$

The three terms in Eq. (33a, b) are explained as follows: The *first* term

$$C_{\mathrm{Bl}}\{\Delta T[K]\times L[\mathrm{m}]\times\lambda[\mathrm{W/(m\cdot K)}]/D[\mathrm{m}]\}\times\mathbf{B}[\mathrm{mm}],\text{or}$$
$$C_{\mathrm{Lil}}\{\Delta T[K]\times L[\mathrm{m}]\times\lambda[\mathrm{W/(m\cdot K)}]/D[\mathrm{m}]\}\times\mathbf{L_i}[\mathrm{mm}],$$

respectively, describes the contribution $\dot{Q}_{\mathrm{Joint}}/L_z$ by *indented* joints (envelopes plus filling material) that depends on joint width, **B** (at constant L_i) or on indentation length, $\mathbf{L_i}$ (at constant B), respectively, to total heat loss. The symbols C_{B1} and C_{Li1} indicate constants preceding the parameters ΔT, L, λ, and D^{-1} and the variables B or L_i, respectively, in Eq. (33a, b).

In the first term, ΔT [K] denotes temperature difference between warm and cold sides, taken over the *total* thickness of the insulations (note that convective boundary conditions on



K6. Fig. 25. (**a**, **b**) 2D-thermal network (schematic) for calculation of heat flow through blunt joints in flat plate, one- or multiple layer panel insulations; (**a**) one-layer panel insulation with thermal resistances parallel and normal to global temperature gradient (*y*-direction), (**b**) positions of a minimum number of joints in one-, two-or three-layer panel insulations (dotted areas indicate the filling of the joints; analogous filling of the horizontal gap between upper and lower neighbouring panels could be preferable but is not indicated in the diagram); the figure serves also to identify the 2D finite element calculations in Figs. 26a, b–28a, b.

the warm side have been assumed in the finite element calculations, which means temperature of the warm side is air temperature). The symbol L [m] in the first term denotes *total* length of the joints, i.e., if there are two joints in z-direction, we have L = 2 m in the one-layer insulation. The thermal conductivity of the material filling the joints is indicated by λ [W/(m · K)]. The symbol D [m] indicates the thickness of *one* panel, also in case the insulation is two- or three-layer panel insulation (sample positions of a minimum number of indented or blunt joints in one-, two or three-layer panel insulations are schematically shown in Fig. 25b). Finally, B [mm] is the width of the joints filled with a microporous material, and L_i [mm] the indentation length.

If the width, B, of the joints is zero; this is not identical to the case "no joints". If $B = 0$, we still have some heat flow through foil sections oriented in vertical directions, at the corresponding edges (end positions) of the panels (compare the paths s_1 and s_3 in Fig. 22a), i.e., parallel to global temperature gradient, though there are no longer a contributions from *filling* of the joints.

The *second* term in Eq. (33a, b)

$$C_{B2} \times \{\Delta T[\mathrm{K}] \times L[\mathrm{m}]/D[\mathrm{m}]\} \text{ or}$$
$$C_{Li2} \times \{\Delta T[\mathrm{K}] \times L[\mathrm{m}]/D[\mathrm{m}]\}$$

with constants C_{B2} and C_{Li2} preceding the parameters, ΔT, L and D^{-1}, describes the contribution $\dot{Q}_{Joint}/L_z$ ($B = 0$) to total heat loss by the *indented* joints (only envelope material) that does *not* depend on joint width, B, or on indentation length, L_i, respectively.

The *third* term in Eq. (33a, b), constants C_{B3} and C_{Li3}, respectively, indicates the heat losses with no joints at all (no foil sections on panel edges, no filling materials).

Alternatively to the finite element result, the third term in Eq. (33a, b) can be estimated using the thermal resistances of each layer in the well-known analytical expression

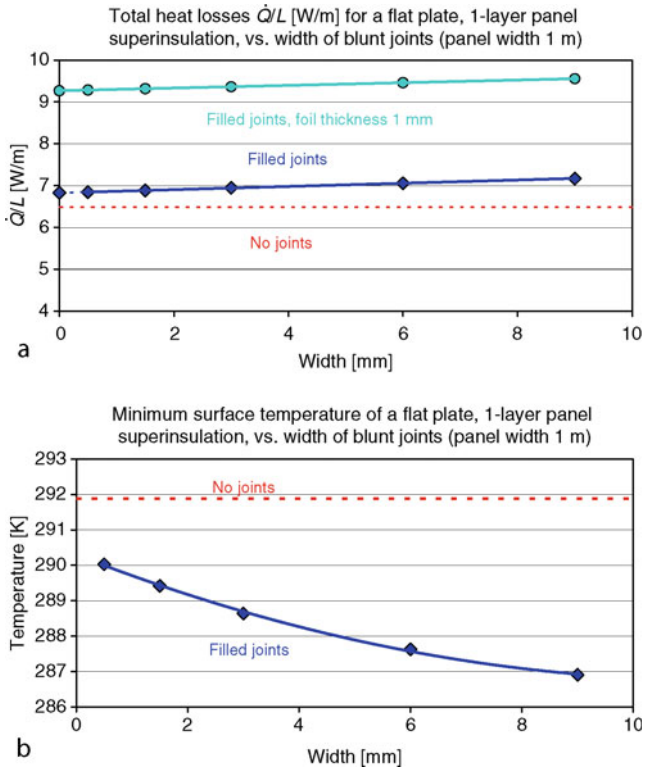
$$\dot{Q}_0 = \Delta T/\left(\Sigma[D_i/(\lambda_i^* A)] + [1/(\alpha^* A)]\right) \qquad (34a)$$

with the summation index, i, running over all thermal conduction resistances of the multilayer structure, and α the heat transfer coefficient describing convection plus radiation on the outer surface. Instead of the thermal conductivity, λ, of evacuated, load-bearing glass fiber boards (see above), the conductivity of other core materials can be taken for calculation of $\dot{Q}_0$ without seriously affecting the results for the heat flow contribution by the joints obtained with the first and second terms in Eq. (33a, b).

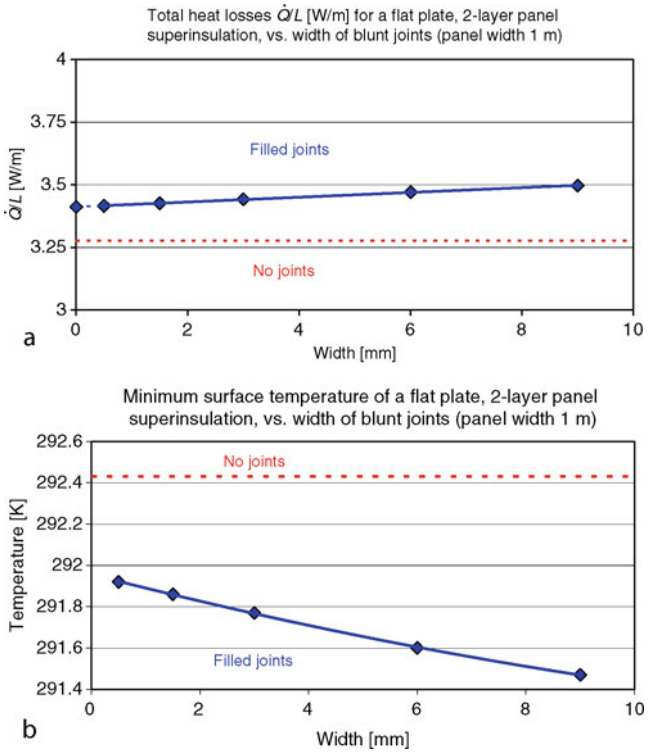
The constants C_{Bk} and C_{Lik} ($1 \le k \le 3$; k denotes term number) for i*ndented* joints in Eq. (33a, b) are given in Table 7. For $\dot{Q}_{Total}/L_z$ (B), they apply to constant L_i = 5 mm, while for $\dot{Q}_{Total}/L_z$ (L_i), they apply to constant B = 3 mm. With these constants, applicability of Eq. (33a, b) is within $35 \le \Delta T \le 45$ [K], with the temperature of the warm side at 293 K, $0.015 \le \lambda \le 0.025$ [W/(m · K)], $0.01 \le D \le 0.02$ [m], $0.5 \le B \le 12$ [mm] and $1 \le L_i \le 20$ [mm]. Total heat losses, $\dot{Q}_{Total}/L_z$, in Eq. (33a, b) are given for a unit length of 1 m in z-direction of the insulations (compare Fig. 22a for the co-ordinate system). Note that B and L_i are to be introduced in Eq. (33a, b) in millimetres.

K6. Table 7. Constants C_{Bk} and C_{Lik} ($1 \leq k \leq 3$; k indicates term number in Eq. (33a, b)) for calculation of heat losses, $\dot{Q}_{Total}/L_z$, of superinsulated, *flat plate* panels with indented joints (joint positions according to Fig. 22); constants are given for a one-layer panel insulation

Constants	Dimensions	Values
C_{B1}	1/m	8.837E-04
C_{B2}	[W/(m · K)]	5.405E-05
C_{B3}	W/m	6.488
C_{Li1}	1/m	−1.287E-05
C_{Li2}	[W/(m · K)]	6.804E-05
C_{Li3}	W/m	6.488



K6. Fig. 26. (**a**, **b**) Heat losses, $\dot{Q}_{Total}$, and minimum temperatures for a flat plate, one-layer panel superinsulation with blunt joints; results are obtained from 2D-finite element simulation. Open circles in Fig. 26a refer to a polymer foil thickness of 1 mm. Panel thickness is 15 mm.



K6. Fig. 27. (**a**, **b**) Heat losses, $\dot{Q}_{Total}$, and minimum temperatures for a flat plate, two-layer panel superinsulation with blunt joints; results are obtained from 2D-finite element simulation. Thickness of each panel is 15 mm.

The results of 2D finite element-calculations for total heat losses, $\dot{Q}_{Total}/L_z$, of *blunt* joins, again using standard polymer foils (thickness in the order of 100 µm) under variation of the width, B, are shown in Figs. 26a, 27a and 28 a. Again, a temperature gradient of 40 K over the corresponding total thicknesses (15, 30, and 45 mm, respectively) of the insulations has been assumed in the calculations. The results have been condensed into the algebraic relationship indicated in Eq. (33a).

The constants C_{Bk} ($1 \leq k \leq 3$; k denotes term number) for *blunt* joints in Eq. (33a) are given in Table 8. With these constants, applicability of Eq. (33a) is within $35 \leq \Delta T \leq 45$ [K], with the temperature of the warm side at 293 K, $0.015 \leq \lambda \leq 0.025$ [W/(m · K)], $0.01 \leq D \leq 0.02$ [m], $0.5 \leq B \leq 12$ [mm] and $1 \leq L_i \leq 20$ [mm]. Total heat losses, $\dot{Q}_{Total}/L_z$, in Eq. (33a, b) are given for a unit length of 1 m in z-direction of the insulations (compare Fig. 22a for the co-ordinate system). Note again that B and L_i must be introduced in millimetres.

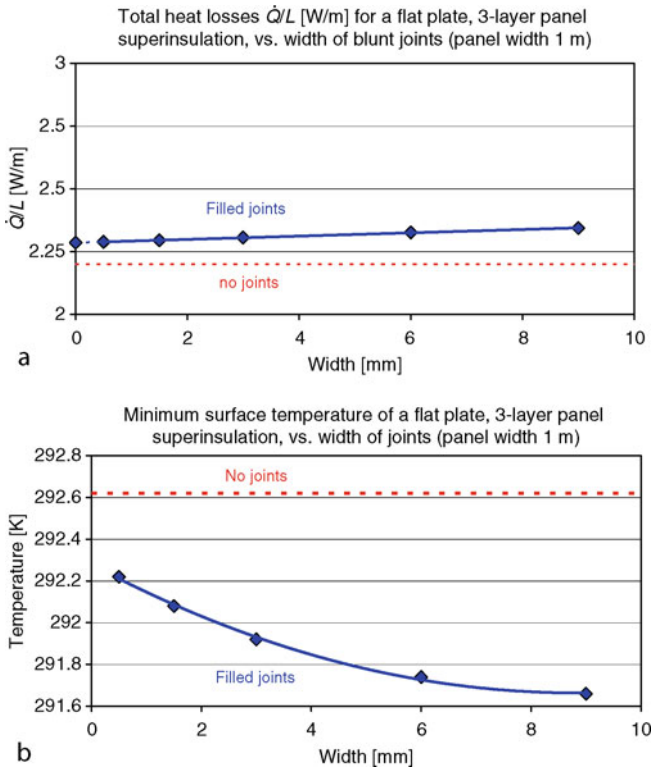
It is again assumed that the joints are filled with a microporous material to avoid solid–solid contacts between neighbouring panels, and convection (the whole structure could be open to air flow). Note that the heat losses increase very strongly if a polymer foil thickness of 1 mm would be used (Fig. 26a). Again, if the width, B, of the joints is zero; this is not identical to the case "no joints".

From the same finite element analysis, Figs. 26b, 27b, and 28b show minimum temperature on the upper surface under convection if $T_1 = T_{ambient}$ and T_2 are 293 and 253 K, respectively. Results are given for one, two and three layer, flat panel insulations with blunt joints. The insulations should be thick enough to avoid surface temperatures below dew point.

Total heat losses, $\dot{Q}_{Total}/L_z$, can be converted into "U-values" describing heat transmission by

$$U = (\dot{Q}_{Total}/L_z)/L_x [W/(m^2 \cdot K)] \qquad (35a)$$

Contrary to *k*-values (compare e.g., Fig. 7a, b), *U*-values not only include the thermal resistance of the insulations but also resistances due to convection with the environment or to a storage volume. Of particular interest are ΔU-values for heat



K6. Fig. 28. (**a**, **b**) Heat losses, $\dot{Q}_{Total}$, and minimum temperatures for a flat plate, three-layer panel superinsulation with blunt joints; results are obtained from 2D-finite element simulation. Thickness of each panel is 15 mm.

K6. Table 8. Constants C_{Bk} ($1 \le k \le 3$; k indicates term number in Eq. (33a, b)) for calculation of heat losses, $\dot{Q}_{Total}/L_z$, of superinsulated, *flat plate* panels with blunt joints (joint positions according to Fig. 24b); the constants are given for one-, two- and three-layer panel insulation

Number of layers	Constants	Dimensions	Values
1	C_{B1}	1/m	7.171E-04
	C_{B2}	[W/(m · K)]	1.277E-04
	C_{B3}	W/m	6.486
2	C_{B1}	1/m	8.961E-05
	C_{B2}	[W/(m · K)]	2.524E-05
	C_{B3}	W/m	3.277
3	C_{B1}	1/m	4.0928E-05
	C_{B2}	[W/(m · K)]	1.0679E-05
	C_{B3}	W/m	2.200

losses arising from contributions by the joints, which can be calculated from the first and second terms in Eq. (33a, b). Concerning the dependence on joint thickness, B, we formally have

$$\Delta U = [(C_{B1} \times \{\Delta T[\mathrm{K}] \times L[\mathrm{m}] \times \lambda[\mathrm{W/(m \cdot K)}]/D[\mathrm{m}]\} \times B[\mathrm{mm}] + C_{B2} \times \{\Delta T[\mathrm{K}] \times L[\mathrm{m}]/D[\mathrm{m}]\})L_x]/(A\Delta T) \quad (35b)$$

As given by Eq. (35b), ΔU is an overall correction averaged over the whole panel surface, A, and assuming for ΔT a uniform temperature difference taken over undisturbed and disturbed surface sections. It is clear that this can only yield an approximation to the real case because the surface temperature is lower at the positions of the joints compared to the undisturbed area (compare Fig. 24c). Nevertheless, this approach is frequently used, compare, e.g., Fricke [49], pp. 65–67, and literature cited therein, and can be justified if, as Fig. 24c confirms, the conductivity of the enevelope materials is small.

Example 7

Calculate total heat loss, $\dot{Q}_{Total}$, the corresponding U-value and the contribution ΔU by joints through a square, flat plate, one-layer panel superinsulation with blunt joints running around the panel. The panel has a thickness $D = 15$ mm, and the joints a width $B = 6$ mm. The thermal conductivity, λ, of the material filling the joints is 0.02 [W/(m · K)]. Standard polymer foils with thickness in the order of 100 µm are taken as envelope housing the core made of an evacuated, load-bearing fiberglass board.

Solution

With the materials specifications, we can take the results of the 2D-finite element simulations reported in Eq. (33a) for $\dot{Q}_{Total}$ and the constants from Table 7. For the one-layer panel insulation with $L_z = 1$ m, $\Delta T = 40$ K, $\lambda = 0.02$ [W/(m · K)], $D = 0.015$ m, $B = 6$ mm and $L_x = 1$ m, we have a total length of the joints of $L = 2$ m around the panel, a total panel surface $A = L_z \times L_x = 1$ m^2 including undisturbed and disturbed regions. Total heat loss, $\dot{Q}_{Total}$, from Eq. (33a) then amounts to

$$\dot{Q}_{Total} = (7.171\mathrm{E}-04 \times 2 \times 0.2/0.015) \times 6 + 1.227\mathrm{E}-04 \times 40 \times 2/0.015 + 6.486\,[\mathrm{W/(m^2 \cdot K)}] = 7.627\,\mathrm{W}$$

According to Eq. (35a), this yields an averaged total U-value,

$$U_{Total} = 7.627/(A\Delta T) = 7.627/(1 \times 40)\,[\mathrm{W/(m^2 \cdot K)}] = 0.191\,[\mathrm{W/(m^2 \cdot K)}]$$

which is rather small due to the very small thermal conductivity of the core material.

The contribution $\Delta\dot{Q}_{Joints}$ from the joints is given by terms 1 and 2 of Eq. (33a), or simply as

$$\Delta\dot{Q}_{Joints} = (7.627 - 6.486)\,\mathrm{W} = 1.140\,\mathrm{W}$$

Averaged over the total panel surface, A, and assuming uniform temperature difference, ΔT, also over the joints, the ΔU-value is

$$\Delta U = \Delta\dot{Q}_{Joints}/(A\Delta T) = 1.140/(1 \times 40)\,[\mathrm{W/(m^2 \cdot K)}] = 0.0285\,[\mathrm{W/(m^2 \cdot K)}]$$

A correction that in percentage of the losses of the undisturbed region amounts to

$$\Delta U\,[\%] = [0.0285/(0.191 - 0.0285) \times 100] = 17.6\%$$

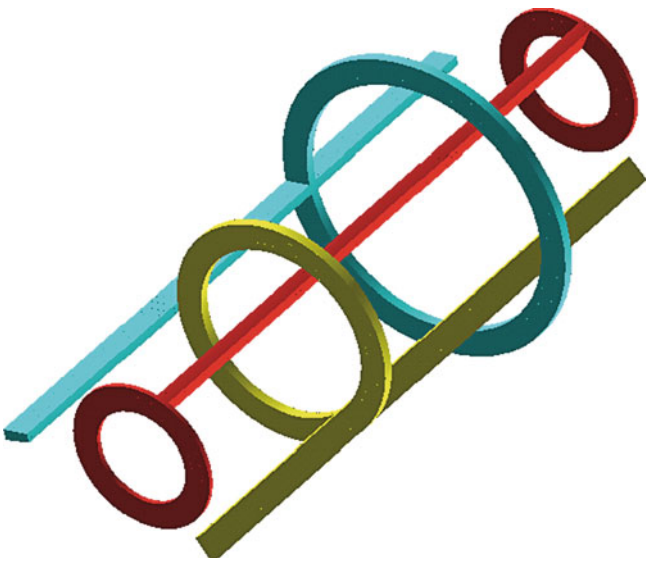
The rather large percentage is due to the very low heat losses of the undisturbed region, in relation to the losses of the joints.

U-values for flat panels, and corrections ΔU for contributions by the joints, for different foil materials, panel thicknesses and widths of joints, all for applications near room temperature, are reported in Fricke [49], pp. 65–71. This reference also describes additional measures to reduce losses by thermal bridges like the joints in panel insulations. The same reference, p. 104, contains a comprehensive list of presently available, industrially produced panel insulations.

3.5.2 Cylindrical Geometry

As before, results will be calculated over a unit length, $L_z = 1$ m. A large part of presently produced panels extends to smaller length, which means not only axial but also circumferential joints have to be been taken into account, over the distance L_z. Fig. 29 schematically shows the geometry of axial and radial joints in a cylindrical, three-layer panel insulation. The circumferential positions of the axial joints have been chosen to obtain minimum heat leakage. It is again assumed that the joints are filled with a microporous material.

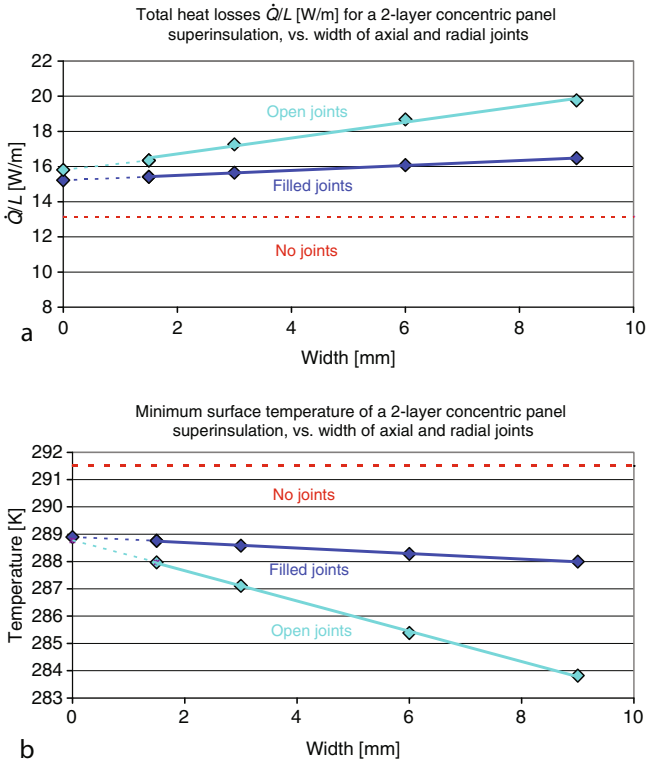
Figures 30a und 31a show total heat loss through two and three layer panel insulations positioned around a piping of 200 mm inner diameter; the data are obtained in detailed 3D finite element calculations. In these examples, $T_1 = T_{ambient}$ and $T_2 = 77$ K. At cryogenic temperatures, polymer foils used as envelopes could be subject to severe thermo-mechanical materials problems, however (embrittlement, strongly differing thermal expansion coefficients of polymers and core materials) which means leakage by pinholes, pores or cracks and, in the long run, increase of residual gas pressure in the core if not additional measures (integrating several aluminized polymer layers into the compound, compare, e.g., Fricke [49], or new materials) are taken to guarantee long-term vacuum-tightness of the envelope materials also under these temperature boundary conditions.



K6. Fig. 29. Position of circumferential and axial joints in a three-layer panel insulation (schematic).

The results again are condensed into the algebraic expressions given in Eq. (33a). If the width, B, of the joints is zero; this is not identical to the case "no joints".

The constants $C_{B,k}$ ($1 \le k \le 3$; k again denotes term number) to apply for *blunt* joints in Eq. (33a) are given in Table 9. With these constants, applicability of Eq. (33a) to the cylindrical geometry is within $200 \le \Delta T \le 180$ [K], with the temperature of the warm side at 293 K (note the convective boundary condition), $0.015 \le \lambda \le 0.025$ [W/(m · K)], $0.01 \le D \le 0.02$ [m] and $0.5 \le B \le 12$ [mm].



K6. Fig. 30. (**a**, **b**) Heat losses, $\dot{Q}_{Total}$, and minimum temperatures for a cylindrical, two-layer panel superinsulation with blunt joints; results are obtained from 3D-finite element simulation. Thickness of each panel is 15 mm.

K6. Table 9. Constants C_{Bk} ($1 \le k \le 3$; k indicates term number in Eq. (33a, b)) for calculation of heat losses, $\dot{Q}_{Total}/L_z$, of superinsulated, *concentric* panels for tube insulations with circumferential and axial blunt joints (joint positions according to Fig. 29); the constants are given for two- and three-layer panel insulations

Number of layers	Constants	Dimensions	Values
2	C_{B1}	1/m	1.364E-04
	C_{B2}	[W/(m · K)]	4.003E-05
	C_{B3}	W/m	13.150
3	C_{B1}	1/m	5.517E-05
	C_{B2}	[W/(m · K)]	1.727E-05
	C_{B3}	W/m	9.381

The total length, L, of the joints has to be taken over circumferential plus axial joints, again for the whole insulation. As before, D the thickness of *each* panel, and B the width of the joints (it is assumed the width is identical for all radial and axial joints).

Like for the flat geometry, the first term in Eq. (33a) describes the contribution $\dot{Q}_{\text{Joint}}/L$ by the joints to total heat loss. The second term, $\dot{Q}_0/L$, indicates that part of the losses that does not depend on joint width, B. The heat leakage for the case "no foils" can be estimated from the corresponding analytical expression, now for cylindrical geometry,

$$\dot{Q}_{\text{Cyl}} = 2\pi^* \Delta T/(\Sigma(1/\lambda_i)^* \ln(r_{i+1}/r_i) + (1/(\alpha^* A))) \qquad (34b)$$

with the summation index, i, running over all thermal conduction resistances of the multilayer structure, and α the heat transfer coefficient describing convection plus radiation on the outer surface.

Instead of the thermal conductivity, λ, of evacuated, load-bearing glass fiber boards (see above), the conductivity of other core materials can be taken for calculation of $\dot{Q}_0$ without affecting the results obtained with the first and second terms in Eq. (33a).

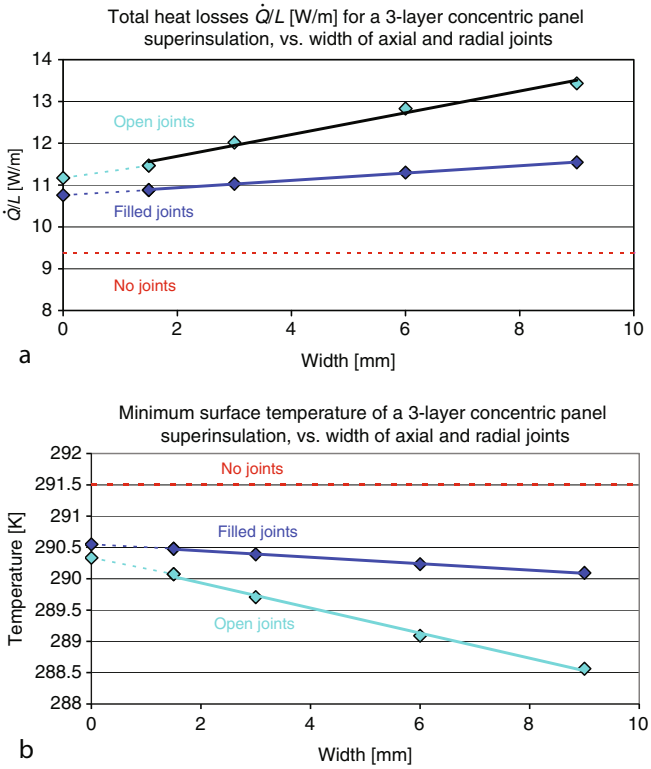
For two- and three-layer cylindrical panel insulations, Figs. 30b and 31b indicate the corresponding minimum surface temperatures. They are calculated assuming a temperature gradient of 216 K over the corresponding thicknesses (30 and 45 mm, respectively) of the two- or three-layer panel insulation of the tube. It is not possible to indicate simple closed form expressions for this purpose. Minimum values will always be found near the radial joints of the outer panel.

The dashed curves in Figs. 30a, b and 31a, b indicate heat losses and surface temperatures if the joints were to be left open (not be filled with a microporous material; the results indicate a worst case scenario). In view of the strongly increased heat losses and reduced surface temperatures, open joints should be avoided.

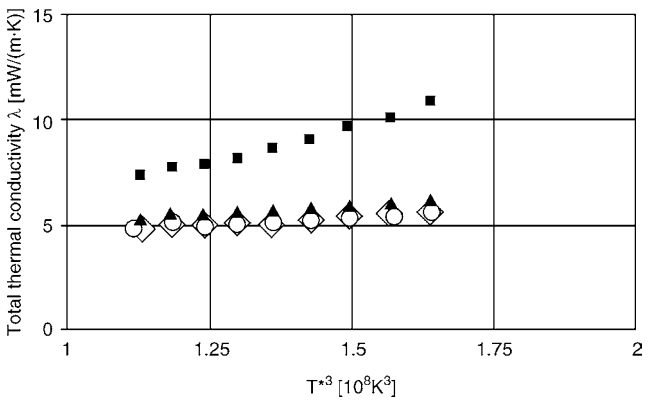
Figure 32 (materials from [50]) and Fig. 33 (data from [52]) show experimental values as examples for heat losses of panel superinsulations.

The lower data points in Fig. 32 have been obtained with silica aerogels doped with opacifiers (MnO_2, Fe_2O_3, or Fe_3O_4, TiO_2) and accordingly follow a linear relationship, compare Eq. (26). Instead, the upper data points refer to a panel that has been prepared without opacifier. Due to the smaller extinction coefficient, and because of the infrared "windows" of silica aerogel (Fig. 16), the approximation is no longer linear but by its curvature indicates transparency of the panel to thermal radiation. As a consequence, E_R^*/ρ is no longer a constant, for given temperature and particle diameter, but becomes dependent on radiation temperature. Reference to Eqs. (26) and (21) shows that in this case not a linear but a curved profile will result in the λ_{Total} versus T_{Rad}^3 diagram.

Experimental data by Caps [52] demonstrate small thermal conductivity, λ_{Total}, of an evacuated panel using pyrogenic silica as core material, in dependence of residual gas pressure. If the gas pressure increases to atmospheric pressure, the total thermal conductivity of the panel is still below the conductivity of motionless air. The increase of the thermal conductivity of this panel series can be described by $\lambda_{\text{Total}} = \lambda_{\text{sc}} + \lambda_{\text{Rad}} + 26/(1 + p_{1/2}/p_{\text{Gas}})$ with $p_{1/2} = 675$ mbar. Based on extremely



K6. Fig. 31. (**a**, **b**) Heat losses, $\dot{Q}_{\text{Total}}$, and minimum temperatures for a cylindrical three-layer panel insulation with blunt joints; results are obtained from 3D-finite element simulation. Thickness of each panel is 15 mm.



K6. Fig. 32. Experimental values for total thermal conductiviy, λ_{Total}, of four evacuated panels, versus $T^{*3} = 4T_{\text{Rad}}^3$; samples are from Degussa AG, Hanau, Germany [50]. The SiO_2 aerogel was compacted to a density of about 200 kg/m^3. Residual gas pressure of the fresh panel was below 1 mbar, residual humidity below 1%, one side of the samples was coated with Al. Data are measured by Fraunhofer Institut für Solare Energiesysteme, Freiburg, Germany [51] using $39.5 \leq T_1 \leq 118$°C $20.8 \leq T_2 \leq 22$°C. Open diamonds, open circles and solid triangles: opacified with MnO_2, Fe_3O_4 and TiO_2, respectively (concentrations not reported); full squares: without opacifier. The samples were delivered to the author by 1992 and have mainted vacuum since then.

small gas permeability of foils and joints reported in the same reference, the supplier expects a lifetime of such a panel safely above 30 years.

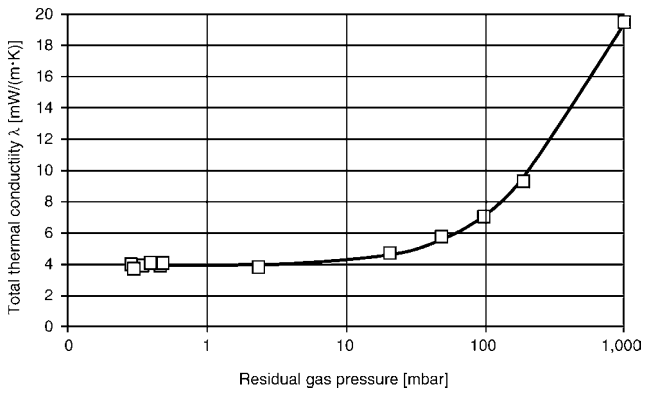
4 Improvement of Thermal Insulations

4.1 Optimum Choice of Materials Properties

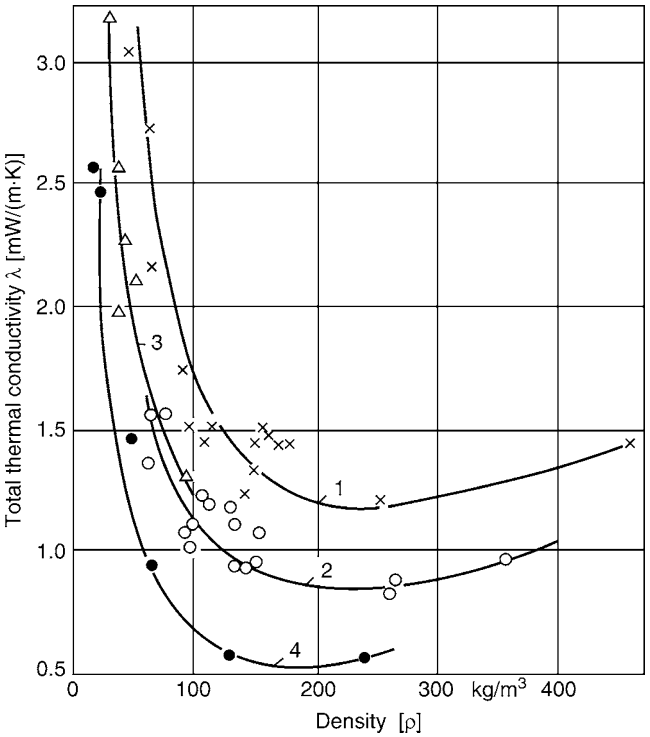
It can be derived directly from Eqs. (2a, b), (17), or (18) and (6) or (20) how thermal insulations, of discontinuous or continuous types, can be improved. Minimum values for $\dot{Q}_{Total}$ or λ_{Total} are obtained as follows:

- For multilayer insulations, by selecting a large number of foils N with low emissivities ε_{Wall} and ε_{Foil}, in accordance with Eq. (6)
- For microporous insulations, by using particulate solid materials with low solid state thermal conductivities, λ_S, and high Young's moduli, Y, of elasticity and by avoiding compressive loads, p /(cf. Eqs. (17) or (18)), and
- By ensuring high linear extinction coefficients, E, in accordance with Eq. (20).
- In both types of insulations, by making sure that high Knudsen numbers, Kn, are obtained; this is realized by evacuating and reducing clearance between foils and spacers, or the pore diameter, δ, respectively, as indicated by Eq. (2a, b); if for continuous insulations experimental values are available for δ, these should be preferred over estimates using Eq. (16a, b)
- For evacuated panels, by using envelope material of as low as possible thermal conductivity, as far as available, to reduce heat losses at the joints. Note, however, increasing temperature gradients in the path sections s_1 and s_3 (Fig. 22b–d) if conductivity of the foils decreases, which can lead to substantial thermal contraction or expansion in this material. For the same reason, sharp edges of the panels should be avoided.

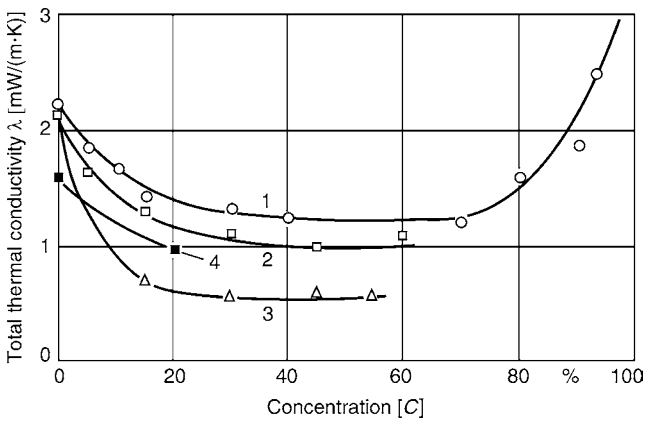
High linear extinction coefficients can be achieved by increasing the density, ρ, of the insulations (Fig. 18a–d) and by means of infrared opacifiers, if available with optimum particle diameters (see below, Fig. 36a–c). In almost all cases, an optimum density (Fig. 34, [1]) or an optimum opacifier concentration can be found (Fig. 35, [38]). If the density or concentration is too low, radiation is still is transmitted through the substance, with the result that λ'_{Rad} assumes high values. Conversely, if the density or



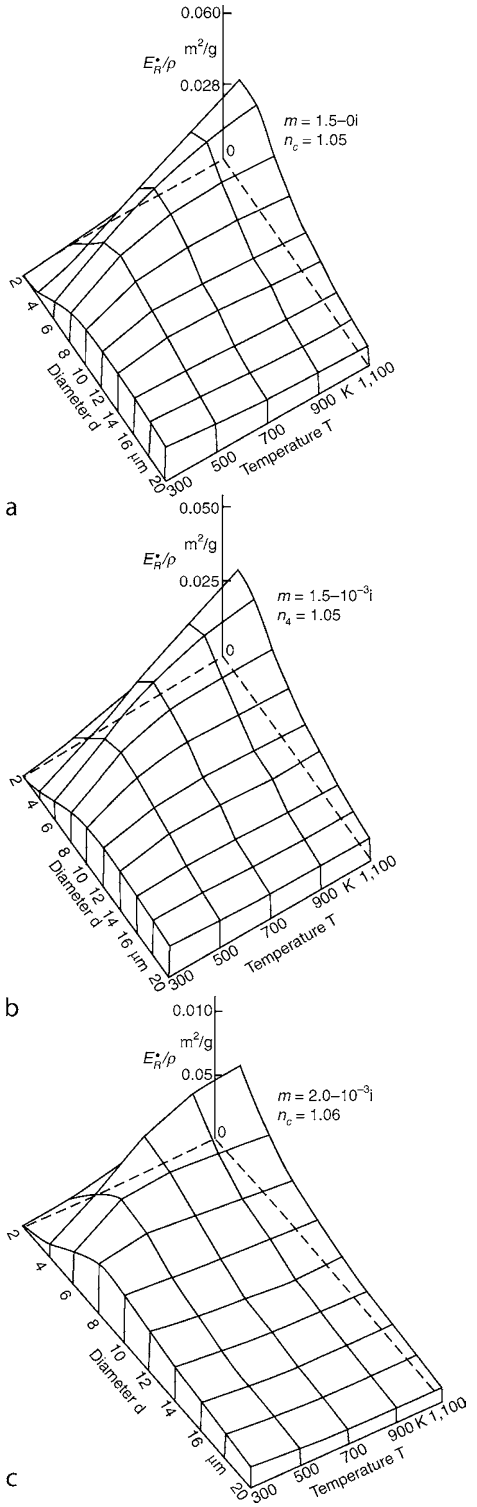
K6. Fig. 33. Experimental values for total thermal conductivity, λ_{Total}, of evacuated panels in dependence of residual gas pressure (The figure is from [52]).



K6. Fig. 34. Total thermal conductivity, λ_{Total}, of evacuated powder and fiber insulations as a function of density ρ; the figure is from [1]. Curves 1: Silica aerogel, 2: Perlite, 3: Foamed material, 4: Glass wool (fiber diameter 1.2 μm); wall temperatures T_1 = 293 K and T_2 = 90 K; curve 1 for the pure Silica aerogel possibly indicates a pseudo-conductivity.



K6. Fig. 35. Total thermal conductivity, λ_{Total}, of evacuated powders ($p_{Gas} \leq 0.1$ Pa) at cryogenic temperatures as a function of concentration C (mass fraction) of opacifier (aluminium particles); data are from [38]; curves 1: Silica aerogel with aluminium flakes, 2: Perlite with aluminium powder, 3: Silica aerogel with aluminum powder, 4: Perlite with aluminium powder.



K6. Fig. 36. (**a**–**c**) Wavelength-averaged, effective linear extinction coefficients, E_R^*/ρ, per unit density, $\rho = \rho_{Particles}$, of spherical particles, as a function of particle diameter, *d*, and radiation temperature, T_{Rad}, for the estimation of the optimum diameter of opacifiers. The diagrams are calculated by the Mie theory using complex, *wavelength-independent* refractive indices, $m = n - ik$, and a density, ρ_S, of the basic solid material the particles are made from, of 5000 kg/m^3. The index $m = 1.5–10^{-3}$ i corresponds roughly to silica; and $m = 2–10^{-3}i$ to titanium dioxide. The relationships for $m = 1.5–0$i (the effect of the absorption coefficient *k*) have been included as a comparison. To approximately determine from these diagrams the extinction coefficient, *E*, for real opacifiers, the indices, *m*, applied in the calculations, should approximate the m of the real materials, in relevant wavelength intervals, $\Delta\Lambda$. If so, *E* can then be obtained using the given E_R^*/ρ by multiplication with the factor ($\rho_{Particles}$ 5000/ρ_S). n_c is the refractive index of the continuum surrounding the particles.

concentration is too high, the greater number of solid contacts affects an increase in λ_{SC}.

The criterion to be adopted in selecting an opacifier, e.g., aluminum powder, metal oxides, or carbon black, is its extinction spectrum as determined by experiment or by application of the Mie theory. In the latter case ([26]), the spectral complex refractive indices must be known, and reliable information on the particle diameter is required.

Optimum particle diameters, which can be read off from Fig. 36a–c, exist for dielectric spherical particles that are not strongly absorbent. The Rosseland averages, $E_R^*(T)/\rho$, entered in these diagrams were determined from the Mie theory by allowing for anisotropic scattering (ρ is the density of the powder). Strictly speaking, the applied complex indices of refraction are *sample* ones, but they approach the infrared optical properties of real materials, at least in certain wavelength intervals. Also, the diagrams have been calculated assuming a density, $\rho_S = 5000$ kg/m^3, identical for the three substances, of the basic solid materials from which the hypothetic opacifying powders were prepared. The calculations, accordingly, demonstrate existence of optimum particle diameters of opacifying materials for a certain range of indices of refraction. Analogous diagrams showing the existence of optimum particle diameters in a *real* substance (Fe_3O_4) have been published by Bauer [53].

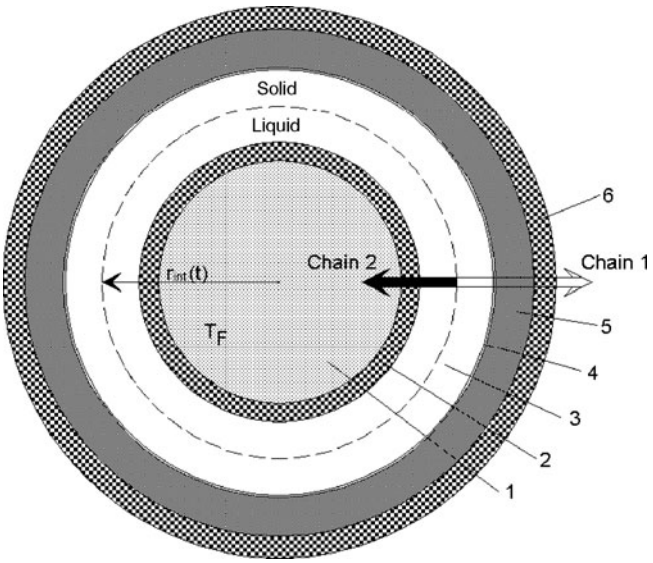
4.2 Improvements by Latent Heat Storage

Extended standby periods of superinsulated devices can be achieved not only from improvement of the proper superinsulations (mostly by variations of its materials composition) but also from a combination with latent heat storage. Cool-down time of low, medium, or high temperature storage units, or of pipings in case of a production breakdown, can considerably be extended by this means. The method is not restricted to superinsulations.

Layers of latent heat storage material are integrated between the inner tube and thermal insulations, as shown e.g., in Fig. 37, which is a cross section (schematic) of a superinsulated pipe furnished with latent heat storage material. The latent heat storage material is located between the inner steel tube (2) and a separator (4) that in case of a superinsulation must be vacuum-tight. It is assumed that the fluid temperature, T_F, exceeds melting temperature, T_m, of the phase change material and ambient temperature, T_a; accordingly, it is assumed that the phase change material during normal operation of the pipe is in liquid state. Phase change of the storage material, between liquid and solid states, during cool-down of the fluid occurs at

the position $r_{int}(t)$ of the cross section, i.e., at a definite radius, under ideal conditions. Since the temperature profile across the pipe changes with time, t, the position of the liquid–solid interface (dashed curve in Fig. 37) changes accordingly, from the outer surface of the inner tube to the inner surface of the separator. These positions denote fully charged or fully discharged states of the storage material, respectively.

In case of a "normal" (non-evacuated) insulation, the position of the phase change material in the cross section of the pipe, with respect to position of the thermal insulations depends on the specific problem (quality of the insulations, temperatures): instead of being surrounded by the thermal insulations, the phase change material could surround the insulations in this case. Which of the two options shall or can be realized has to be concluded from thorough thermal analysis, for example, based on thermal network calculations of heat losses and temperature excursions (clearly, if superinsulation is used, the phase change material will be surrounded by the insulations). Note that heat transfer in phase change materials may be complicated by inhomogenous solidification and hysteresis after numerous cycles.



K6. Fig. 37. Cross section (schematic) of a pipe with superinsulations and incorporated latent heat storage material; components are indicated as follows: (1) fluid, (2) inner tube, (3) latent heat storage material, (4) vacuum tight separator, (5) thermal insulations, (6) outer tube. The thin dashed line indicates an (ideal) interface between solid and liquid phases of the storage material. The large arrows indicate directions (chains) of heat flow from the latent heat storage material [from the interface at which phase change occurs, with the radius $r_{int}(t)$] to ambient (Chain 1) or to fluid (Chain 2).

Figure 38 schematically shows a thermal resistance network (compare Sect. 2.5) that is designed according to Fig. 37. Heat transfer occurs through two chains. The origin of both chains is the interface between solid and liquid phase of the storage material.

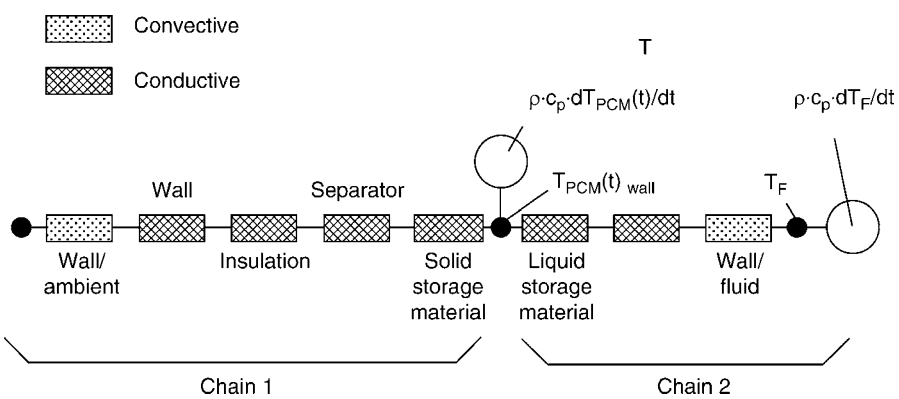
Chain 1 directed outwards is located between phase change interface and ambient, via separator and thermal superinsulations. In this chain, we have thermal conduction and radiation resistances (storage material that is already solidified, separator, insulations, outer tube) and a convective resistance between outer surface of the outer tube and ambient. Chain 2 directed inwards is located between interface and fluid, with conductive resistances given by the storage material still being in liquid state and the inner tube, and with a convective resistance between inner surface of the inner tube that is wetted by the fluid.

Heat flow $\dot{Q}_S$(W) from the storage material along both chains is described by the first of the following two equations (the indices "PCM" and "F" denote phase change material, and fluid, respectively):

$$\rho^*_{PCM} c^*_{PCM} \mathrm{d}T_{PCM}/dt = \dot{Q}_{Chain\,1} + \dot{Q}_{Chain\,2} \qquad (36a)$$

$$\rho^*_{F} c^*_{F} \mathrm{d}T_{F}/dt = \dot{Q}_{chain\,2} \qquad (36b)$$

with opposite orientation of $\dot{Q}_{Chain\,1}$ and $\dot{Q}_{Chain\,2}$. In Eq. (36a, b), the symbols ρ and c denote density and specific heat of storage material and fluid, respectively. During phase change, the temperature of the storage material is constant, and the term $\rho_{PCM}{}^* c_{PCM}{}^* \mathrm{d}T_{PCM}/\mathrm{d}t$ in Eq. (36a) then has to be replaced by the change with time of the latent heat content of the storage unit as long as this content is above zero (during discharge; or below its maximum value during charging).



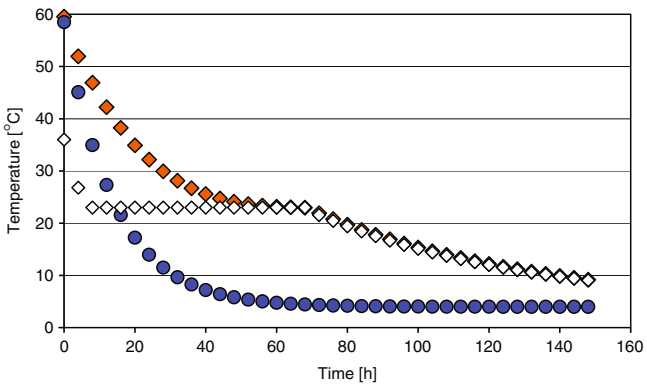
K6. Fig. 38. Thermal resistance network (1D chains) for calculation of temperature excursions of fluid (index F) and storage (index PCM) unit, with the definitions of the thermal resistances of Chains 1 and 2.

Using only these two equations is an approximation to the real case: also the other N-2 components of the pipe (tube materials, insulations, etc.) have heat capacities (and, accordingly, stored thermal energy) so that a number of in total N equations, like Eq. (36a, b), would be necessary to completely describe the energy household of the pipe. In most cases, the contribution of the heat capacities of the other N-2 components is small and in a good approximation can be neglected in Eq. (36a, b). Problems could come up only in exceptional (and unrealistic) cases when the thickness of the storage material would be extremely small in comparison to the thickness of the insulations. This means solution of both equations yield values of temperature excursions averaged over the volumes of fluid and storage material and neighboring tube or insulation components.

Both chains are composed of terms like $\Delta T_{i,j}(t)/R_{i,j}$, where $\Delta T_{i,j}(t)$ and $R_{i,j}$ denote temperature difference and thermal conductive resistances, between two neighboring surfaces i and j, or a convective resistance between surfaces and ambient or fluid, respectively. While most of the $R_{i,j}$ may be considered as constant (independent of temperature and time), this is not valid for the resistance between the phase change interface and the neighboring surface of separator (Chain 1) and between the interface and the outer surface of the inner tube (Chain 2), because the thickness of solid and liquid partial volumes of the storage material changes with time. Accordingly, $\dot{Q}_{\text{Chain1}}$ and $\dot{Q}_{\text{Chain2}}$ are not constant but functions of time, i.e., $\dot{Q}_k = \dot{Q}_k[T(t),t]$, with k = Chain 1 or Chain 2, which means it is not possible to separate both variables in Eq. (36a, b). Instead, a stepwise (numerical) integration of the two equations is necessary.

In a rough approximation, all materials data may be considered as constant (independent of temperature).

Figure 39 shows temperature excursions obtained from thermal network calculations assuming a hot liquid originally at 60°C is cooled down in an insulated pipe that is located in a cold environment (4°C). The figure demonstrates that standby periods can extended considerably.



K6. Fig. 39. Temperature excursion of latent heat storage material (open diamonds) and of the fluid with (red diamonds) and without (blue circles) integration of a phase change material into the cross section of a pipe. Results are from thermal network calculation (compare Fig. 38), using temperatures of fluid, T_F, and ambient temperature, T_a, of 60°C and 4°C, respectively. Heat of solidification of the phase change material is 1.3 x 10^5 Ws/(kg), thickness about 75 mm, in a tube of about 250 mm inner diameter, with a conventional thermal insulation of 40 mm thickness and 0.2 W/(m · K) thermal conductivity (Courtesy ABB Corporate Research, Ladenburg, Germany (2008)).

Instead of assuming a sharp interface between solid and liquid phases, stratification and convection in the liquid storage material and in the fluid, and enthalpy diagrams taking account also hysteresis of the storage materials must also be considered for a rigorous analysis.

5 Symbols

Alpha-numeric symbols

a, b	Constants in Eq. (26)
A	Area (cross section in equations for calculation of heat flow) (m^2)
B	Width of joints (mm)
C	Specific heat (W s K^{-1} kg^{-1})
C	Constants in Eqs. (1) and (33a, b)
D	Panel thickness or thickness of insulations (compare text) (m)
d	Particle diameter (m)
E	Linear extinction coefficient (including scattering) in the Lambert-Beer law (m^{-1})
E^*	Effective value of E corrected for anisotropic scattering (m^{-1})
E_R^*	Rosseland average taken over spectral E^* values (m^{-1})
f	Degree of freedom, to calculate specific heat
k	k-Value; $k = \dot{Q}_{\text{Total}}/(A\,\Delta T)$, or correction factor in Table 2 (W $m^{-2}K^{-1}$)
k	Imaginary part of complex index m of refraction
K	Constants in Eq. (30)
Kn	Knudsen number defined by Eq. (4)
Li	Length of indentations of joints (m)
rn	Complex refractive index of a dispersed material or of opacifiers
M	Number of algrebraic equations in thermal network
n	Effective value of the real part of the complex refractive index, m
N	Number of foils or number of algebraic equations
p	Pressure exerted by compressive load or gas pressure (Pa)
$\dot{q}$	Heat flux (W m^{-2})
R	Thermal resistance (conduction, radiation, convection) (K/W)
s	path sections in Fig. 22a–d
$\dot{Q}$	Heat flow (W)
T	Absolute temperature (K)
T_1, T_2	Wall temperatures, $T_1 > T_2$ (K)
T_{Rad}	Mean temperature of radiation Eq. (21) (K)
U	U-value (heat transmission) defined in Eq. (35a) [W/(m^2 · K)]
ΔU	Correction to undisturbed U-value by contributions from joints to heat losses [W/(m^2 · K)]
Y	Young's modulus of elasticity (Pa)

Greek symbols

α	Accommodation coefficient for a gas at a wall, or heat transfer coefficient

β	Weight applied to Knudsen number, Kn, cf. Eq. (3)
γ	Poisson's ratio
δ	Foil spacing, or pore diameter in dispersed media (μm)
ε	Wavelength-averaged, hemispherical thermal emissivity
φ	Correction factor concerning angle of incidence of radiation on fiber axis
Λ	Wavelength (μm)
Λ_{max}	Wavelength at which black body radiant intensity is a maximum (μm)
λ	Thermal conductivity [W m^{-1} K^{-1}]
λ_0	Thermal conductivity of a gas at standard pressure [W m^{-1} K^{-1}]
λ'	Thermal pseudo-conductivity (compare footnote 1 and Appendix A1 [W m^{-1} K^{-1}]
Π	Porosity; $\Pi = 1 - (\rho/\rho_S)$
ρ	Density of dispersed media like powders or fibers (kg m^{-3})
σ	Stefan-Boltzmann constant, $\sigma = 5.67040 \times 10^{-8}$ [W/(m^{2}K^4)] [W m^{-2} K^{-4}]
τ_0	Optical thickness, cf. Eq. (19)

Subscripts

a or ambient	Ambient condition, e.g., room temperature
B_k	Subscript to constant C in Eq. (33a) that refers to width, B, of joints; k is an index running over the terms in this equation
c	continuum
Chain 1,2	Heat flow directions in Figs. 37 and 38
e	Electron
E	Electromagnetic
F	Fluid
Foil	Index to thermal conductivity or emissivity, λ
Gas	Residual gas
i	Index running over thermal resistances switched in series in Eq. (34a, b)
IGP	Intergranular porosity
Lik	Subscript to constant C in Eq. (33b) that refers to length, L_i, of an indentation; k is an index running over terms in this equation
MPP	Micropore porosity
p	(constant) pressure
P	Powder
PCM	Phase change (latent heat storage) material
Rad	Radiation
S	Solid
SC	Solid–solid contact conduction
V	Volume
W	Wall
0	Conductivity at normal (ambient pressure) or zero conditions (zero foils)

Superscripts

$*$	The asterix applied to extinction coefficients indicates that the quantity specified in this way is corrected for anisotropic scattering. If applied to temperature, the asterix indicates a radiative (mean) temperature, cf. Eq. (21).

6 Appendices

6.1 Appendix A1: Pseudo-conductivity, Minimum Optical Thickness for Non-transparency

6.1.1 Pseudo-conductivity

If a completely transparent medium (optical thickness $\tau_0 \to 0$) is placed between infinitely extended, planar parallel walls 1 and 2 of same thermal emissivity, $\varepsilon_1 = \varepsilon_2 = \varepsilon$, radiative flux, $\dot{q}_{Rad}$, is given by Eq. (7b),

$$\dot{q}_{Rad} = \frac{\sigma \cdot \left(T_1^4 - T_2^4\right)}{2/\varepsilon - 1} \left[\mathrm{W/m^2}\right]$$

Note that $\dot{q}_{Rad}$ does not depend on the wall separation, D. The definition of thermal conductivity, as a materials *constant* (or, better, as a physical quantity) in Fourier's empirical conduction law,

$$\dot{Q} = \lambda A \Delta T / D$$

cannot be applied for calculation of a radiative conductivity, λ_{Rad}, i.e.,

$$\lambda_{Rad} = \dot{q}_{Rad}\, D/\Delta T$$

because *this* quantity would not be constant but depend on wall separation, D, and on emissivity, ε.

The same applies if the optical thickness of a dispersed medium is small, Eq. (24),

$$\dot{q}_{Rad} = \frac{\dot{Q}_{Rad}}{F} = \frac{\sigma \times \left(T_1^4 - T_2^4\right)}{\frac{2}{\varepsilon_w} - 1 + \frac{3}{4} \times \tau_0^*} \left[\mathrm{W/m^2}\right]$$

In this case, the dependence of λ_{Rad} on D and would be smaller than in the case considered before, but still be detectable. This means that a quantity λ_{Rad} in a dispersed medium of small optical thickness, if conductivity is understood in the original sense of Fourier's conduction law, does not exist. If yet λ_{Rad} is calculated from either equations for $\tau_0 \to 0$ or for very small, but non-vanishing τ_0, it is a "pseudo"-radiative conductivity, λ'_{Rad}, that would be meaningless for a user if wall separation, D, and emissivity, ε, are not specified. A radiative conductivity exists only if optical thickness is so large that radiation at any position, x, within the medium has its origin at *this* position. Radiation emitted from walls surrounding the medium cannot be seen within the medium.

The same applies to *cylindrical* geometry. Assume two infinitely extended, concentric walls of which No. 1 is the inner, wall 2 the outer wall, again of the same thermal emissivity, $\varepsilon_1 = \varepsilon_2 = \varepsilon$, without foils in-between, $N = 0$. Radiative flow, $\dot{q}_{Rad}$, is given by

$$\dot{Q}_{Rad,0} = \sigma A_1 \left(T_1^4 - T_2^4\right) / [1/\varepsilon + (A_1/A_2)(1/\varepsilon - 1)] \quad \text{(A1)}$$

Compare this with the usual conduction law, now in cylindrical geometry,

$$\dot{Q} = \pi L (T_1 - T_2)/[(1/2\lambda)\ln(r_2/r_1)] \quad \text{(A2)}$$

(compare Chap. E1), with L the length of the cylinders and r_1, r_2 the corresponding radii. Solving for a λ yields

$$\lambda'_{\text{Rad},0} = \sigma r_1 \{\ln(r_2/r_1)/[1/\varepsilon + (r_1/r_2)(1/\varepsilon - 1)]\} 4T^3_{\text{Rad}} \quad \text{(A3)}$$

using $A_{1,2} = 2\pi r_{1,2} L$, and $4T^3_{\text{Rad}} = (T_1^4 - T_2^4)/(T_1 - T_2)$, from Eq. (21).

Also in this geometry, λ'_{Rad}, the radiative conductivity, depends on geometry by the factor $r_1 \ln(r_2/r_1)$ and on emissivity and thus is a pseudo-conductivity. If we keep r_1 constant, we have a dependence of λ'_{Rad} on $\ln(r_2)$, which is weaker, but detectable, than in the planar geometry.

If there are N foils between walls 1 and 2, the radiative flow reads

$$\dot{Q}_{\text{Rad,N}} = \dot{Q}_{\text{Rad},0} \Big/ \left\{1 + (\eta_W/\eta_{\text{Foil}}) r_1 \sum 1/[r_1 + (n/(N+1))(r_2 - r_1)]\right\} \quad \text{(A4)}$$

using the reduced emissivities, $\eta_i = \varepsilon_i/(2 - \varepsilon_i)$ like in Sect. 2.3 (i = W or Foil) and the summation taken over $1 \le n \le N$; compare Kaganer [1], pp. 33–34, for the denominator $1 + (\eta_W/\eta_{\text{Foil}}) r_1 \sum 1/[r_1 + (n/(N+1))(r_2 - r_1)]$. If this is set equal to the heat flow, $\dot{Q}$, in Eq. (A2), we have

$$\lambda'_{\text{Rad}} = \lambda'_{\text{Rad},0} \Big/ \left\{1 + (\eta_W/\eta_{\text{Foil}}) r_1 \sum 1/[r_1 + (n/(N+1))(r_2 - r_1)]\right\} \quad \text{(A5)}$$

of which the dependency on geometry is more complicated but again weaker compared to the previous cases. This is confirmed by Kaganer [1], p. 106, Table 19: Experimental values of the pseudo-conductivity of multilayer insulations, at residual gas pressure below 0.01 Pa, depend only weakly on thickness.

If instead of infinitely extended planar or cylindrical walls the case of walls of *finite* lengths is considered, the situation is quite analogous, with the same principal conclusions on λ'_{Rad} as before, but radiative exchange factors between the planar or cylindrical surfaces and end-faces have to be considered in the derivation of $\dot{Q}_{\text{Rad}}$; this is beyond the scope of this Appendix.

Assume now, in planar or cylindrical geometry, that the nonradiative components in the total thermal conductivity, λ_{Total}, as given in Eq. (25), are independent of wall separation, D (even this condition is not fulfilled if likewise the residual gas pressure would be very small). Now if λ'_{Rad} is a pseudo-conductivity, which means the radiative component is substantial, the same applies to λ_{Total} if λ'_{Rad} is introduced into Eq. (25). Like for λ_{Rad}, values given for λ_{Total} are meaningless for a user unless D and ε are specified.

Accordingly, total thermal conductivity, λ_{Total}, exists only if *all* its components exist, in the meaning of Fourier's conduction law. It is not possible to define a total thermal conductivity for a container that is filled with a transparent gas. Rather, a gaseous conductivity, independent of wall separation, may exist if the pressure is high enough that the mean collision distance between gas molecules is small compared with the wall distance. Therefore, "thermal conductivity" of transparent gases is at the most a partial conductivity, and values of λ_{Gas} given in the literature must have been cleaned from nonlocal, i.e., radiative, contributions (compare Tsederberg [54], p. 88, on the work of Wilner and Borelius). As a consequence, a large optical thickness at all wavelengths is imperative for the existence of total thermal conductivity.

Another conductivity that is mentioned frequently in the literature is "apparent conductivity." This expression is used if a strong curvature of $T(x)$ or if large temperature gradients $dT(x)/dx$ are expected in a planar medium near its boundaries. Calculating conductivity as usual from measured total $\dot{Q}$ gives only approximate values since local values of $dT(x)/dx$ can differ strongly from $-\Delta T/D = -(T_1 - T_2)/D$. The existence of large temperature gradients near the boundaries is due to weak thermal coupling of the medium to its surroundings, for example, to the walls (in the very special case of a nonconducting medium, even a temperature jump can be observed; see [55] and literature cited therein.

Weak thermal coupling to the wall occurs if the optical thickness of the medium is small. Therefore the real background for "pseudo-conductivity" and "apparent conductivity" seems to be the same. However, if one speaks of apparent conductivity, it is implicitly assumed that $dT(x)/dx$, though strongly varying, exists everywhere in the medium. In a medium for which a pseudo-conductivity has been calculated, $dT(x)/dx$ might not exist at all, e.g., in a Dewar vessel. On the other hand, "true" conductivity is associated with $dT(x)/dx$ that exists everywhere in the medium and is identical, or is at least very close, to $-(T_1 - T_2)/D$.

The literature is full of confusion about conductivity, pseudo-conductivity and apparent conductivity, up to present; it is not astonishing that a "thickness problem" was broadly discussed in 1980s in publications dealing with microporous insulations. Pseudo- and apparent conductivity neither are synonyms nor are they identical with "true" conductivity that does not depend on specific properties of the device (surface, thickness, emissivity of the walls) by which it was measured. A pseudo-conductivity may be defined for a Dewar vessel (as an extreme case) or for evacuated multifoil insulations but there is no continuous or differentiable temperature field at all. Even if gas pressure is high, radiative contributions can be substantial.

6.1.2 Minimum Optical Thickness

Minimum optical thickness, $\tau_0 \ge 15$, required in Sect. 3.3 for definition of a nontransparent medium results from a Monte Carlo simulation (compare Caps [26] or standard literature on radiative transfer), in dependence of optical thickness, of radiation transmitted by scattering through a homogeneous

medium. A strongly *anisotropic* radiation source (like laser radiation) has been assumed in this simulation. *Isotropic* distribution of the residual radiation was obtained if $\tau_0 \geq 15$. Isotropic distribution of radiation means that the radiation source, at these positions, τ_0, no longer can be identified. If this is fulfilled also at all wavelengths, the medium is nontransparent.

6.2 Appendix A2: Experimental Values of the Thermal Emissivity, ε, of Solids and Thin Foils

Touloukian [56] is one of the traditional data sources that in addition to Chap. K1 can be consulted for experimental values of the integrated, hemispherical emissivity, ε, of solids. For Al-surfaces,

7) "Alcoa No. 2 reflector plate measured in vacuum": ε. = 0.026 at 76 K

8) "Alcoa No. 2 reflector plate sanded with fine emery": ε. = 0.032 at 76 K

9) "Alcoa No. 2 reflector plate cleaned with alkali" ε. = 0.035 at 76 K

12) "sheet, liquid honed" ε. = 0.14 at 76 K

31) "plate hand-polished" ε. = 0.06 at 227

While these data demonstrate the dependence of the emissivity of the solid Al on its surface quality (morphology), these data, and the emissivities given in Chap. K1, *cannot* provide automatically the emission properties also of thin Al films, in particular of aluminized thin polymer foils. In general, thermal transport properties of thin films are not the same as of bulk material. This concerns thermal conductivity as well as emissivity of the films.

With respect to conductivity, thin films do not grow under thermodynamic equilibrium conditions, which means the concentration of defects can be very large. Further, at cryogenic temperatures, the mean free path, l_e, of electrons may be much larger than the thickness, d, of Al-coatings on Mylar foils, and the thermal conductivity may be strongly reduced by scattering at interfaces, imperfections, textures and grain boundaries. At room temperature, l_e in very pure Al amounts to about 0.04 μm, just the usual thickness of a one-side Al-film on Mylar foil.

Second, if l_e is large in comparison to the penetration depth, l_E, of the electromagnetic field, the electrons are subject to variations of field strength in the film (anomalous skin-effect). This results in an increase of the thermal emissivity of the Al-film, if the thickness is very small.

Radiative properties of thin films can be found in the elder literature, e.g., Turner [57], and, specialized on Al-coated polymer foils, in recent publications, e.g., [58] or [59]. Musilova specifies very small emissivity values for Al-coated polyester foils, between $0.012 \leq \varepsilon \leq$ and 0.018, at temperatures between 30 and 140 K.

Concerning single- or double sided metallizations on polymer foils, emittance of an uncoated side is higher than that of a coated side. Al-coatings with thickness less than 40 nm are partly transparent to infrared radiation. This means an infrared "observer" sees the emissive properties of the underlying polymer film. Kutzner [18], p. 400, Table 1, correlates coating thickness of vapor-deposited Al films with electrical surface resistance.

The presence of spacers requires a correction of the emissivity of the foils to "effective values" if their surface density is substantial. Tien [60] reports thermal emissivity of *continuous* Mylar foil of about $\varepsilon = 0.4$. The surface density of modern spacer materials amounts to only about 5 g/m^2 polyester, i.e., Mylar tulles, with 50 μm filaments and mesh size of about 2 mm. The contribution to the effective emissivity of a multilayer insulations by this material accordingly will be very small. This may be quite different if fiberglass papers or other spacer materials with higher surface densities are applied.

6.3 Appendix A3: Transient Experimental Method to Separate $\dot{Q}_{sc}$ from $\dot{Q}_{Rad}$ in Multilayer Superinsulations

To describe the method, let $\dot{Q}_{Total,st}$ and $\dot{Q}_{Shields,st}$ denote total *stationary* heat losses of a storage tank and *stationary* heat losses through its multi-foil insulations, respectively. Thermal bridges, $\dot{Q}_{Bridge,st}$, also stationary, comprise thermal contacts of the shields to the ambient and the bellow of the cryostat (compare Fig. 11) but without supports of the inner tank. We have

$$\dot{Q}_{Total,st} = \dot{Q}_{Shields,st} + \dot{Q}_{Bridge,st} \tag{A6}$$

Kaganer [1] pp. 164–167, derives Eq. (A6) for *transient* evaporation rates, $\dot{Q}_{Total}(t)$,

$$\begin{aligned} &\mathrm{In}\left[\left(\dot{Q}_{Total}(t) - \dot{Q}_{Total,st}\right)/\dot{Q}_{Total,st}\right] \\ &\quad = \mathrm{In}\left(2\dot{Q}_{Shields,st}/\dot{Q}_{Total,st}\right) - \pi^2\, a\, t/D^2 \end{aligned} \tag{A7}$$

In Eq. (A7), the symbol a denotes thermal diffusivity of the insulations, and D its thickness. By plotting the experimental $\dot{Q}_{Total}(t)$ in the co-ordinates

$$\dot{Q}(t) = \mathrm{In}\left[\left(\dot{Q}_{Total}(t) - \dot{Q}_{Total,st}\right)/\dot{Q}_{Total,st}\right] \tag{A8}$$

versus time, t, the curve, $\dot{Q}(t)$, shows a straight part at large times so that the diffusivity, a, of the insulations and the heat losses $\dot{Q}_{Shields}$ can be determined from slope and intercept with the ordinate at $t = 0$, respectively. If density and heat capacity of the foils are known, a radiative "pseudo"-conductivity can be calculated from the corresponding "pseudo-diffusivity."

Rough, order of magnitude agreement is found for the diffusivity, with values typical for multilayer superinsulations, and for $\dot{Q}_{Shields,st}$ [20]. Successful application of Kaganer's method significantly depends on existence of a wide linear portion of the curve $\dot{Q}(t)$, and, consequently, on the quality of linear fits to the data.

Laboratory experiments should be performed for further check of the method.

Fluid Dynamics and Pressure Drop

L1.1 Pressure Drop in Single Phase Flow in Pipes

Werner Kast[2] (*Revised by Hermann Nirschl*[1])
[1]Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany
[2]Technische Universität Darmstadt, Darmstadt, Germany

1 General Pressure Drop Equation

Energy requirements for flow through a heat exchanger are related to the heat transfer coefficient α. If adequate pressure is available, high values of α, and thus small transfer areas, can be achieved. In equipment design, the capital and running costs must be weighed up against one another to determine the most economic system.

As a rule, determination of performance cannot be restricted to the calculation of pressure drop within the tubes or in the space surrounding the tube bundle, because it represents only a fraction of the flow losses in equipment. The calculation must include connections, extensions, and restrictions to flow, valves, bends, elbows, and baffles outside the tube bundle. Data for this purpose are presented in the following pages.

In the chapters that follow, the general term "fluid" embraces compressible gases with pronounced fluctuations in density and liquids that undergo only slight changes in density and have little compressibility. Application of similarity rules is valid only for substances that obey Newton's law, that is, whose viscosity is independent of shear. The many fluids that do not conform to this requirement, that is, non-Newtonian liquids, constitute a separate branch of study [1]. Strongly diluted gases also do not exhibit Newtonian flow. In this case, the mean free path of the molecules can be likened to the dimensions of a tube, and the friction is largely governed by the frequency of collisions between the particles and the fixed walls. Hence, special treatment is required for flow studies in a high vacuum [1, 2].

The following equation for the determination of pressure drop applies to all kinds of flow patterns, for example, laminar or turbulent:

$$\Delta p = \zeta a \frac{\rho w^2}{2} \qquad (1)$$

with ζ as the drag coefficient and a as a factor that depends on the nature of the flow problem.

Thus, for flow through pipes and ducts,

$$a = f(l/d_i)\ (\mathrm{l} = \text{length of pipe});$$

for flow through valves and pipeline fittings,

$a = 1$;

for crossflow over tube bundles,

$$a = f(n, l/d_i) \quad (n = \text{number of tubes}).$$

The average values for the density ρ and the velocity w in the direction of flow should be inserted in Eq. (1). If the change in density caused by the pressure drop is significant, the calculation should be performed in a number of steps. The same procedure is usually adopted in practice for non-isothermal flow. More accurate equations that allow for the expansion of gases and vapors and for heat losses during flow can be found in the literature [3, 4].

The principles of fluid dynamics lie outside the scope of Part L, although a close relationship exists between them and the determination of pressure drop. Attention is thus drawn to the works of reference on this subject [5–7].

L1.2 Pressure Drop in Flow Through Pipes

Werner Kast[2] (*Revised by Hermann Nirschl*[1])
[1]Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany
[2]Technische Universität Darmstadt, Darmstadt, Germany

1 Pressure Drop in Flow Through Pipes of Circular Cross-section

The pressure drop in pipe flow is given by

$$\Delta p = \zeta \frac{l}{d_i} \frac{\rho w_i^2}{2} \tag{1}$$

The drag coefficient ζ depends on the Reynolds number for flow within the tube, that is,

$$\mathrm{Re_i} = \frac{w_i \rho d_i}{\eta} \tag{2}$$

The properties η and ρ of the fluid and the velocity w_i refer to the average pressure $(p' + p'')/2$ and the average temperature $(\vartheta' + \vartheta'')/2$ in the tube. They may change considerably in the direction of flow; in this case, it is advisable to calculate the pressure drop in the individual sections.How heat transfer can be determined if allowance is made for the relationship of the physical properties to temperature was demonstrated in Chap. C2. Likewise, the pressure drop can be reliably calculated in streams with large fluctuations in temperature if it is determined together with the heat transfer coefficient at two points at the least [8].

Below the critical Reynolds number $\mathrm{Re_i} \approx 2320$, flow is laminar; above it, turbulent flow is likely. In the transition range of $\mathrm{Re_i} \approx 2320$ to $\mathrm{Re_i} \approx 8000$, flow may still be laminar in tubes with smooth inner surfaces if the inflow is quite calm and the tube inlet is well finished. As the pipe surfaces become rougher, the transition from laminar to turbulent flow is shifted in the direction of lower Reynolds numbers, but it never falls below a value of 2,320.

1.1 Laminar Flow

The Hagen-Poiseuille law, which is described by (Eq. 3), applies very accurately to smooth (glass, brass, or copper) tubes; it is also valid for rough tubes of up to $k = 0.07$, that is, slightly rusted steel or cast iron tubes:

$$\Delta p = \frac{32 \eta w_i l}{d_i^2} \tag{3}$$

The law can also be expressed in terms of the drag coefficient by combining (Eqs. 1–3), that is,

$$\zeta = \frac{64}{\mathrm{Re_i}} \tag{4}$$

1.2 Turbulent Flow

The roughness of the tube wall is an important factor. The only surfaces for which an accurate rule can be quoted for the resistance are those that are technically smooth (glass, drawn brass, copper tubes. etc.).

According to Blasius, the following simple formula applies in the $\mathrm{Re_i} \approx 3{,}000$ to $\mathrm{Re_i} \approx 100{,}000$ range:

$$\zeta = \frac{0.3164}{\sqrt[4]{\mathrm{Re_i}}} \tag{5}$$

The Hermann equation is convenient for the higher range from $\mathrm{Re_i} \approx 2 \cdot 10^4$ to $\mathrm{Re_i} \approx 2 \cdot 10^6$:

$$\zeta = 0.00540 + \frac{0.3964}{\mathrm{Re_i}^{0.3}} \tag{6}$$

For even higher Reynolds numbers ($\mathrm{Re} > 10^6$), ζ can be obtained from the Prandtl and von Kármán equation, that is,

$$\frac{1}{\sqrt{\zeta}} = -0.8 + 2 \log\left(\mathrm{Re_i} \sqrt{\zeta}\right) \tag{7}$$

1.3 Effect of Roughness

Much greater resistance to flow is encountered if the surfaces are rough. It depends solely on the roughness in turbulent flow; but, in the transition zone, it also depends on the Reynolds number $\mathrm{Re_i}$. The numerous observations that have been made have failed to establish a general relationship between pressure drop and roughness that would embrace the multiplicity of cases that are likely to occur in practice. In other words, a factor of uncertainty is attached to the determination of pressure drop in rough pipes. The following instructions may lead to greater accuracy, and are preceded by some brief explanations to ensure that they are correctly applied.

There are essentially two forms of roughness:

- Extended undulations and
- Slight protuberances

The latter may be rounded off and uniformly distributed, or they may be sharp and angular and distributed at random. At low Reynolds numbers, the boundary layer of the fluid is often thick enough to cover all projections. Although the pressure drop in this case is somewhat higher than that in a smooth tube, the relationship to Re_i is subject to much the same laws. As the Reynolds number increases, the boundary layer becomes thinner, so that the protuberances are exposed in the sequence of their sizes, and the turbulence is progressively increased until the relationship is quadratic. Hence the shape of the resistance curves derived from measurements gives an idea of the roughness. Likewise, changes in the shape over long running periods can indicate the thickness and nature of any deposits. The roughness depends on the material from which the inner surfaces of the tube have been formed and progresses from undulatory to protuberant in roughly the following sequence: vitreous, bituminized, drawn, sandblasted, galvanized, briefly stored, rusted, fouled after long periods of operation, and covered by scale.

Regardless of the numerous forms that roughness can assume and how it is distributed, it can be defined in general terms by a "relative roughness," which is given by

$$\varepsilon = \frac{K}{d_i} \tag{8}$$

where K is the average height of all the projections. Values that can be adopted as a guide for pipes are listed in Table 1. If flow is completely governed by roughness, the quadratic relationship for the resistance applies, and ζ is independent of Re_i. The Prandtl/Kármán equation for this case is

$$\frac{1}{\sqrt{\zeta}} = 2\log\left(\frac{d_i}{K}\right) + 1.14 \tag{9}$$

The relationship to both Re_i and K/d_i is allowed for in the Colebrook and White equation for the transition between flow over smooth and flow over rough surfaces, that is,

$$\frac{1}{\sqrt{\zeta}} = -2\log\left[\frac{2.51}{Re_i\sqrt{\zeta}} + \frac{K/d_i}{3.71}\right] \tag{10}$$

For practical convenience, (Eqs. 9) and (10) are presented graphically in Fig. 1.

The roughness in drawn steel tubes is predominantly undulatory, but the extent appears to differ with the diameter. The drag coefficient for this common type of tube can be obtained from the Hausen diagram, which is reproduced in Fig. 2.

The pressure drop Δp can be determined by inserting in (Eq. 1) the drag coefficient obtained from Figs. 1 or 2.

A rough estimate of the pressure drop in coolers can be derived from Figs. 3 and 4. Figure 3 applies for smooth tubes, for example, brass, copper, and glass; Fig. 4, for drawn steel tubes; and values of ζ are obtained from Fig. 2 (steel tubes) and Eqs. (5–7) (brass tubes). The water temperature in all cases is 25°C, and no allowance has been made for inlet and outlet losses.

L1.2. Table 1. Absolute roughness in millimeters for various materials

Drawn glass, lead, copper and brass tubes		0–0.0015
Drawn steel tubes	New	0.04 (0.02–0.1)
	Cleaned after long service	0.15–0.20
	Moderately rusted or slightly fouled	$\leq$ 0.40
	Heavily fouled	$\leq$ 3.0
Galvanized sheet steel	Smooth (air ducts)	0.07
Galvanized steel tubes	Normally galvanized	0.15
Welded steel pipes	New	0.05 (up to 0.1)
	New, bituminized	0.05
	Used, cleaned	0.15–0.20
	Uniformly rusted	$\leq$ 0.40
	Slightly fouled	1–1.5
	Heavily fouled	2–4
Riveted steel pipe		0.9 (0.5–10)
Cast iron pipes	New	0.26 (up to 1)
	New, bituminized	0.10–0.15
	Slightly rusted	1.0–1.5
	Fouled	1.5–4.0
Concrete conduits	Smooth finish	0.3 (up to 0.8)
	Rough	1.2 (up to 3)
Fibrous concrete pipes	(Eternit; Toschi)	0.05–0.1
Wooden boards	Unplaned	0.7
	Planed	0.2
Brickwork	Normal bonds	1.3
Plastic tubes		$\leq$ 0.0015

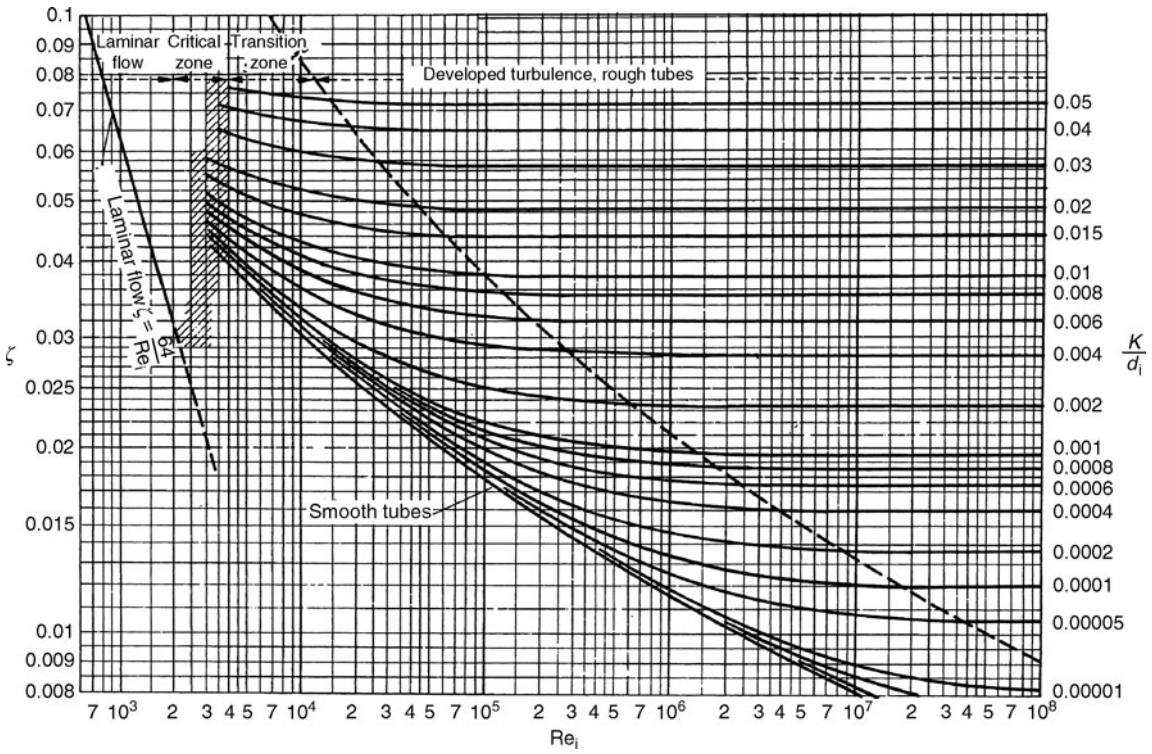
Figures 5–13 are valid for air at 50°C in steel pipes of standard diameters. The relevant drag coefficients are obtained from Fig. 2. These diagrams can also be applied to obtain approximations for any other gas, provided that any changes in the Reynolds number have only a slight effect on ζ. No allowance has been made for inlet and outlet losses. The approximate transition from laminar to turbulent flow, as determined from (Eq. 10), is indicated in the diagrams.

Values submitted as a guide in estimating the velocity w of various media in tubes are listed in Table 2.

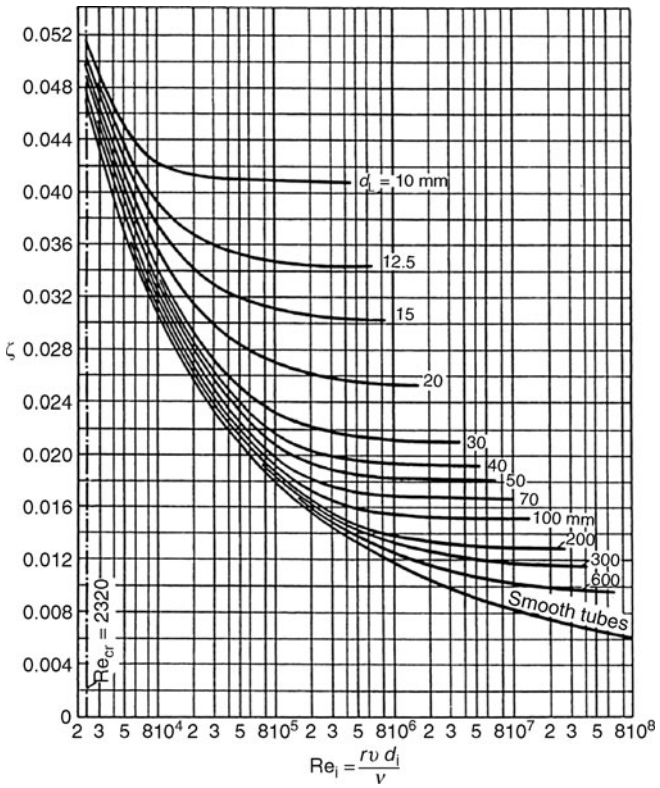
However, the optimum velocity in any particular case must be determined by a profitability study, in which the peculiarities of the entire process may frequently prove to be the deciding factor.

1.4 Coils

As is evident from Fig. 14, the geometry of a coil can be described by the inner diameter d_i of the tube that has been wound into the form of a coil, the average diameter D_w of the winding, and the pitch h.



L1.2. Fig. 1. Drag coefficient ζ for rough tubes as a function of the roughness K/d_1 and the Reynolds number Re_i.



L1.2. Fig. 2. Drag coefficient ζ for freshly drawn steel tubes. Compiled by Hausen [9] from experimental values submitted by various research workers.

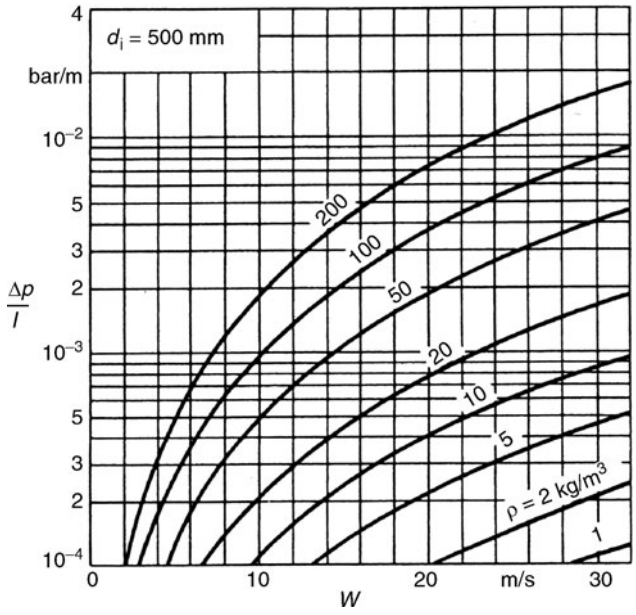
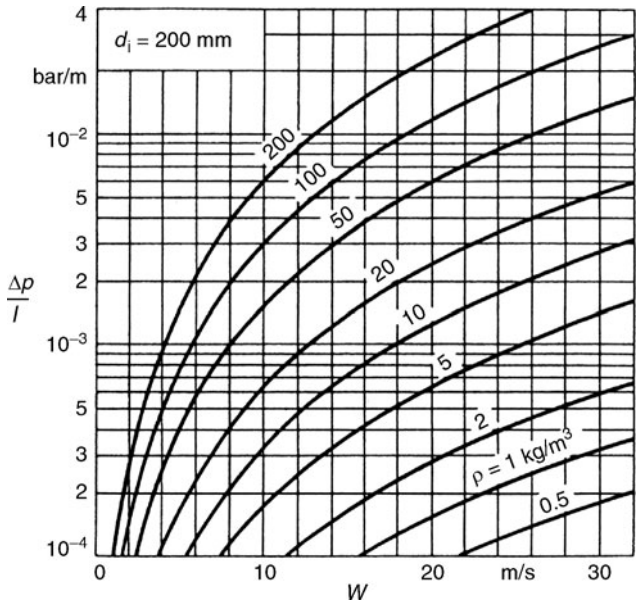
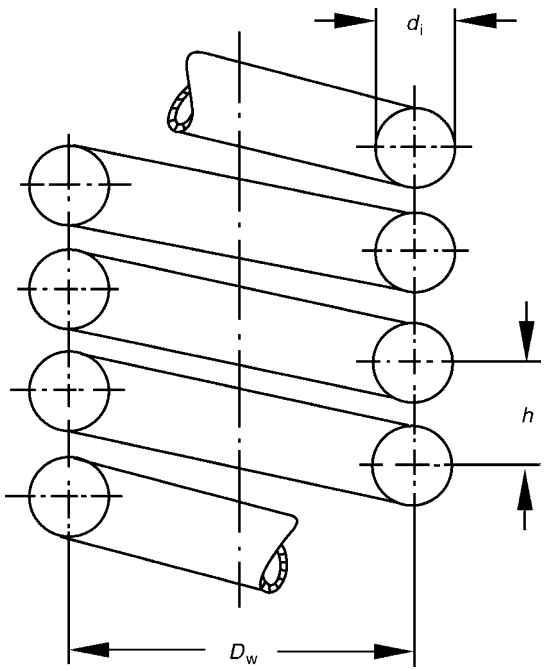
L1.2. Fig. 11. Pressure drop for air flow at 50°C in drawn steel tubes (d_i = 100 mm).



L1.2. Fig. 13. Pressure drop for air flow at 50°C in drawn steel tubes (d_i = 500 mm).



L1.2. Fig. 12. Pressure drop for air flow at 50°C in drawn steel tubes (d_i = 200 mm).



L1.2. Fig. 14. Geometry of a coil.

Owing to the tube's curvature, centrifugal forces are initiated during flow and give rise to a secondary current in the form of a double vortex. The pressure drop is thus greater than that in a straight tube and, in analogy to (Eq. 1), is given by

$$\Delta p = \zeta_w \frac{l}{d_i} \frac{\rho w_i^2}{2} \qquad (1a)$$

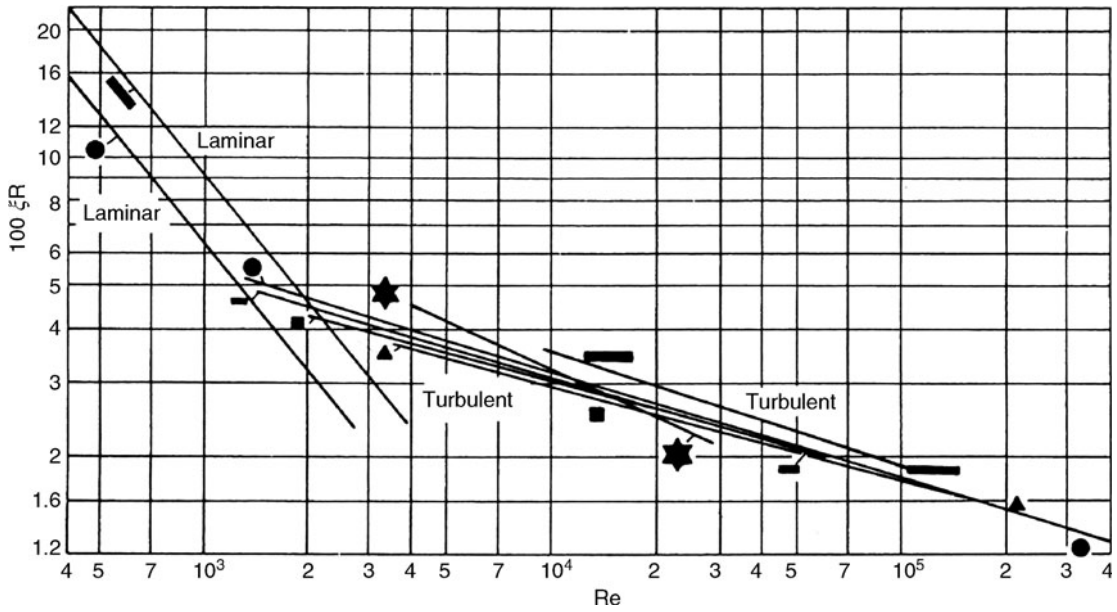
where l is the length of the coiled tube.

The drag coefficient ζ_w defined by this equation depends on the Reynolds number Re_i, as given by (Eq. 2), and on the d_i/D ratio, where D is the average diameter of curvature of the coil and is obtained from

$$D = D_w \left[1 + \left(\frac{h}{\pi D_w}\right)^2\right].$$

Significant differences between D and D_w exist only if the tubes are strongly bent and the pitch h of the coils is large. If $h < D_w$, it can be safely assumed that $D = D_w$ in the determination of pressure drop.

Gnielinski [10] compared the measured values determined by many research workers and came to the conclusion that the drag coefficients in isothermal laminar and isothermal



L1.2. Fig. 15. Drag coefficient for flow in smooth straight tubes of various cross-sections (Schiller [13]).

L1.2. Table 2. Velocities of various media in tubes

Oil	In oil lines	*w* in m/s
		1–2
Water	In lines of some length	0.5–1
	In heat exchanger tubes	1–3
	Downstream from reciprocating pumps	1–2
	Downstream from centrifugal pumps	1.5–3
	Upstream from turbines	2–7
Gases	At low pressures	5–30
	At moderate pressures	5–20
	At high pressures	3–6
Compressed air	In ducts	2–4
Steam	1–10 bar	15–20
	10–40 bar	20–40
	40–125 bar	30–60

turbulent flow could be calculated from the Mishra and Gupta [11] equations. That for laminar flow in the $1 < \{\mathrm{Re_i}\sqrt{d_i/D}\} < \{\mathrm{Re_{i,crit}}\sqrt{d_i/D}\}$ range is

$$\zeta_w = \frac{64}{\mathrm{Re_i}}\left[1 + 0.033\left(\log_{10}\left\{\mathrm{Re_i}\sqrt{\frac{d_i}{D}}\right\}\right)^{4.0}\right] \qquad (11)$$

The corresponding equation for turbulent flow in the $\mathrm{Re_{i,crit}} < \mathrm{Re_i} < 10^5$ range is

$$\zeta_w = \frac{0.3164}{\mathrm{Re_i^{0.25}}}\left[1 + 0.095\left(\frac{d_i}{D}\right)^{1/2}\mathrm{Re_i^{1/4}}\right] \qquad (12)$$

As the curvature ratio d_i/D increases, the transition from laminar to turbulent flow is shifted in the direction of higher Reynolds numbers. It would appear that flow disturbances are initially attenuated by the secondary stream and do not effect a transition to turbulence until the flow velocity reaches a certain high value that depends on the curvature.

An equation suggested by Schmidt [12] is valid for the critical Reynolds number:

$$\mathrm{Re_{i,crit}} = 2300\left[1 + 8.6\left(\frac{d_i}{D}\right)^{0.45}\right].$$

Equations (11) and (12) may not be applied to short bends because the energy consumption is increased at the start of the bend as a result of the cross-currents formed and the attendant complete rearrangement of the velocity profile. Consequently, the drag coefficient for a 90° bend is much higher than the figure calculated from these equations.

2 Pressure Drop in Flow Through Pipes of Noncircular Cross-section

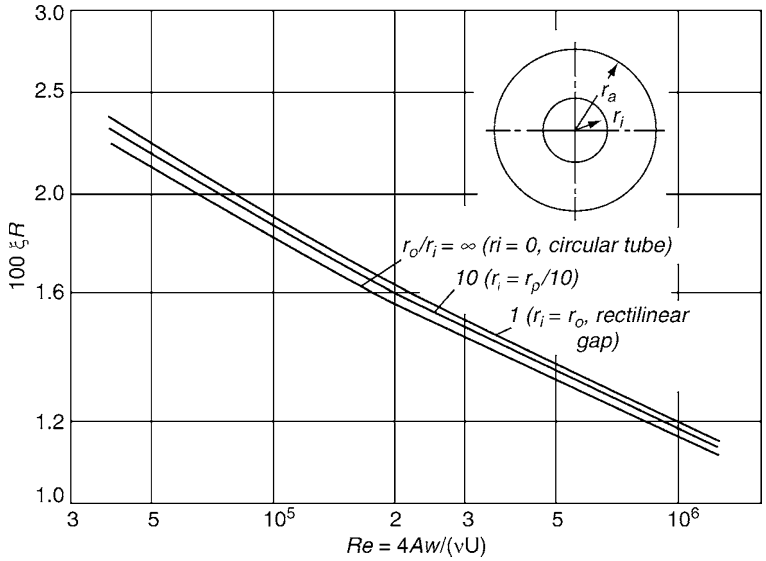
2.1 Turbulent Flow

According to Schiller [13] and Fromm [14], the hydraulic diameter d_h allows (Eq. 5) to be applied for any given cross-section. It is given by

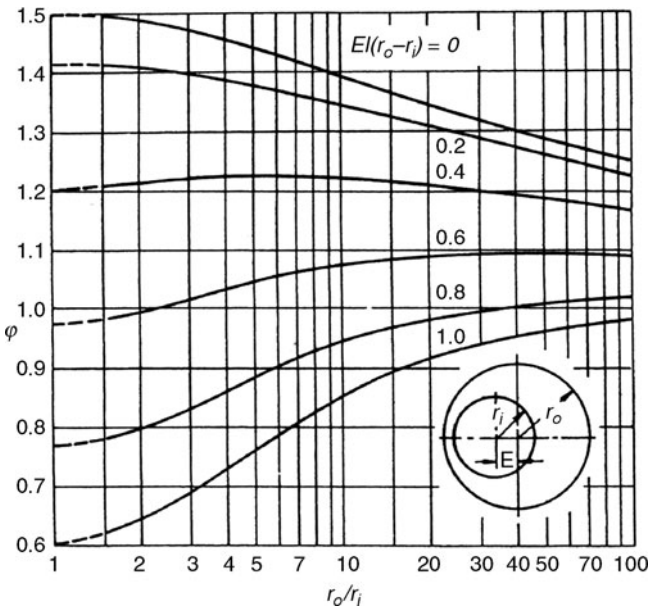
$$d_h = 4A/U \qquad (13)$$

where A is the cross-sectional area and U is the length of the participating periphery.

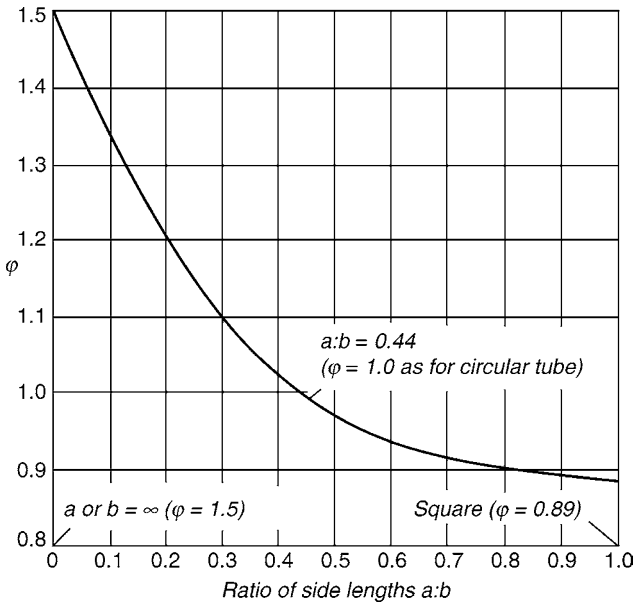
A plot of the drag coefficient ζ against Reynolds number Re for pipes of various cross-sections is reproduced in Fig. 15, and the relationship for flow through an annulus is shown in Fig. 16. Gnielinski [16] gives an equation for the drag



L1.2. Fig. 16. Drag coefficient for flow in the annulus of smooth concentric tubes of various diameters (Tiedt [15]).



L1.2. Fig. 17. Relationship between φ and r_o/r_i for laminar flow in the annulus of concentric $\{E/(r_o - r_i) = 0\}$ and excentric $\{E/(r_o - r_i) > 0\}$ tubes. $\varphi = 1.0$ for $r_o/r_i = \infty$.



L1.2. Fig. 18. Factor φ for laminar flow in tubes of rectangular cross-section.

coefficient depending on Reynolds number for an annulus $\zeta = (1,8 \log \mathrm{Re}^* - 1,5)^{-2}$ with the Reynolds number Re^* modified with the diameter ratio which is arbitrary. For details see [16].

2.2 Laminar Flow

For the determination of the drag coefficient in laminar flow, a factor φ, which depends on the geometry of the cross-section, is introduced into (Eq. 4), that is,

$$\zeta = \varphi \frac{64}{\mathrm{Re}} = \varphi \frac{16\nu U}{wA} \tag{14}$$

It can be obtained from Figs. 17 and 18. For an annulus $\zeta = \frac{64}{\mathrm{Re}^*}$. For details see again [16].

L1.3 Pressure Drop in Flow Through Pipes of Changing Cross-section

Werner Kast[2] (*Revised by Hermann Nirschl*[1])
[1]Karlsruher Institut für Technologie (KIT), Karlsruhe, Germany
[2]Technische Universität Darmstadt, Darmstadt, Germany

1 Abrupt Restrictions in Cross-section

Flow into a sudden restriction or from the head of a heat exchanger into tube bundle entails the following pressure drop in addition to the Bernoulli equation:

$$\Delta p = \zeta_{in} \frac{\rho w_i^2}{2}. \quad (1)$$

The additional pressure drop is caused by the vena contracta at the inlet and by the vortices that attenuate after a length of about 8 d_i to 10 d_i has been traversed in the tube. According to Stephan [17], a much longer attenuation path l_A has to be traversed before the final smooth flow profile is attained. Thus, if flow is laminar,

$$l_A \approx 0.13 \mathrm{Re}_i d_i. \quad (2)$$

If flow is turbulent,

$$l_A \approx 0.0575 \mathrm{Re}_i d_i. \quad (3)$$

Initially, the flow velocity is the same over the entire cross-section. Within the length l_A, it is decreased at the tube walls owing to the deceleration caused by increased friction and the kinetic (shear) energy required to establish the flow profile. Thus, the pressure drop is greater than the linear values obtained from Eqs. (1) and (3) on Subchap. L1.2.

All these effects are embraced by the term ζ_{in}.

If the fluid mass at the tube inlet is stationary or flows at a very low velocity, energy must be applied to accelerate it to the average velocity w_i, and the entire pressure drop is

$$\Delta p = (\zeta_{in} + 1) \frac{\rho w_i^2}{2}. \quad (4)$$

1.1 Narrowed Tubes

According to Kays [18], if the reduction in the diameter of the tube is abrupt as is shown in Fig. 1, ζ_{in} can be obtained from Fig. 2, in which it is shown as a function of the area ratio A_2/A_1 of the two cross-sections with the Reynolds number Re_i as parameter.

1.2 Inflow in Tube Bundles

Studies by Linke [19] have revealed that ζ_{in} depends on the spacing ratio s/d_i in the tube bundle (cf. Fig. 3) if flow is turbulent and Re > 20,000. If flow is laminar, ζ_{in} can be estimated by analogy from Fig. 2. Gnielinski [20] also gives values for ζ on the jacket side of the inlet and outlet ports of a double pipe heat exchanger.

1.3 Outflow from Vessels

It can be seen from Fig. 4, which was drawn up from data compiled by Weisbach, that the drag coefficient ζ_{in} greatly depends on the conditions at the tube inlet.

The values given can be transferred into Fig. 2 by entering them on the $A_2/A_1 = 0$ ordinate and connecting them to the zero ordinate at $A_2/A_1 = 1.0$ by the closest approximation to a straight line.

2 Continuous Reduction in Cross-sectional Area

If the cross-section is continuously reduced as is illustrated in Fig. 5, the stream of liquid in the jet is not separated provided that $\alpha < 40°$. The pressure drop is very low and of the order of

$$\Delta p = 0.04 \frac{\rho w_2^2}{2}. \tag{5}$$

Hence, almost the entire pressure is converted into kinetic energy in convergent tubes.

As the angle α increases, the case approaches that of an abrupt transition, in which the pressure drop is substantially greater. Long conical nipples are supplied for small angles α. In this case, the additional length must be calculated, for example, to obtain the average values for A and w.

If the inner surfaces of the tube are smooth and the Reynolds numbers are high, a factor of even less than 0.04 may be inserted in (Eq. 5).

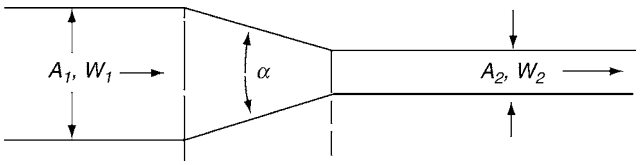
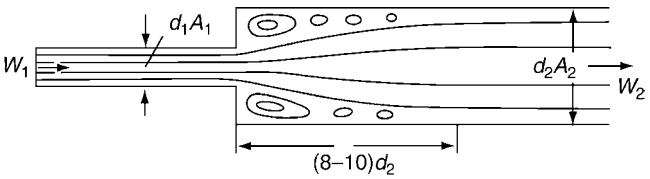
L1.3. Fig. 4. Drag coefficient ζ_{in} for outflow from vessels containing a stationary liquid.



L1.3. Fig. 5. Continuous reduction in cross-sectional area.



L1.3. Fig. 6. Sudden widening of cross-section.

3 Abrupt Widening of Cross-section

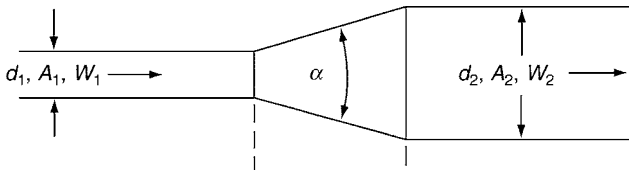
Figure 6 illustrates the flow of a liquid from a tube into a wide space, for example, the head of a heat exchanger or into a broader tube. An expanding jet with pronounced turbulence is thus formed. After it has traversed a length of 8 d_2 to 10 d_2, it is again accommodated against the walls of the tube. This outlet pressure drop is given by

$$\Delta p = (1 - A_1/A_2)^2 \cdot \frac{\rho w_i^2}{2}. \qquad (6)$$

where w_i is the velocity and ρ the density of the liquid in the tube. (Equation 6) is valid for turbulent flow. A correlation for the corresponding pressure drop in laminar flow has been established by Kays [18].

4 Continuous Widening of Cross-section

In continuously expanded tubes, as illustrated in Fig. 7, wall friction and turbulence do not permit ideal conversion of kinetic into pressure energy in accordance with the Bernoulli equation. The pressure drops in this case are given by



L1.3. Fig. 7. Continuous widening of cross-section.

$$\Delta p = \zeta' \left(1 - \frac{A_1}{A_2}\right)^2 \frac{\rho w_i^2}{2}. \qquad (7)$$

$$\Delta p = \zeta' \left(\frac{A_2}{A_1} - 1\right)^2 \frac{\rho w_i^2}{2}. \qquad (8)$$

where ζ' is a drag coefficient that is related to the angle of divergence as is indicated in Fig. 8.

The minimum pressure drop occurs at low angles, which depend as follows on the degree of turbulence:

Re	0.5	1.0	1.5	2.0	10^5
α	10	8.4	7.6	7.1	°

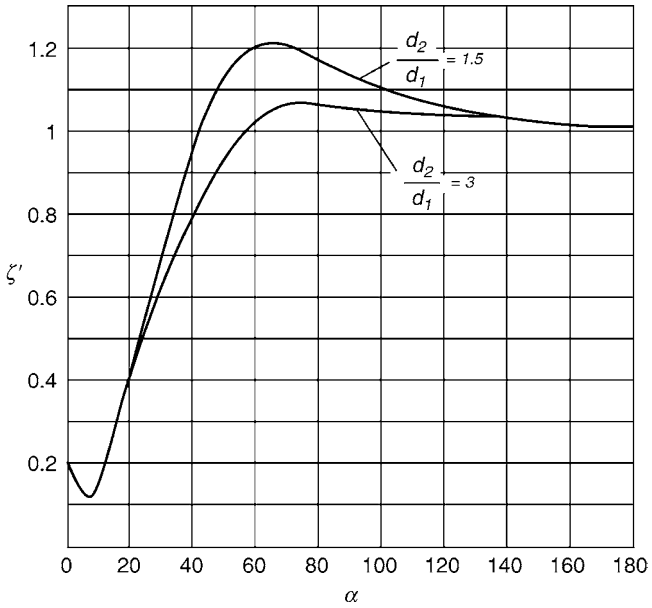
At even higher Reynolds numbers, the angle must be reduced to 5–6°. Another factor to observe is the roughness of the walls. For instance, the preferred angle for smooth walls ($K = 0.02$) is 7°; and for rough surfaces ($K = 0.04$), 9°.

5 Orifice, Nozzle, and Venturi meters

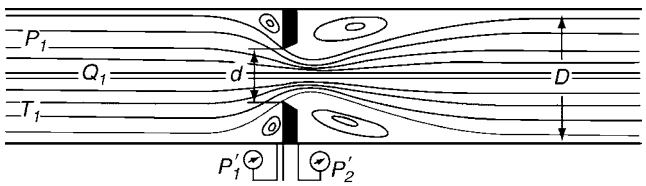
A schematic diagram illustrating flow through an orifice meter is presented in Fig. 9. The pressure drop is less than the differential pressure that can be read off on the gauge, because a large proportion of the kinetic energy is reconverted into pressure energy. The remaining pressure drop is given by

$$\Delta p = b(p_i' - p_2'),$$

where $p'_1 - p'_2$ in N/mm^2 is the differential pressure recorded on the instrument; b is a correction factor for orifice, nozzle, and



L1.3. Fig. 8. Drag coefficient ζ for expanded sections of tubes as a function of the angle of divergence and the tube diameter ratio d_2/d_1.



L1.3. Fig. 9. Flow through an orifice meter.

venturi meters and can be obtained from Fig. 10, in which it is shown as a function of the diameter ratio $m = (d/D)^2$.

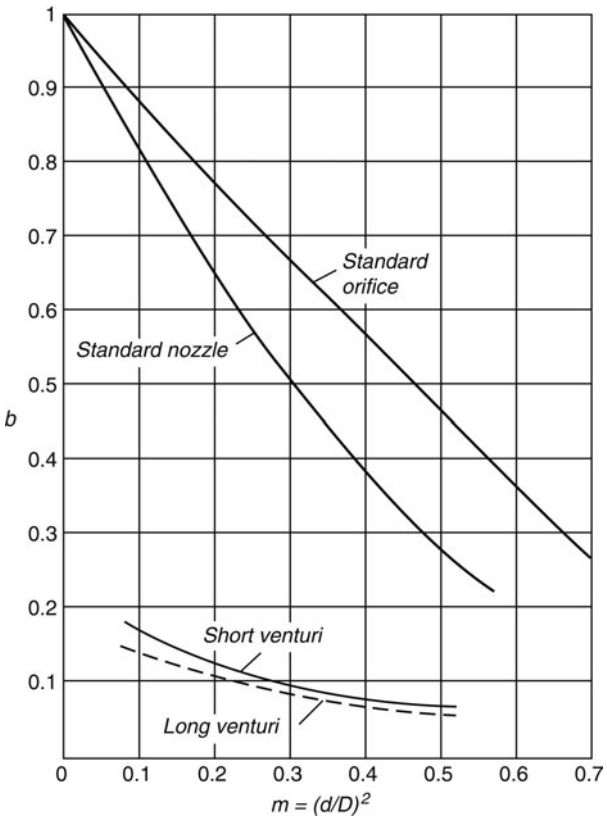
6 Tees and Oblique Junctions

The drag coefficients that occur in the following are valid for turbulent flow and can be regarded as being independent of Re_i. Laminar flow is rarely encountered in practice, and does not set in until $Re_i < 1{,}000$. The values for ζ increase considerably with a decrease in Re_i. (Equations 1–3) apply to the additional pressure drop caused by impact and vortices during demixing and mixing. Consequently, the frictional resistance in the tubes must be calculated up to the intersect of the tee-axes. If w_z is the velocity of the entire stream G_z, the pressure drop in the branch G_a will be given by (Eq. 9), and in the branch G_d, by (Eq. 10):

$$\Delta p_a = \zeta_a \frac{\rho w_z^2}{2}. \tag{9}$$

$$\Delta p_d = \zeta_d \frac{\rho w_z^2}{2}. \tag{10}$$

The drag coefficients ζ_a and ζ_d are presented in Figs. 11 and 12. They are valid for tubes of circular cross-section, branches of the same diameter as that of the header, and junctions with sharp edges. If the edges are rounded off, the coefficients become



L1.3. Fig. 10. Correction factor b for the determination of the remaining pressure drop at orifice, nozzles, and venturis.

somewhat smaller. The reduction may be about 10–30% if the radius of curvature is large, that is, $r = 0.1\ d_a$. Values for junctions at different angles can be obtained by interpolation.

For a flow into a junction in which the one branch has been blanked off, the effect of the angle between the branch and the header and the diameter ratio $m = (d_1/d_2)^2$ is shown in Fig. 13.

Values for the pressure drop on Y-junctions and tees of the types illustrated in Figs. 11, 12, and 14 can be represented by

$$\Delta p = \zeta_v \frac{\rho w_v^2}{2}. \tag{11}$$

where w_v is the velocity in the limbs.

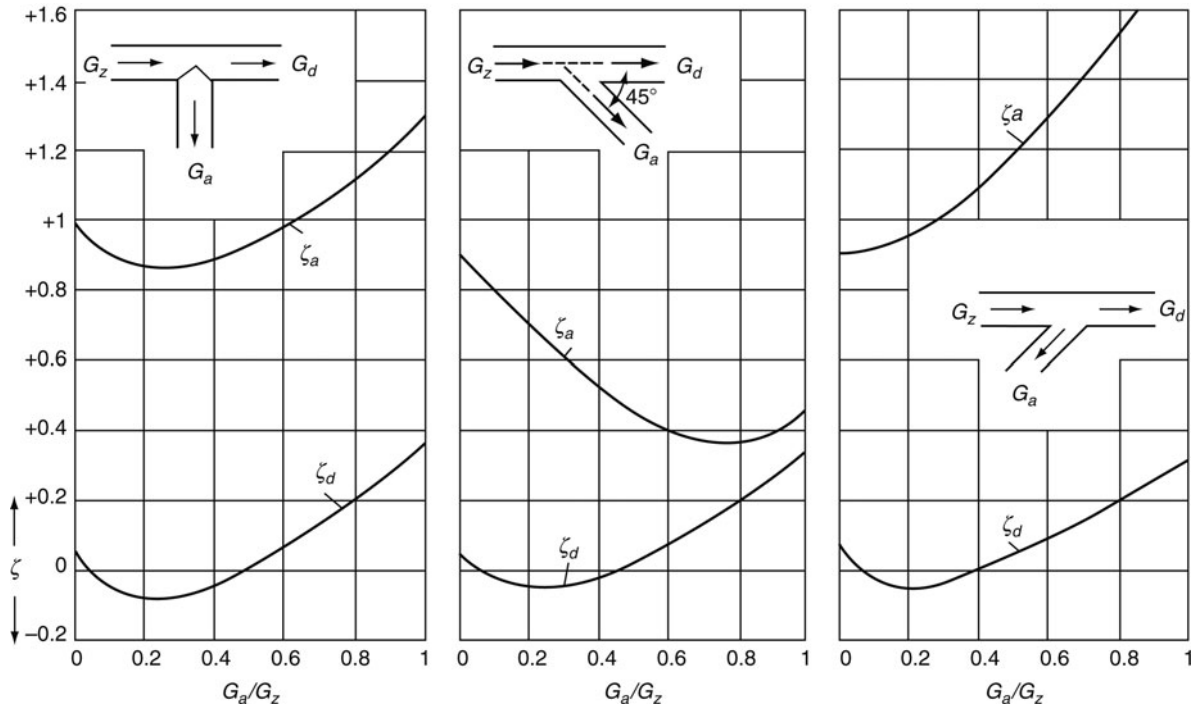
The sum of the cross-sectional areas of the two limbs in the relevant experiments was 1.1 times the cross-sectional area of the header, and the edges were slightly rounded. In the one case, each of the convergent or divergent streams accounted for one half of the flow rate. In the other case, one limb was blanked off, and the entire stream flowed into or out of the other.

Drag coefficients for tees and Y-junctions are listed in Table 1.

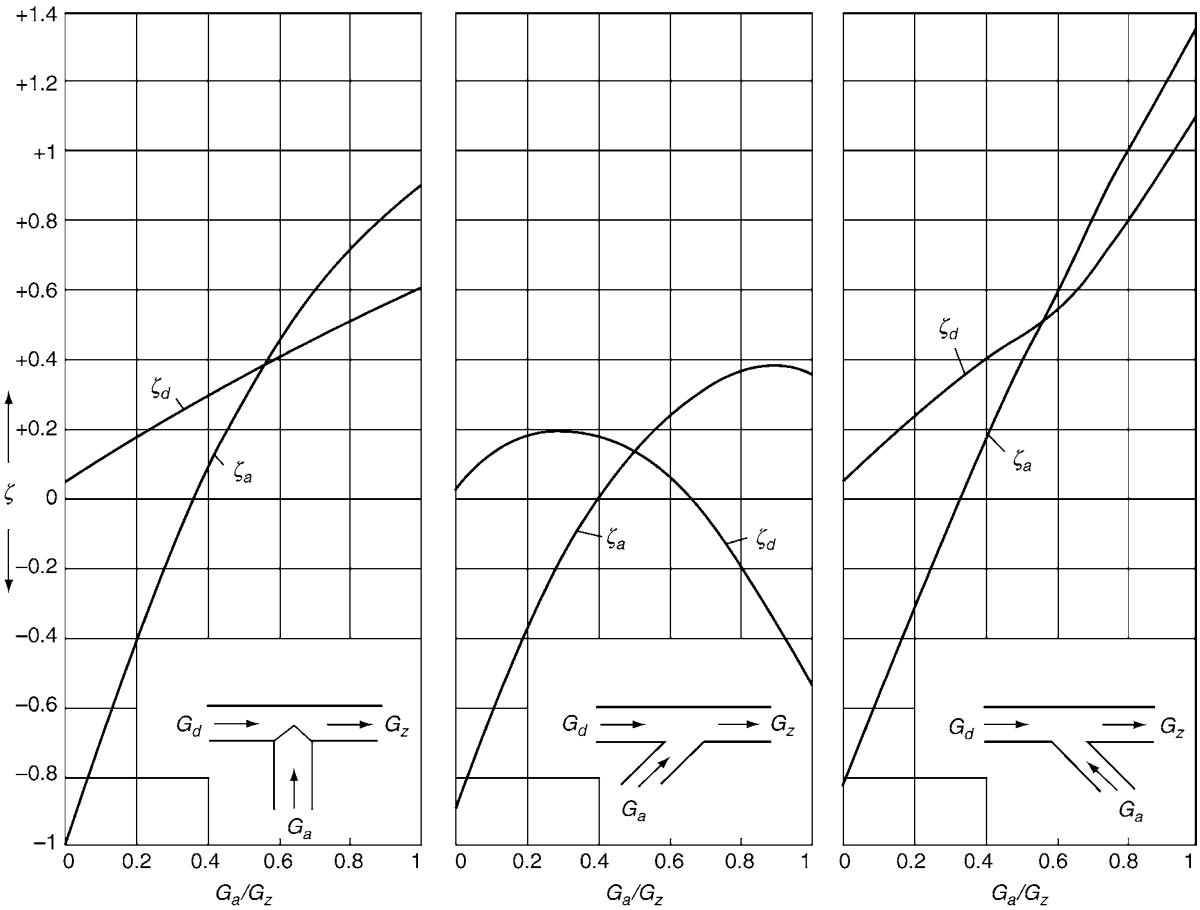
7 Changes in the Direction of Flow

Pressure drops additional to those caused by wall friction occur as a result of flow separation and cross-currents when flow is diverted through bends. They are given by

$$\Delta p = \zeta_b \frac{\rho w^2}{2}.$$



L1.3. Fig. 11. Flow divergence – drag coefficients ζ_a and ζ_d as functions of the flow rate ratio G_a/G_z.



L1.3. Fig. 12. Flow convergence – drag coefficients ζ_a and ζ_d as functions of the flow rate ratio G_a/G_z.

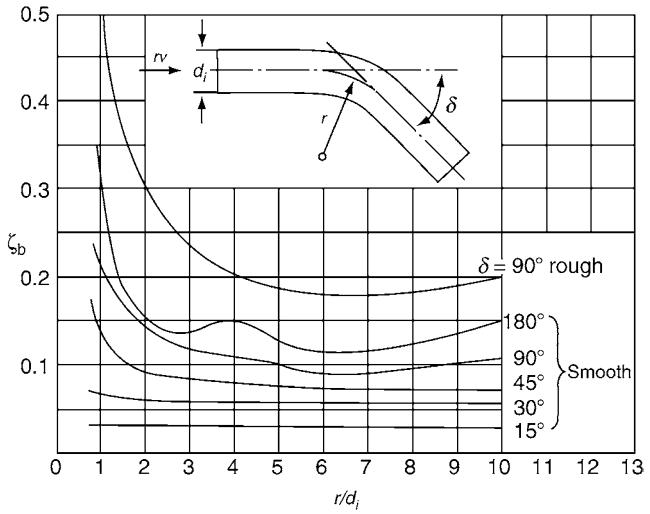
L1.3. Fig. 14. Tee (**a**) and Y-piece (**b**) for divergent and convergent flow. — divergent flow; ––– convergent flow.

L1.3. Table 1. Drag coefficients for tees and Y-junctions

		Values of ζ_v for symmetrical	
		Divergence	Convergence
Y-junction	d_i = 350 mm	0.067	0.17
	d_i = 140 mm	0.035	0.08
Tee	d_i = 144/162 mm	2.87	1.56
		Values of ζ_v for lateral	
		Outflow	Inflow
Y-junction	d_i = 350 mm	0.19	0.24
	d_i = 140 mm	0.25	0.24
Tee	d_i = 144/162 mm	0.72	0.99



L1.3. Fig. 15. Drag coefficient ζ_b for high Reynolds numbers in bends (Re $> 10^5$).

7.1 Bends

The drag coefficient ζ_b increases with the angle δ through which the stream is diverted. Another major factor is the ratio of the bend radius r to the tube inner diameter d_i. The results obtained for Re $> 10^5$ are shown in Fig. 15.

It is evident form Fig. 16 that the drag coefficient for 90°-bends increases significantly with a decrease in Reynolds number.

The drag coefficient for three-dimensional curvature can be obtained by adding the values of ζ_b for the individual sections of curved pipe, but this applies only if each is separated from the other by a straight tube of more than 10 d_i length. The closer they are spaced, the more confused the flow pattern. However, the total pressure drop is less than that of the sum for the individual curves, as can be seen by comparing the coefficients for 90° and 180° bends in Fig. 17. According to Zimmermann [21], the procedure to adopt for 90° bends connected in series is that illustrated in Fig. 17.

7.2 Bends with Sharp Edges

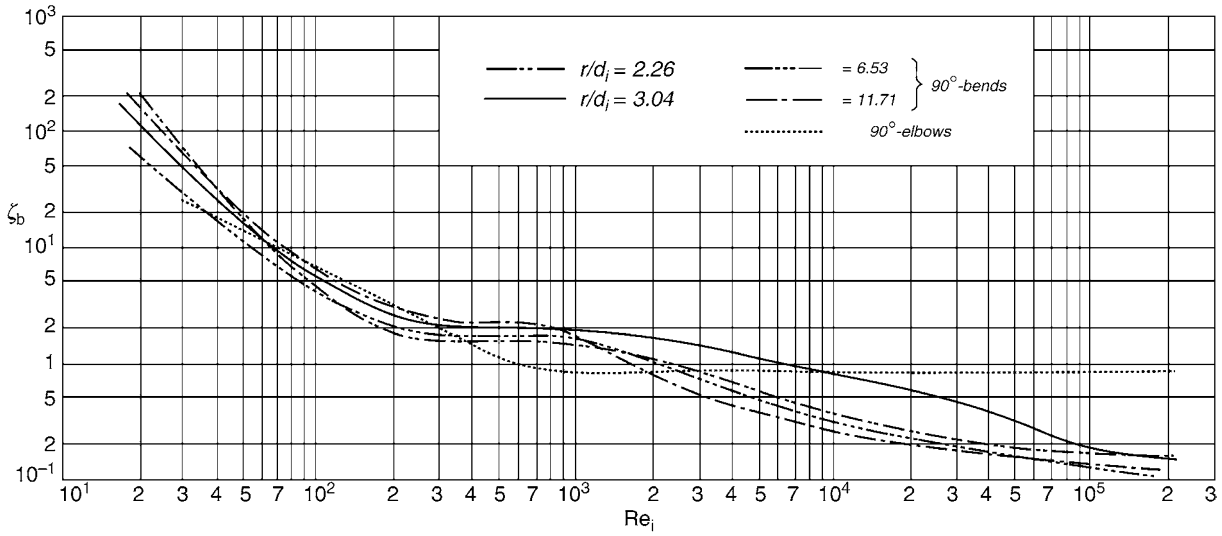
As a result of the sharp diversion of flow in bends, pronounced turbulence occurs and gives rise to high values for ζ_b.

For water pipes with bolted connections at both ends the following figures for 90° bends are available.

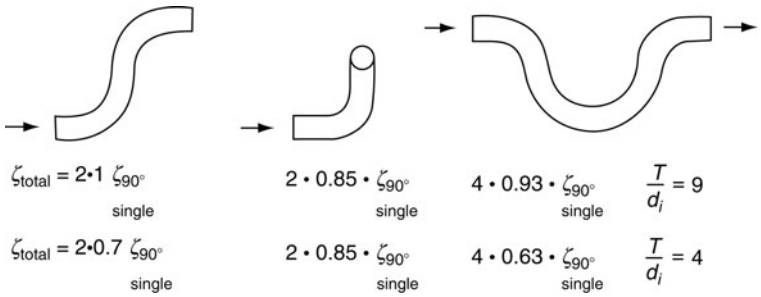
d_i	14	20	25	34	39	49	mm
ζ_b	1.7	1.7	1.3	1.1	1.0	0.83	
	Fillet with sharp edges on the inside; bends rounded on the outside						
ζ_b	1.2	1.1	0.86	0.53	0.42	0.51	
	Bends						

Herning [6] submitted the following for 90° cast iron bends:

d_i	50	100	300	200	400	500	mm
ζ_b	1.3	1.5	1.8	2.1	2.2	2.2	



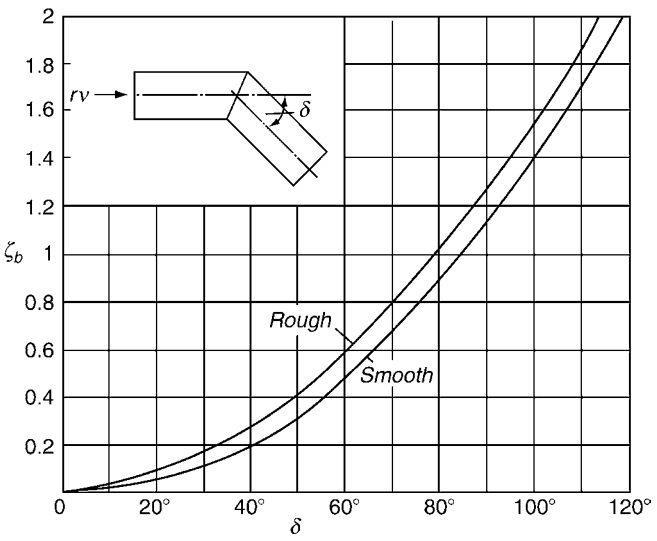
L1.3. Fig. 16. Drag coefficient ζ_b for smooth-walled 90°-bends as a function of Reynolds number Re_i.



L1.3. Fig. 17. Drag coefficient ζ_b for three-dimensional bends.

7.3 Elbows

Turbulence in elbows is even greater than that in sharp bends, and results in very high values of ζ_b. As can be seen from Fig. 16, these values remain constant over a wide Re_i range ($Re_i > 500$). The effect of the angle δ can be seen in Fig. 18. Drag coefficients ζ_b for segmented bends are smaller than the sum of the values for the individual segments. Relevant figures are presented in Fig. 19, which is reproduced from Richter's [5] compilations of values obtained by Schubart and Kirchbach. A pronounced minimum pressure drop is evident at certain relative elbow spacings a/d.



L1.3. Fig. 18. Drag coefficients ζ_b for single elbows as a function of the angle δ.

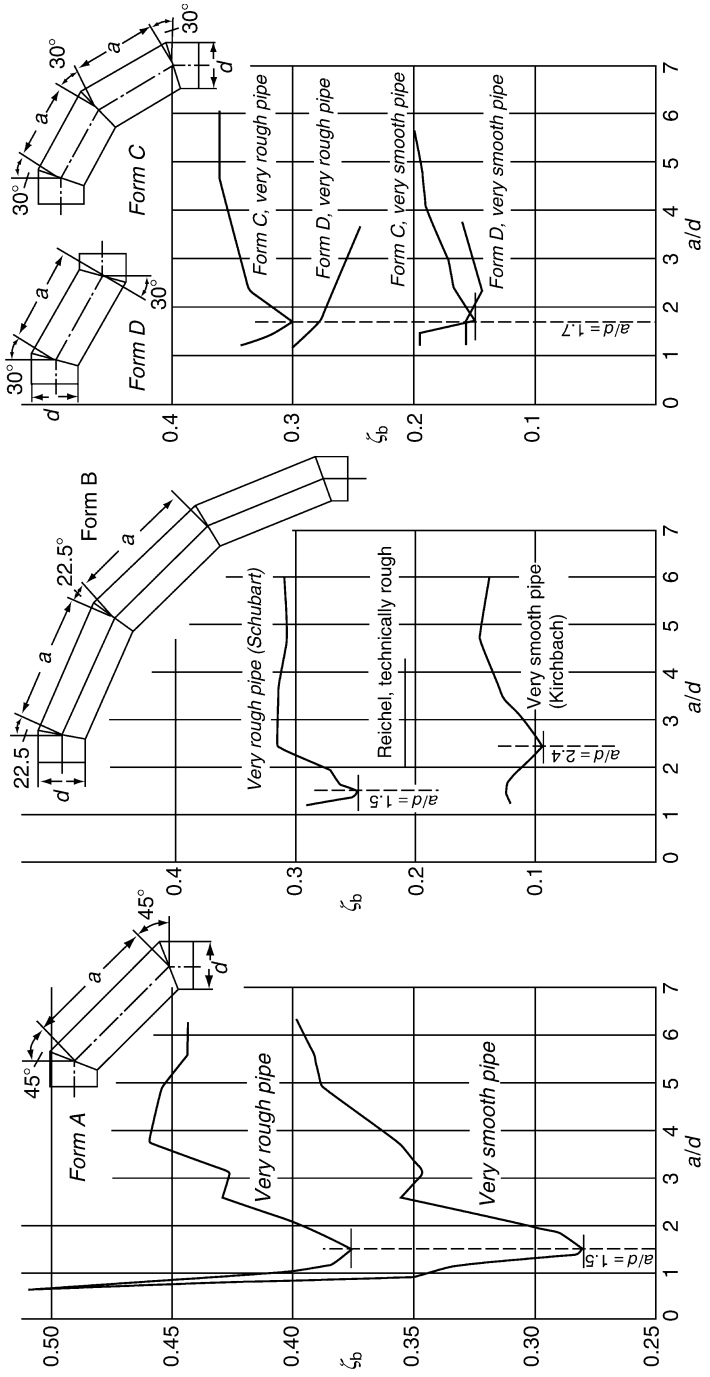
8 Valves

The pressure drop of valves is given by

$$\Delta p = \zeta_v \frac{\rho w^2}{2}$$

where w is the velocity in the cross-section taken through the rated pipe diameter.

The drag coefficients ζ_v are constant over a wide range of Reynolds numbers, because flow is almost completely turbulent. Laminar flow does not set in until the Reynolds number is less than Re = 100 to Re = 500. The drag coefficients ζ_v increase rapidly with a decrease in Reynolds number. The data that follow can serve merely as a guide because of the great



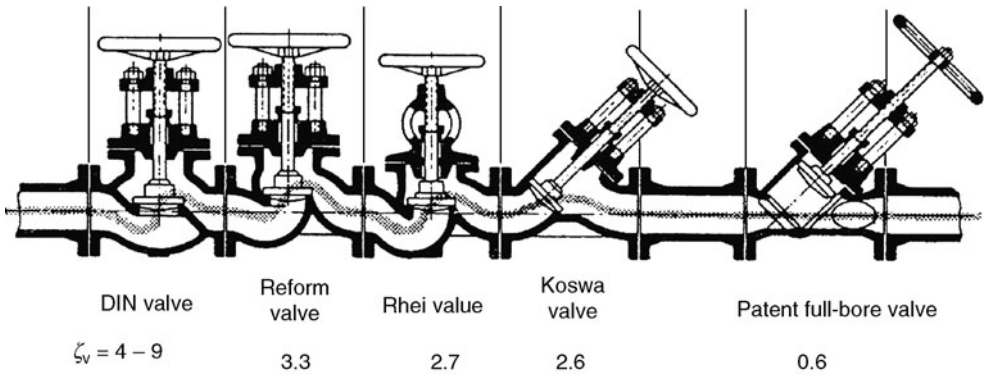
L1.3. Fig. 19. Drag coefficients ζ_b for segmented bends as a function of the a/d ratio.

differences in machining and design that exist between the various types of valves on the market.

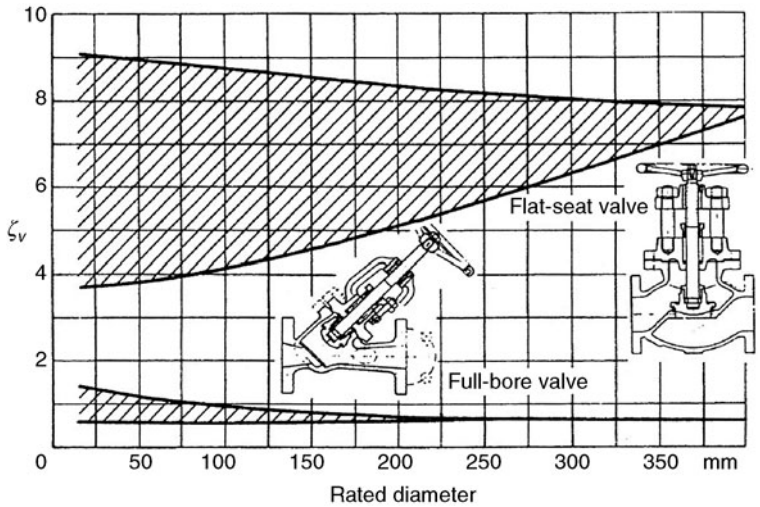
8.1 Regulating Valves

The more the changes in the direction of the flow and in the cross-section and the more the projecting edges that give rise to turbulence and eddy currents, the higher the resistance to flow offered by a valve. This is evident from the sketches of well-known types of valves that are reproduced in Fig. 20.

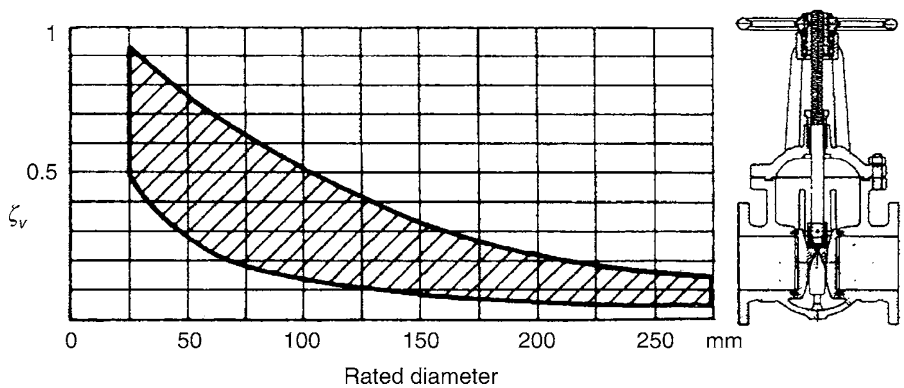
The effect of the diameter differs. The drag coefficient ζ_v for Koswa and full-bore valves decreases as the rated diameter increases; and that for the German Standard DIN valve, which has an unfavorable hydraulic characteristic, becomes somewhat higher. The relationship which was plotted from measurements



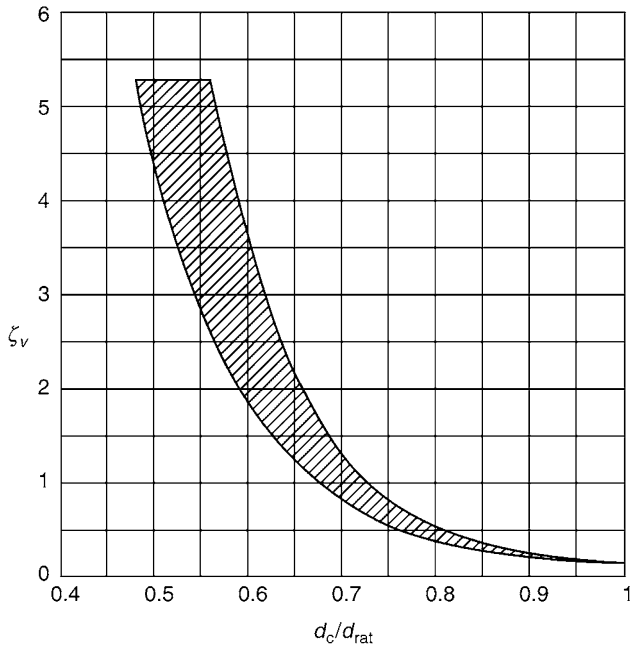
L1.3. Fig. 20. Drag coefficients ζ_v for some types of valves with rated diameters of 100 mm.



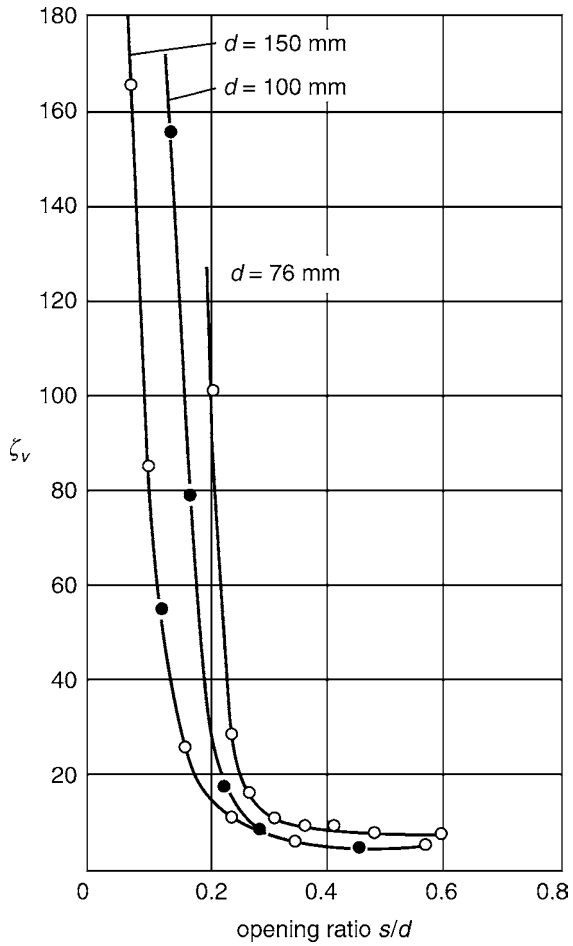
L1.3. Fig. 21. Drag coefficients ζ_v for completely opened regulating valves of various rated diameters.



L1.3. Fig. 22. Drag coefficients ζ_v for completely opened double-disc parallel-gate valves with straight passages.



L1.3. Fig. 23. Drag coefficients ζ_v for completely opened gate valves with restriction to flow.



L1.3. Fig. 24. Throttling characteristic for a flat-seat valve of the design illustrated in Fig. 21.

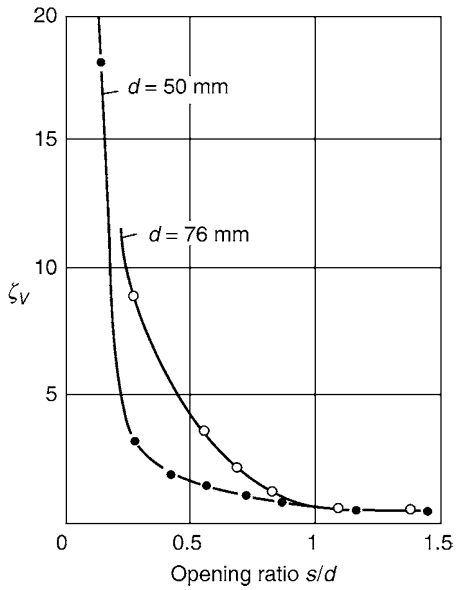
performed by various research workers is shown in Fig. 21. Herning [6] submitted the following values of ζ_v for angle valves:

Rated diameter	50	100	200	300	400	mm
ζ_v	3.3	4.1	5.3	6.2	6.6	

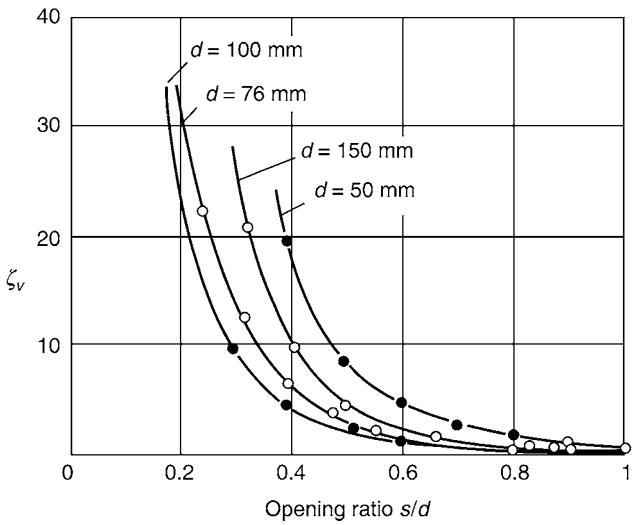
The values for ζ_v published by Richter [3] are somewhat lower, i.e., $2 > \zeta_v > 3$.

8.2 Gate Valves

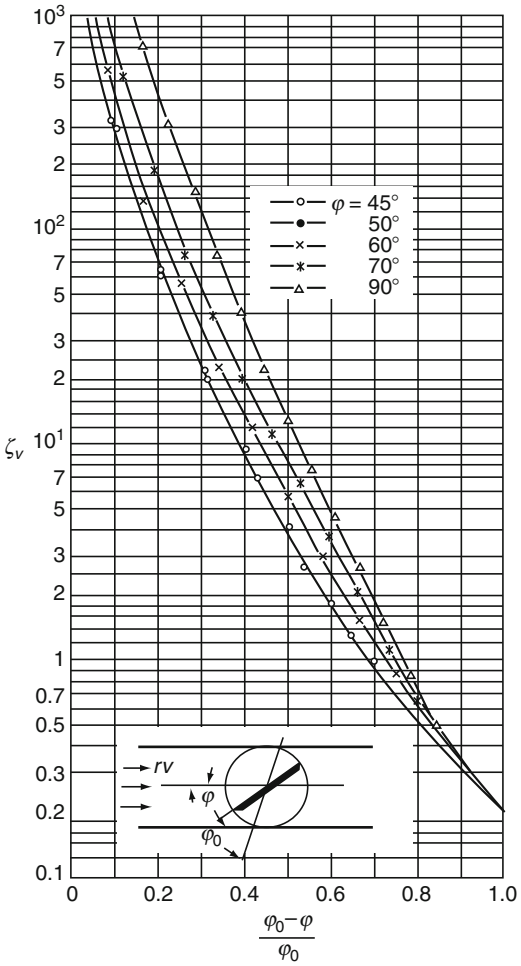
Double-disc parallel-gate valves are shutoff devices that offer the least resistance to flow. Relevant values of ζ_v, compiled



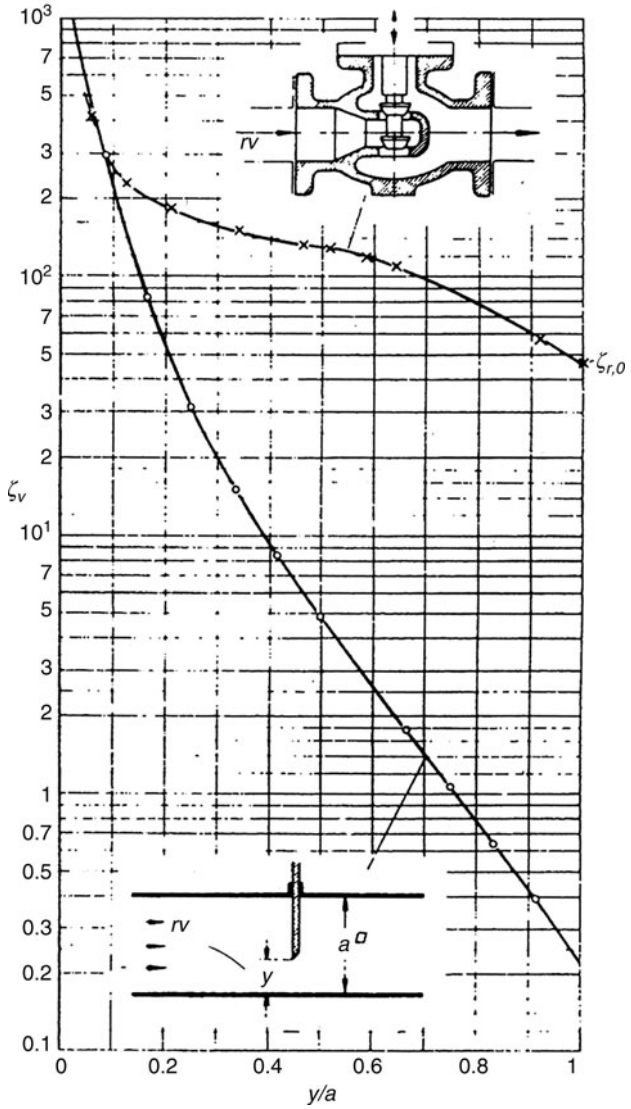
L1.3. Fig. 25. Throttling characteristic for a full-bore valve of the design illustrated in Fig. 21.



L1.3. Fig. 26. Throttling characteristic for a gate valve of the design illustrated in Fig. 22.



L1.3. Fig. 27. Characteristic for a butterfly valve.



L1.3. Fig. 28. Characteristics for a gate and a control valve.

from measured values, have been plotted in Fig. 22. Those for gate valves with constrictions, for example, pressure-valves, increase rapidly with the constriction ratio d_c/d_{rat}, where d_c is the diameter of the constriction and d_{rat} is the rated diameter. This is demonstrated in Fig. 23, in which the hatched area represents data obtained from the literature and manufacturers' leaflets.

8.3 Throttle Valves and Gates

As a rule, the drag coefficient ζ_v does not increase noticeably until the opening lift s is less than one half. Appropriate curves are reproduced in Figs. 24–26.

8.4 Cocks

ζ_v for cocks with straight or widened passages is $\zeta_v = 0.6$–1.0. Considerably higher coefficients, for example, up to $\zeta_v = 4$, may result from constrictions or intersections.

8.5 Butterfly Valves and Gates

The relationship between ζ_v and the position of the flap can be seen from Figs. 27–28 for square channels. It would appear permissible to apply these values to pipes. Drag coefficients for a control valve have been included in Fig. 28.

L1.4 Pressure Drop of Tube Bundles in Cross Flow

Edward S. Gaddis
Technische Universität Clausthal, Clausthal-Zellerfeld, Germany

1 Tube Bundles with Circular Tubes

1.1 Parallel Arrangement of Tube Rows

1.1.1 Introduction

Figure 1 shows the dependence of the drag coefficient ξ on the Reynolds number Re for a flow across a tube bundle with parallel arrangement of tube rows; the tube bundle has circular tubes with in-line or staggered tube arrangement. Five different regions are clear in Fig. 1. At low Reynolds number ($Re < 100$), the flow is laminar and the drag coefficient can be represented by the relation $\xi \propto Re^{-1}$. In the turbulent range, between $Re \approx 10^4$ and a critical Reynolds number $Re_{crit.}$, the drag coefficient – according to measurements made by different authors – may be represented with a good accuracy by the relation $\xi \propto Re^{-m}$ ($m << 1$). In the transition region between laminar and turbulent flow, the drag coefficient has a minimum for in-line tube arrangement [1]; such a minimum was not noticed with staggered tube arrangement. In the critical region between $2 \times 10^5 < Re_{crit.} < 6 \times 10^5$, there is a minimum for staggered tube arrangement and a second minimum for in-line tube arrangement [2, 3]. The flow at Reynolds numbers higher than the critical Reynolds number is usually denoted as trans-critical flow.

The equations presented hereafter for the prediction of the pressure drop for a flow across a tube bundle with in-line or with staggered tube arrangement are valid for a wide range of Reynolds numbers, covering the laminar, the transition, and the turbulent range nearly up to the critical Reynolds number. The equations are based on superposition of the equations of Bergelin et al. for laminar flow in a modified form [4, 5] and the equations of Gaddis and Gnielinski [5] for turbulent flow.

1.1.2 Determination of Pressure Drop

The pressure drop Δp across the tube bundle due to friction and flow separation in the wake region behind the individual tubes may be calculated from

$$\Delta p = \xi n_{MR} \frac{\rho w_e^2}{2}. \quad (1)$$

In Eq. (1), ξ is the drag coefficient, n_{MR} the number of main resistances in the flow direction, ρ the density and w_e the mean flow velocity in the narrowest cross section. For in-line tube arrangement and for staggered tube arrangement with the narrowest cross section between adjacent tubes in the same row (i.e., $b \geq 0.5\sqrt{2a+1}$), the number of the main resistances in the flow direction n_{MR} is identical with the number of the tube rows n_R. For staggered tube arrangement with the narrowest cross section in the diagonal between tubes in adjacent tube rows (i.e., $b < 0.5\sqrt{2a+1}$), the number of the main resistances in the flow direction may be calculated from the equation $n_{MR} = n_R - 1$. Figure 2 shows the position of the narrowest cross section in the different tube bundles and its relation to a and b.

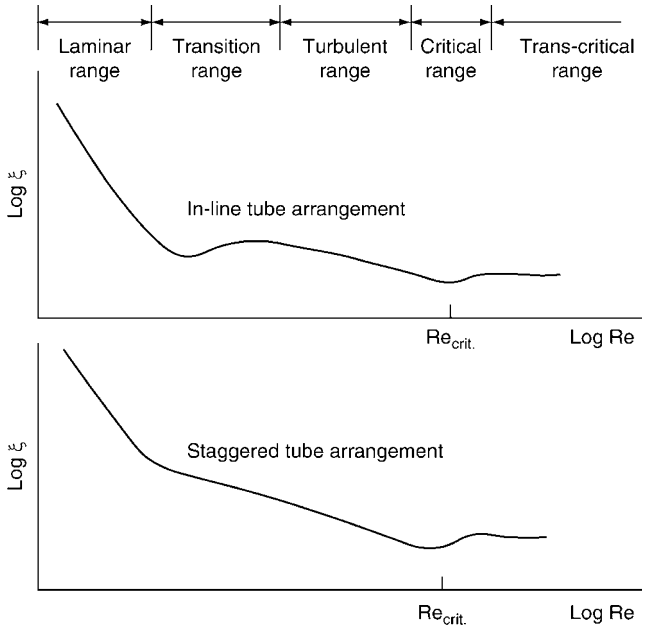
The drag coefficient ξ is a function of the Reynolds number Re, the transverse pitch ratio a and the longitudinal pitch ratio b, where

$$Re = \frac{w_e d_o \rho}{\eta},$$
$$a = \frac{s_1}{d_o},$$
$$b = \frac{s_2}{d_o}.$$

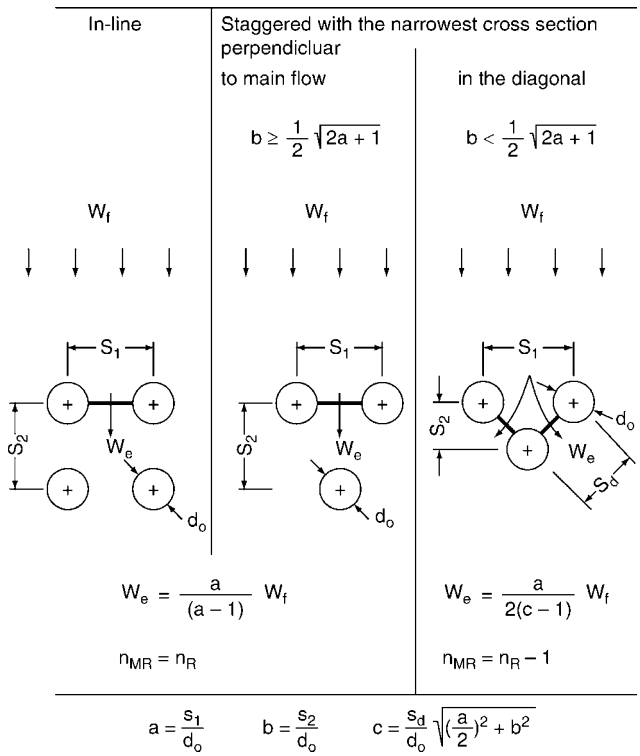
1.1.3 Determination of Drag Coefficient

Definition of an Ideal Tube Bundle

An ideal tube bundle is defined arbitrarily as follows: Physical properties of fluid independent of temperature, number of tube rows $n_R \geq 10$, number of tubes per row ≥ 10, ratio of tube length to tube diameter ≥ 10, fluid velocity in the free cross section at inlet of tube bundle is uniform and perpendicular to the free cross section and smooth tube surface. Deviations from the ideal situation can be taken into account by means of correction factors.



L1.4. Fig. 1. Schematic presentation of the dependence of the drag coefficient ξ on the Reynolds number Re.



L1.4. Fig. 2. Illustration of the concept 'narrowest cross section,' which is presented with a thick line.

Drag Coefficient for an Ideal Tube Bundle

In-line tube arrangement The drag coefficient for an ideal tube bundle with in-line tube arrangement may be calculated from the following equations [5]:

$$\xi = \xi_{\text{lam}} + \xi_{\text{turb}} F_f \tag{2a}$$

with

$$F_f = 1 - \exp\left(-\frac{\text{Re} + 1000}{2000}\right). \tag{2b}$$

The drag coefficient ξ_{lam} for laminar flow is given by

$$\xi_{\text{lam}} = \frac{f_{\text{a,l,f}}}{\text{Re}} \tag{3}$$

with

$$f_{a,l,f} = \frac{280\pi\left[(b^{0.5} - 0.6)^2 + 0.75\right]}{(4ab - \pi)a^{1.6}}. \tag{4}$$

The drag coefficient ξ_{turb} for turbulent flow is given by

$$\xi_{\text{turb}} = \frac{f_{\text{a,t,f}}}{\text{Re}^{0.1(b/a)}} \tag{5}$$

with

$$f_{\text{a,t,f}} = \left[0.22 + 1.2\frac{\left(1 - \frac{0.94}{b}\right)^{0.6}}{(a - 0.85)^{1.3}}\right] \times 10^{0.47((b/a)-1.5)} + [0.03(a-1)(b-1)]. \tag{6}$$

Staggered tube arrangement The drag coefficient for an ideal tube bundle with staggered tube arrangement may be calculated from the following equations [5]:

$$\xi = \xi_{\text{lam}} + \xi_{\text{turb}} F_v \tag{7a}$$

with

$$F_{\text{v}} = 1 - \exp\left(-\frac{\text{Re} + 200}{1000}\right). \tag{7b}$$

The drag coefficient ξ_{lam} for laminar flow is given by

$$\frac{\xi_{\text{lam}} = f_{\text{a,l,v}}}{\text{Re}} \tag{8}$$

with

$$f_{\text{a,l,v}} = \frac{280\pi\left[(b^{0.5} - 0.6)^2 + 0.75\right]}{(4ab - \pi)a^{1.6}} \quad \text{for } b \geq 0.5\sqrt{2a+1} \tag{9}$$

and

$$f_{\text{a,l,v}} = \frac{280\pi\left[(b^{0.5} - 0.6)^2 + 0.75\right]}{(4ab - \pi)c^{1.6}} \quad \text{for } b < 0.5\sqrt{2a+1}. \tag{10}$$

The drag coefficient ξ_{turb} for turbulent flow is given by

$$\xi_{\text{turb}} = \frac{f_{\text{a,t,v}}}{\text{Re}^{0.25}} \tag{11}$$

with

$$f_{\text{a,t,v}} = 2.5 + \left(\frac{1.2}{(a - 0.85)^{1.08}}\right) + 0.4\left(\frac{b}{a} - 1\right)^3 - 0.01\left(\frac{a}{b} - 1\right)^3. \tag{12}$$

The diagonal pitch ratio c in Eq. (10) may be calculated from

$$c = \left((a/2)^2 + b^2\right)^{0.5}.$$

Physical Properties of Fluid The physical properties in the above equations are based on the fluid temperature ϑ and the fluid pressure p. In a tube bundle with a gaseous medium and a very large number of tube rows, the pressure may differ considerably between the inlet and outlet of the tube bundle; in such cases the physical properties are evaluated at the mean gas pressure $p_m = (p_{in} + p_{out})/2$. A change in the gas density ρ in the main flow direction from the gas density at inlet of the tube bundle – due to a change in the gas pressure – leads to a change in the gas velocity in the narrowest cross section w_e. The quantities ρ and w_e are related to one another through the continuity equation by the relation ρw_e = constant (the narrowest cross section does not change in the tube bundle). Thus, in conjunction with the mean gas density ρ_m corresponding to the mean gas pressure p_m, the mean velocity in the narrowest cross section $w_{e,m}$ should be used. Since the gas pressure at outlet of the tube bundle is not known *a priori*, an iteration procedure is required. An alternative for calculating the pressure drop in tube bundles with a very large number of tube rows ($n_R >> 10$) and changing medium density in the flow direction is to calculate the pressure drop row by row using Eq. (1) with $n_{MR} = 1$ and modified physical properties and gas velocity w_e at each row. The pressure drop across the tube bundle is then a summation of the calculated values. The computations according to this last procedure reduce calculation errors but are lengthier.

Graphical Presentation of the Equations

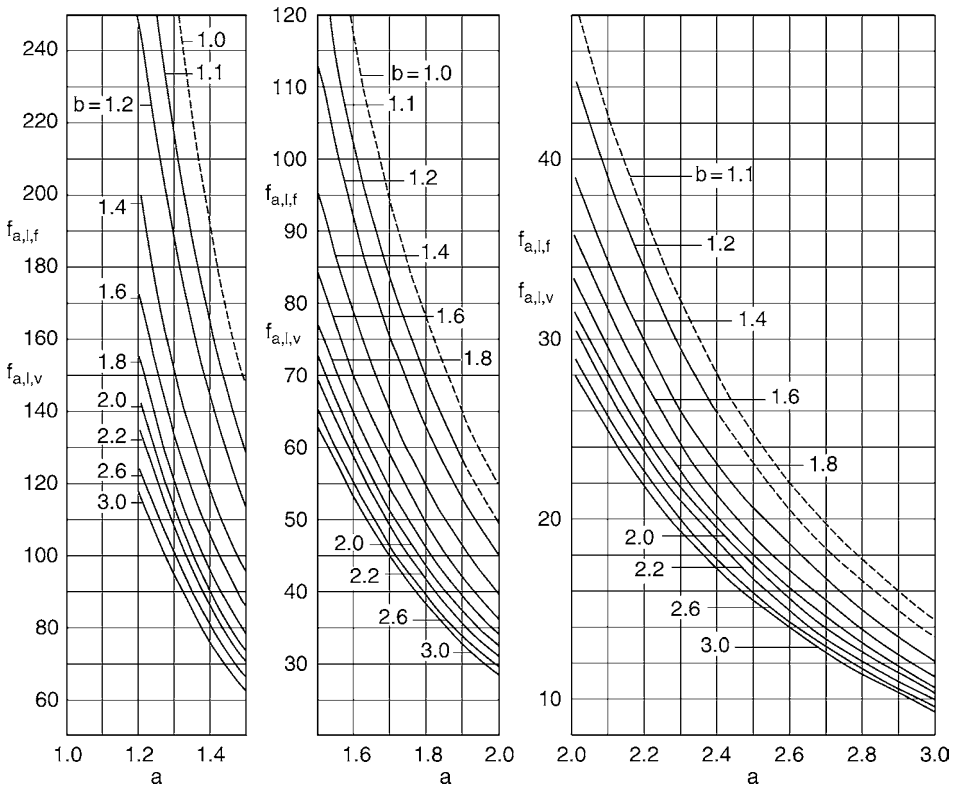
Figures 3, 4, 7, and 9 enable a quick evaluation of the factors $f_{a,l,f}$, $f_{a,t,f}$, $f_{a,l,v}$, and $f_{a,t,v}$, Fig. 5 enables the evaluation of the factors F_f and F_v and Fig. 8 shows the position of the narrowest cross section for staggered tube arrangement. Figures 6 and 10 give the drag coefficient ξ as a function of the Reynolds number Re for six commonly used ideal tube bundles; Fig. 6 is for three in-line and Fig. 10 for three staggered tube arrangements.

Correction Factor for Temperature Dependence of Physical Properties

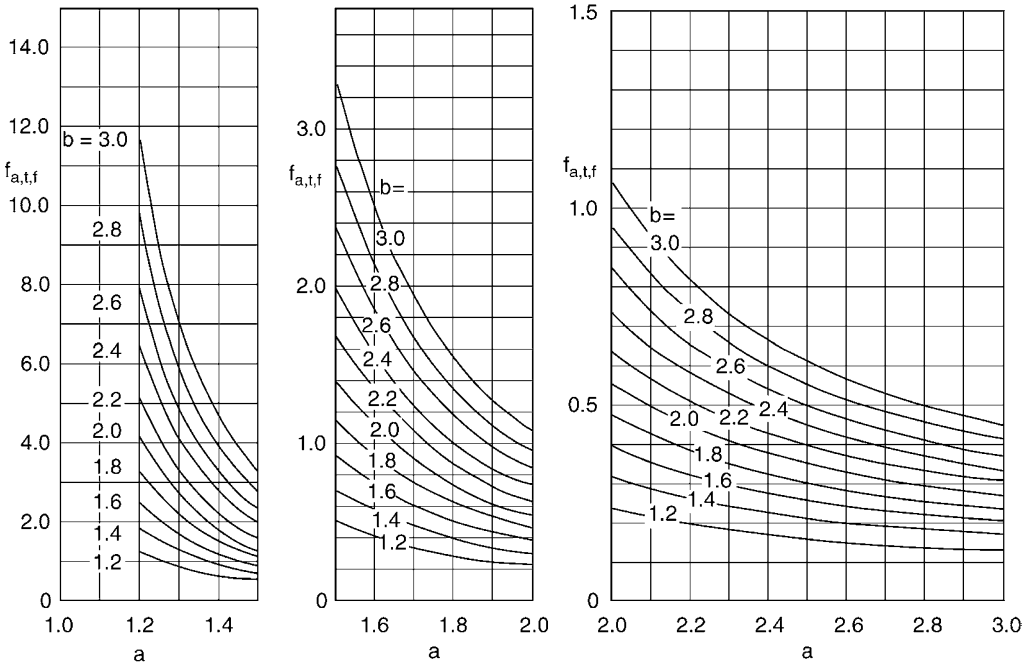
Heating or cooling of the tube bundle leads to a change in the physical properties in the thermal layer near the tube surface; it can be allowed for by multiplying the drag coefficient ξ_{lam} for laminar flow by a correction factor $f_{z,l}$ and the drag coefficient ξ_{turb} for turbulent flow by a correction factor $f_{z,t}$.

In the laminar flow range, the correction factor $f_{z,l}$ may be calculated from [4]

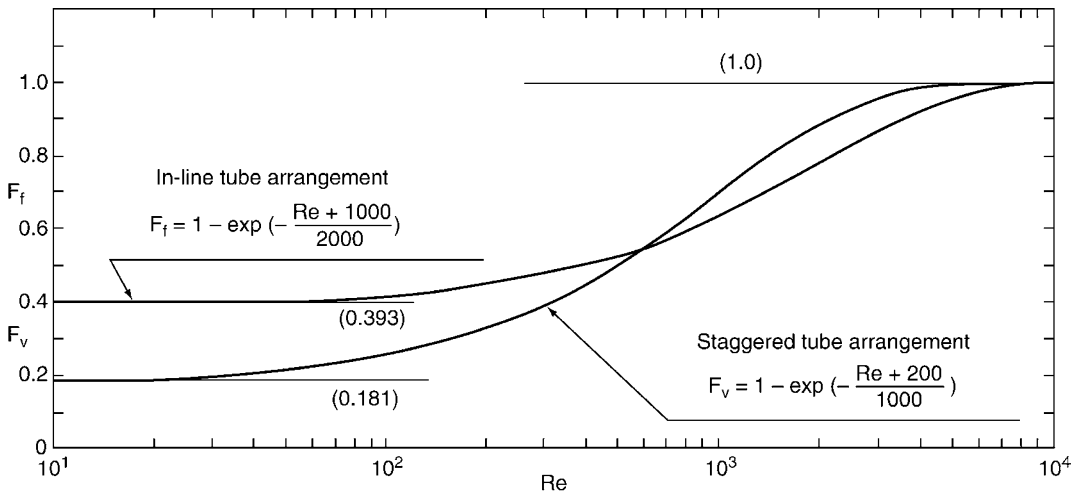
$$f_{z,l} = \left(\frac{\eta_w}{\eta}\right)^{\overline{\left[\left(\frac{4ab}{\pi} - 1\right)\mathrm{Re}\right]^{0.25}}} \qquad (13)$$



L1.4. Fig. 3. Dependence of $f_{a,l,f}$ and $f_{a,l,v}$ on a and b for in-line tube arrangement and for staggered tube arrangement with $b \geq 0.5\sqrt{2a+1}$ according to Eqs. (4) and (9) respectively.



L1.4. Fig. 4. Dependence of $f_{a,t,f}$ on a and b for in-line tube arrangement according to Eq. (6).



L1.4. Fig. 5. Dependence of the factors F_f and F_v appearing in Eqs. (2a), (2b), (7a) and (7b) on Re.

and in the turbulent flow range, the correction factor $f_{z,t}$ introduced by Sieder and Tate [6] for flow through circular tubes may be used, or

$$f_{z,t} = \left(\frac{\eta_w}{\eta}\right)^{0.14}. \tag{14}$$

In the above equations, the dynamic viscosity η and the density ρ under non-isothermal flow conditions are evaluated at the mean fluid temperature $\vartheta_m = (\vartheta_{in} + \vartheta_{out})/2$ and the dynamic viscosity η_w at the mean wall temperature ϑ_w.

Correction Factor for Small Number of Tube Rows

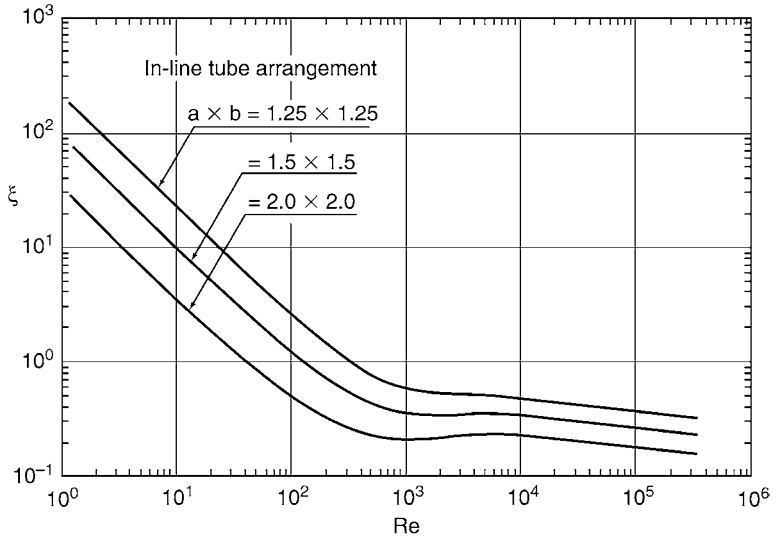
According to Bergelin et al. [4], the number of tube rows has an effect on the drag coefficient for the tube bundle in the laminar flow range only if the flow is non-isothermal and the number of tube rows n_R is less than 10. This effect can be allowed for by multiplying the drag coefficient ξ_{lam} in Eqs. (2a) and (7a) by the correction factor $f_{zn,l}$ [4], where

$$f_{zn,l} = \left(\frac{\eta_w}{\eta}\right)^{\frac{0.57\left(\frac{\eta_R}{10}\right)^{0.25}}{\left[\left(\frac{4ab}{\pi} - 1\right)Re\right]^{0.25}}} \quad \text{for } n_R < 10 \tag{15}$$

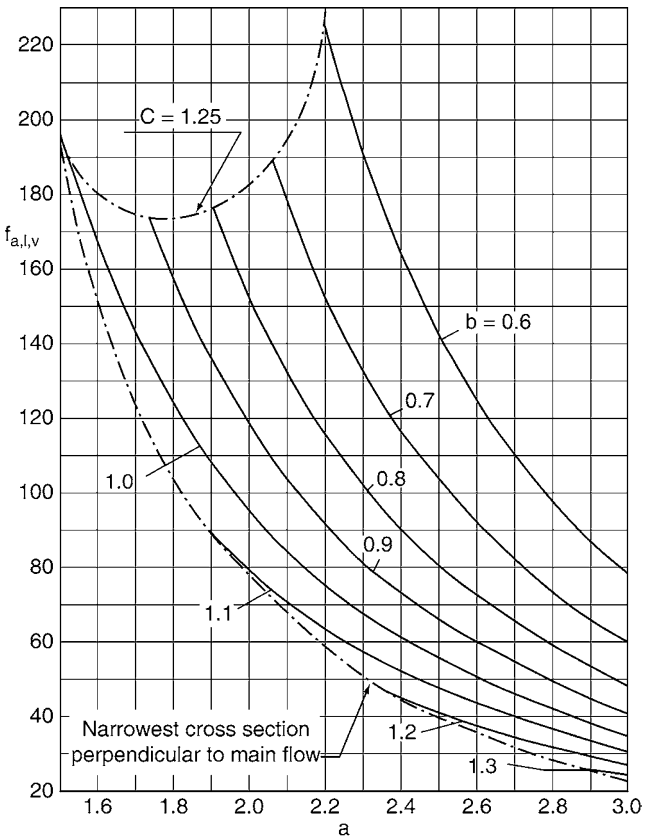
and

$$f_{zn,l} = f_{z,l} \text{ for } n_R \geq 10 \quad (\text{see, Eq.}(13) \text{ for } f_{z,l}). \tag{16}$$

The correction factor $f_{zn,l}$ given by Eq. (15) takes into consideration at the same time the influence of temperature change under non-isothermal conditions. Thus, in the case of a non-isothermal flow and $n_R < 10$ Eq. (13) becomes redundant.

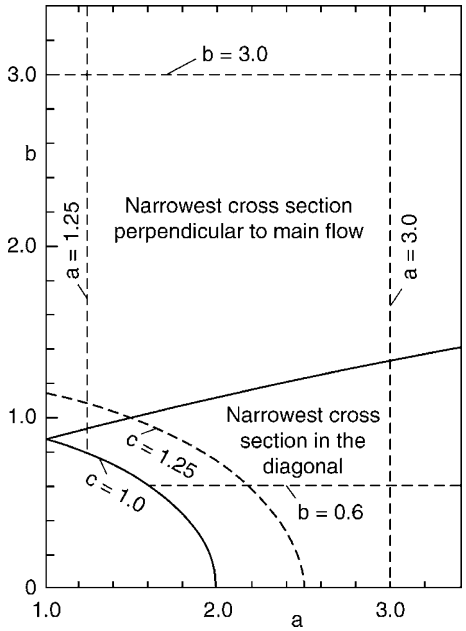


L1.4. Fig. 6. Dependence of the drag coefficient ξ on the Reynolds number Re for three commonly used ideal tube bundles with in-line tube arrangement.

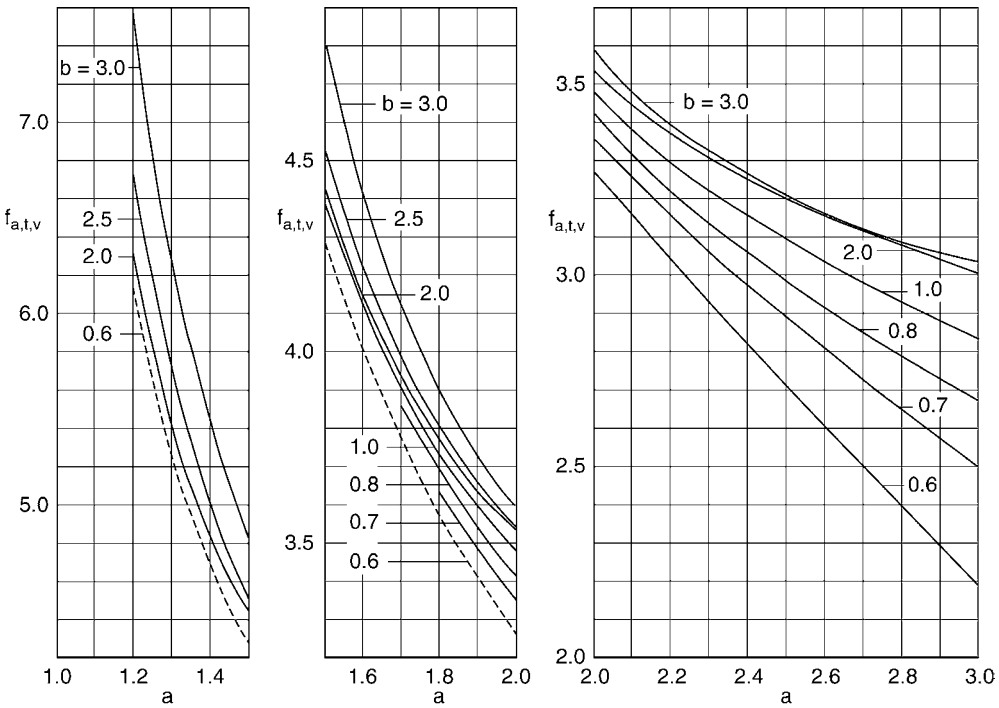


L1.4. Fig. 7. Dependence of $f_{a,l,v}$ on a and b for staggered tube arrangement with $b < 0.5\sqrt{2a+1}$ according to Eq. (10).

In the turbulent flow range, the change in the drag coefficient ξ_{turb} for a tube bundle with change in the number of tube rows between 5 and 10 is small [7] and may be ignored. However, sudden expansion of the flow area from that of the last tube row to the total available free area in the tube bundle leads to an additional pressure drop, which is negligible for a tube bundle with a large number of tube rows but may be remarkable in a tube bundle with a small number of tube rows. This may be compensated for by adding a correction factor $f_{n,t}$ to the drag coefficient ξ_{turb} in case of an isothermal flow or to the corrected drag coefficient $\xi_{turb} f_{z,t}$ in case of a non-isothermal flow [5], where



L1.4. Fig. 8. Position of the narrowest cross section for staggered tube arrangement in dependence on *a* and *b*.



L1.4. Fig. 9. Dependence of $f_{a,t,v}$ on *a* and *b* for staggered tube arrangement according to Eq. (12).

$$f_{n,t} = \xi_0 \left(\frac{1}{n_R} - \frac{1}{10} \right) \text{ for } 5 \leq n_R < 10 \tag{17}$$

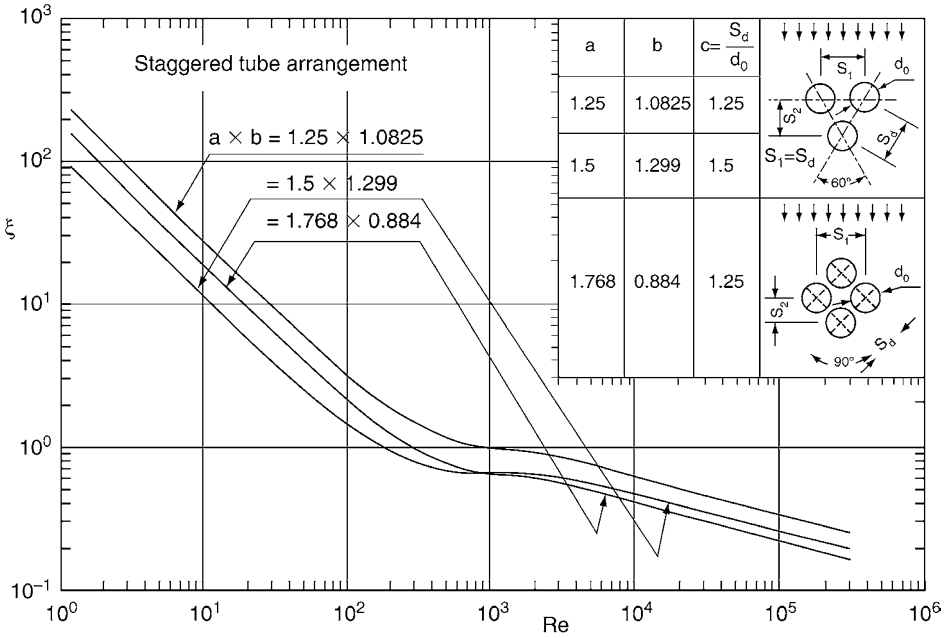
and

$$f_{n,t} = 0 \text{ for } n_R \geq 10. \tag{18}$$

For a tube bundle with in-line tube arrangement or with staggered tube arrangement and the narrowest cross section perpendicular to the main flow, the coefficient ξ_o due to sudden expansion of the flow area may be calculated from

$$\xi_o = \frac{1}{a^2} \tag{19}$$

and for a tube bundle with staggered tube arrangement and the narrowest cross section in the diagonal, ξ_o may be calculated from



L1.4. Fig. 10. Dependence of the drag coefficient ξ on the Reynolds number Re for three commonly used ideal tube bundles with staggered tube arrangement.

$$\xi_o = \left[\frac{2(c-1)}{a(a-1)}\right]^2. \tag{20}$$

General Equations for Drag Coefficient

The general equations for calculating the drag coefficient for the non-isothermal case considering at the same time tube bundles with a smaller number of tube rows than that given in the definition of an ideal tube bundle are as follows:

For in-line tube arrangement:

$$\xi = \xi_{lam} f_{zn,l} + \left(\xi_{turb} f_{z,t} + f_{n,t}\right) F_f. \tag{21}$$

For staggered tube arrangement:

$$\xi = \xi_{lam} f_{zn,l} + \left(\xi_{turb} f_{z,t} + f_{n,t}\right) F_v. \tag{22}$$

To reduce computational effort (e.g., when using a hand calculator) the drag coefficient for small Reynolds numbers ($Re \leq 10$), may be calculated only from the laminar term ($\xi_{lam} f_{zn,l}$) and for high Reynolds numbers ($10^4 \leq Re \leq 3 \times 10^5$) only from the turbulent term ($\xi_{turb} f_{z,t} + f_{n,t}$) of the equations; in that last case, the factors F_f and F_v are effectively equal to unity.

Validity Range of Equations

The available experimental measurements used to develop the above equations covered the following ranges:

Reynolds number: $1 \leq Re \leq 3 \times 10^5$
and number of tube rows: $n_R \geq 5$.

The tube bundles used in the experimental investigations had transverse and longitudinal pitch ratios as follows:

In the range $Re < 10^3$:

For in-line tube arrangement: $a \times b = 1.25 \times 1.25, 1.5 \times 1.5, 2.0 \times 2.0$.

For staggered tube arrangement: $a \times b = 1.25 \times 1.0825, 1.5 \times 1.299, 1.768 \times 0.884$.

In the range $Re \geq 10^3$:

For in-line tube arrangement: $1.25 \leq a \leq 3.0, 1.2 \leq b \leq 3.0$.

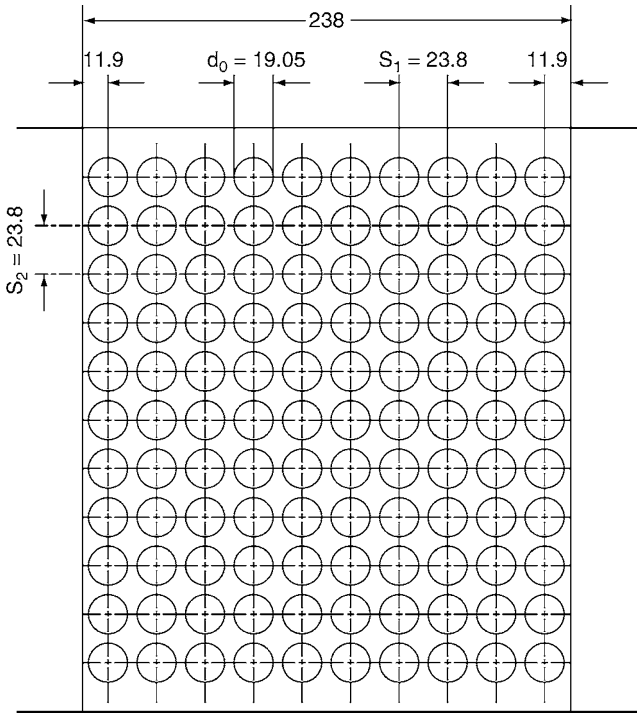
For staggered tube arrangement: $1.25 \leq a \leq 3.0, 0.6 \leq b \leq 3.0$, $c \geq 1.25$.

Experimental measurements made at high Reynolds numbers and with gas as flow medium had always a flow velocity in the narrowest cross section of the tube bundle, which was much less than the sound velocity. Thus, density changes within the narrowest cross section can be ignored. The above ranges give the range of validity of the equations.

Example 1

A heat exchanger with a rectangular cross section has a tube bundle with 11 tube rows and in-line tube arrangement. Each tube row has ten circular tubes with an external diameter of 19.05 mm and a tube length of 0.4 m. Other dimensions of the heat exchanger are given in Fig. 11. The heat exchanger is used to cool oil of a volumetric flow rate $\dot{V}$ of 62 $m^3\ h^{-1}$ from the inlet temperature $\vartheta_{in} = 80.4\ °C$ to the outlet temperature $\vartheta_{out} = 78.8°C$. The mean wall temperature ϑ_w of the tubes amounts to 40.9°C. It is required to calculate the pressure drop Δp due to friction and flow separation. The following data for the physical properties of oil are given:

At a mean oil temperature $\vartheta_m = (80.4 + 78.8)/2 = 79.6°C$,
oil density $\rho = 837\ kg\ m^{-3}$ and
oil dynamic viscosity $\eta = 1.72 \times 10^{-2}$ Pas
and at the mean wall temperature $\vartheta_w = 40.9°C$,
oil dynamic viscosity $\eta_w = 8.55 \times 10^{-2}$ Pas.



L1.4. Fig. 11. Dimensions of the heat exchanger in the example (dimensions in mm).

Solution:

The following quantities are calculated:

$$w_f = \frac{\dot{V}}{F} = \frac{62/3600}{0.238 \times 0.4} = 0.181\,\mathrm{m\,s^{-1}}$$

$$a = \frac{s_1}{d_o} = \frac{23.8}{19.05} = 1.25$$

$$b = \frac{s_2}{d_o} = \frac{23.8}{19.05} = 1.25$$

$$w_e = \frac{a}{a-1} w_f = \frac{1.25}{1.25-1} \times 0.181 = 0.905\,\mathrm{m\,s^{-1}} \text{ (see Fig. 2)}$$

$$\mathrm{Re} = \frac{w_e d_o \rho}{\eta} = \frac{0.905 \times (19.05 \times 10^{-3}) \times 837}{1.72 \times 10^{-2}} = 839$$

Equation (4):

$$f_{a,l,f} = \frac{280\pi\left[(b^{0.5} - 0.6)^2 + 0.75\right]}{(4ab - \pi)a^{1.6}}$$

$$= \frac{280 \times \pi \times \left[(1.25^{0.5} - 0.6)^2 + 0.75\right]}{(4 \times 1.25 \times 1.25 - \pi) \times 1.25^{1.6}} = 201.7$$

Equation (3):

$$\xi_{lam} = \frac{f_{a,l,f}}{\mathrm{Re}} = \frac{201.7}{839} = 0.24$$

Equation (13):

$$f_{z,l} = \left(\frac{\eta_w}{\eta}\right)^{\frac{0.57}{\left[\left(\frac{4ab}{\pi}-1\right)\mathrm{Re}\right]^{0.25}}} = \left(\frac{8.55 \times 10^{-2}}{1.72 \times 10^{-2}}\right)^{\frac{0.57}{\left[\left(\frac{4\times1.25\times1.25}{\pi}-1\right)\times839\right]^{0.25}}} = 1.19$$

Equation (6):

$$f_{a,t,f} = \left[0.22 + 1.2\frac{\left(1 - \frac{0.94}{b}\right)^{0.6}}{(a-0.85)^{1.3}}\right] \times 10^{0.47((b/a)-1.5)} + [0.03(a-1)(b-1)]$$

$$= \left[0.22 + 1.2 \times \frac{\left(1 - \frac{0.94}{1.25}\right)^{0.6}}{(1.25-0.85)^{1.3}}\right] \times \left[10^{0.47\left(\frac{1.25}{1.25}-1.5\right)}\right] + [0.03 \times (1.25-1) \times (1.25-1)] = 1.13$$

Equation (5):

$$\xi_{turb} = \frac{f_{a,t,f}}{Re^{0.1(b/a)}} = \frac{1.13}{(839)^{0.1\times(1.25/1.25)}} = 0.576$$

Equation (14):

$$f_{z,t} = \left(\frac{\eta_w}{\eta}\right)^{0.14} = \left(\frac{8.55 \times 10^{-2}}{1.72 \times 10^{-2}}\right)^{0.14} = 1.25$$

Equation (18):

$$f_{n,t} = 0 \text{ (since } n_R > 10)$$

Equation (2b):

$$F_f = 1 - \exp\left(-\frac{\mathrm{Re} + 1000}{2000}\right) = 1 - \exp\left(-\frac{839 + 1000}{2000}\right) = 0.601$$

Equation (16):

$$f_{zn,l} = f_{z,l} = 1.19 \text{ (since } n_R > 10)$$

Equation (21):

$$\xi = \xi_{lam} f_{zn,l} + \left(\xi_{turb} f_{z,t} + f_{n,t}\right) F_f = 0.24 \times 1.19 + (0.576 \times 1.25 + 0) \times 0.601 = 0.718$$

$$n_{MR} = n_R = 11 \quad \text{(in-line tube arrangement)}$$

The pressure drop Δp due to friction and flow separation is calculated from Eq. (1), or

$$\Delta p = \xi n_{MR} \frac{\rho w_e^2}{2} = 0.718 \times 11 \times \frac{837 \times 0.905^2}{2} = 2.71 \times 10^3 \text{ Pa} = 2.71 \times 10^3 \times 10^{-5} = 2.71 \times 10^{-2} \text{ bar}.$$

1.1.4 Other Components of Pressure Change

In case of a gaseous medium, the flow velocity may change considerably between the inlet and outlet of the tube bundle due to change in gas density. A change in gas density can be due to heating or cooling and/or due to pressure drop across the tube bundle. The change in velocity between inlet and outlet of the tube bundle causes an additional pressure change Δp_{mom} due to change in momentum flow rate, which may be calculated from $\Delta p_{mom} = (\rho w_f^2)_{out} - (\rho w_f^2)_{in}$. At the same time, the hydrostatic pressure difference $\Delta p_s = \rho h_s g$ between inlet and outlet of the tube bundle – in case of a high density medium (liquid) and a large tube bundle inclined to the horizontal – should also be considered. These two factors contribute to the pressure at the outlet of the tube bundle, which can be calculated from $p_{out} = p_{in} - \Delta p \pm \Delta p_{mom} \pm \Delta p_s$. While the term Δp always represents a pressure drop in the flow direction, both terms Δp_{mom} and Δp_s can be positive, negative or have a zero value.

Example 2

The heat exchanger used in Example 1 has a height $h_s = 0.3$ m and the direction of the flow is vertical downwards; the oil pressure at the inlet is 1.5 bar. It is required to calculate the oil pressure at the heat exchanger outlet.

Solution:

The change in the oil velocity in the free cross section between the inlet and outlet of the heat exchanger – due to change in density – is negligible. Thus, the change in oil pressure Δp_{mom} due to change in momentum flow rate is given by

$$\Delta p_{mom} = \left(\rho w_f^2\right)_{out} - \left(\rho w_f^2\right)_{in} = 0 \text{ bar}.$$

The hydrostatic head of the oil h_s is 0.3 m and the oil density ρ at mean liquid temperature ϑ_m is 837 kg m^{-3} (see Example 1). Thus, the change in oil pressure Δp_s due to the hydrostatic head of oil is given by

$$\Delta p_s = \rho h_s g = 837 \times 0.3 \times 9.81 = 2.46 \times 10^3 \text{ Pa} = 2.46 \times 10^3 \times 10^{-5} = 2.46 \times 10^{-2} \text{ bar}$$

and is positive in flow direction.

The pressure drop Δp due to friction and flow separation is calculated in Example 1 as

$$\Delta p = 2.71 \times 10^{-2} \text{ bar}$$

and is negative in flow direction.

Thus, the oil pressure p_{out} at the heat exchanger outlet is given by

$$p_{out} = p_{in} - \Delta p + \Delta p_{mom} + \Delta p_s = 1.5 - 2.71 \times 10^{-2} + 0 + 2.46 \times 10^{-2} = 1.5 \text{ bar}.$$

In the example, the irreversible pressure drop due to friction and flow separation is fully equalized through the pressure gain due to the available hydrostatic head of liquid; the oil pressure at the outlet is equal to that at the inlet.

1.1.5 Reference to Special Cases

Extreme Large Reynolds Numbers

Measurements of the drag coefficient in tube bundles for Reynolds numbers in critical and trans-critical ranges are reported from Hammeke et al. [8], Achenbach [2, 9, 10], and Poshkas et al. [11]. The experimental measurements are presented in tabular or graphical forms.

Rough Tubes

The tube roughness has an effect on the critical Reynolds number and on the drag coefficient in the critical and trans-critical ranges [9, 10]. Experimental measurements in a tube bundle with a staggered tube arrangement ($a = 2.0$, $b = 1.4$) show that an increase in the relative roughness of the tube surface leads to a decrease in the critical Reynolds number and to an increase in the drag coefficient in the trans-critical range [9]. A tube bundle with in-line tube arrangement and the same pitch ratios a and b shows a different performance; at high Reynolds numbers ($Re > 2 \times 10^6$), the drag coefficient decreases with increasing surface roughness [10]. At Reynolds numbers $Re < Re_{crit}$, the roughness of the tube surface in the examined ranges has practically no influence on the drag coefficient [9, 10].

Extreme Small Pitch Ratios

A number of tube bundles with very small transverse and longitudinal pitch ratios (for in-line tube arrangement: $1.01 \le a \le 1.06$, $b = a$, and for staggered tube arrangement: $a \times b = 1.03 \times 0.89$) were examined by Samoshka et al. [12] in the range $Re > 10^4$. The tube bundle with staggered tube arrangement has a higher drag coefficient than that with in-line tube arrangement and the same transverse pitch ratio. All examined tube bundles have in the range $10^4 < Re < 10^5$ for the dependence of ξ on Re in double logarithmic presentation a higher inclination than that for commonly used pitch ratios (larger exponent m for $\xi \propto Re^{-m}$).

Oblique Flow Over Tube Bundles

Under otherwise similar conditions, the following relation holds [13, 14]:

$$f_s = \frac{(\Delta p)_{\varphi < 90^o}}{(\Delta p)_{\varphi = 90^o}} < 1.0,$$

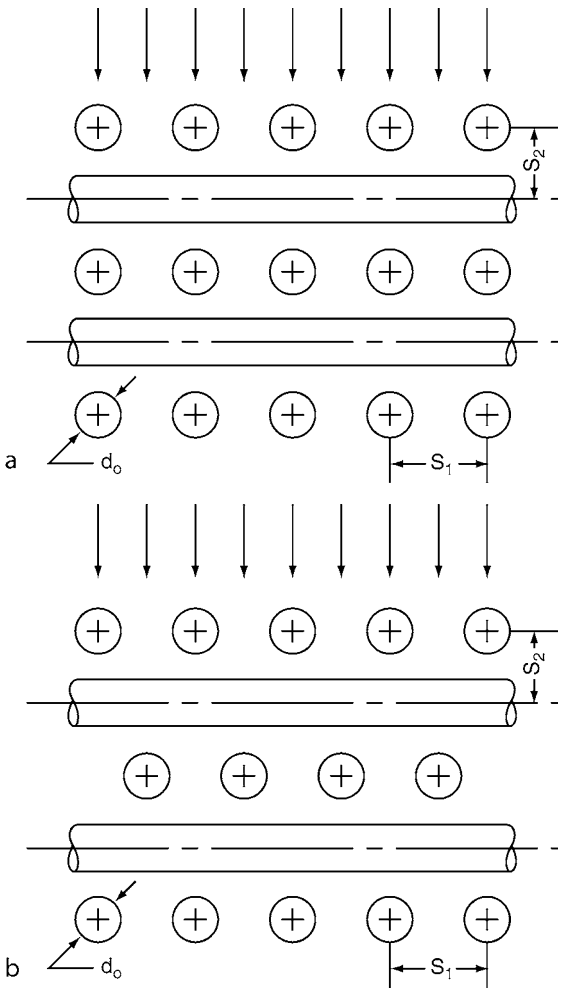
where φ is the angle between the flow direction and the tube axis. A comparison between own experimental measurements and theoretical predictions for f_s is given by Groehn [15].

Part Staggered Tube Arrangement

Bressler [16] and Niggeschmidt [3] examined tube bundles with part staggered tube arrangement under turbulent flow conditions. The dependence of the drag coefficient on the degree of deviation from the normal staggered case was reported.

1.2 Cross Arrangement of Tube Rows

Tube bundles with cross arrangement of tube rows and in-line or staggered tube arrangement according to Fig. 12 were examined by London et al. [17], Brauer [18], Klier [19], and Hammeke et al. [8]. While London et al. and Brauer examined tube bundles with the least possible longitudinal pitch ratio $b = s_2/d_o = 1$, Klier and Hammeke et al. examined tube bundles with a longitudinal pitch ratio $b > 1$. In addition, Brauer examined the influence of the cross angle β between tubes in adjacent rows on the pressure drop; the experimental measurements show that the pressure drop is maximum, when the cross angle $\beta = 60°$.



L1.4. Fig. 12. Tube bundles with cross arrangement of tube rows (cross angle $\beta = 90°$): (**a**) In-line cross arrangement; (**b**) Staggered cross arrangement.

According to Brauer [18], the pressure drop for an in-line tube arrangement or for a staggered tube arrangement with a longitudinal pitch ratio $b = s_2/d_o = 1$ may be calculated from

$$\Delta p = \xi_h \frac{4L}{d_h} \frac{\rho w_h^2}{2}. \tag{23}$$

The mean flow velocity w_h in the tube bundle is given by

$$w_h = \frac{\dot{V}}{F_h}. \tag{24}$$

The hydraulic cross section F_h and the length of the tube bundle L are calculated from

$$F_h = F\frac{V_f}{V} = n_a n_b s_1^2 \left(1 - \frac{\pi d_o}{4 s_1}\right) \tag{25}$$

and

$$L = n_R d_o. \tag{26}$$

The drag coefficient ξ_h in Eq. (23) for tube bundles with a cross angle $\beta = 90°$ is calculated from the following equations:
For in-line tube arrangement:

$$\xi_h = \frac{C_f}{Re_h^{0.09}} \text{ for } 5 \times 10^3 \le Re_h \le 10^5 \tag{27}$$

and for staggered tube arrangement (with $b = 1$):

$$\xi_h = \frac{C_v}{Re_h^{0.15}} \text{ for } 4 \times 10^3 \le Re_h \le 10^5. \tag{28}$$

The Reynolds number in Eqs. (27) and (28) is defined by

$$Re_h = \frac{w_h d_h \rho}{\eta} \tag{29}$$

and the hydraulic diameter d_h is calculated from

$$d_h = \left(\frac{4 s_1}{\pi d_0} - 1\right) d_o. \tag{30}$$

The factors C_f and C_v in Eqs. (27) and (28), which are presented in graphical form [18], depend on the transverse pitch ratio $a = s_1/d_o$ and are given in Table 1 approximately for discrete values of a in the range $1.25 \le a \le 5.0$. For intermediate values of a, the constants C_f and C_v can be calculated by interpolation. Table 1 shows that C_f and C_v have a minimum at about $a \approx 1.5$.

Brauer used his own experimental measurements as well as those of London et al. for developing the above equations. The tube bundles used in the experimental investigations had a total number of tube rows $n_R \ge 10$.

According to Hammeke et al., the pressure drop for an in-line tube arrangement with a transverse pitch ratio $a = 2.06$, a longitudinal pitch ratio $b = 1.37$, and constant medium density is given by

$$\Delta p = \xi n_R \frac{\rho w_e^2}{2}, \tag{31}$$

where

$$\xi = \frac{2.64}{Re^{0.21}} \text{ for } 5 \times 10^3 \le Re \le 5 \times 10^4 \tag{32}$$

and

L1.4. Table 1. Dependence of the constants C_f and C_v in Eqs. (27) and (28) on a

a	C_f	C_v
1.25	0.50	0.80
1.50	0.38	0.62
2.00	0.55	0.75
3.00	0.62	1.28
4.00	0.61	1.74
5.00	0.60	2.17

$$\xi = \frac{0.892}{\mathrm{Re}^{0.11}} \text{ for } 5 \times 10^4 \leq \mathrm{Re} \leq 2 \times 10^5. \quad (33)$$

The Reynolds number Re in Eqs. (32) and (33) is formed – as in Sect. 1.1.2 – with the tube diameter d_o and the flow velocity in narrowest cross section w_e. The examined tube bundle had a tube diameter $d_o = 51$ mm and a total number of tube rows $n_R = 10$. The working medium was gas at different pressures.

At Reynolds numbers in the range $2 \times 10^5 \leq \mathrm{Re} \leq 10^6$, Hammeke et al. presented the dependence of ξ on Re in a graphical form; the experimental measurements show that at $\mathrm{Re} > 10^6$ the drag coefficient ξ is nearly constant ($\xi \approx 0.325$). Further experimental measurements indicate that, the roughness of the tube surface at $\mathrm{Re} > 2 \times 10^5$ has a considerable effect on the pressure drop performance of the tube bundle.

Klier examined tube bundles with different geometries than those used by Brauer and Hammeke et al. and recommends in conjunction with Eq. (31) the following equations for predicting the drag coefficient ξ:

For in-line tube arrangement:

$$\xi = \frac{0.879}{\mathrm{Re}^{0.12}} \text{ for } a = 2.0 \quad (34)$$

and

$$\xi = \frac{1.482}{\mathrm{Re}^{0.147}} \text{ for } a = 1.5. \quad (35)$$

According to Klier, the pressure drop for in-line tube arrangement in the examined range of the longitudinal pitch ratio ($1.5 \leq b \leq 4.5$) does not depend on b.

For staggered tube arrangement:

$$\xi = \frac{1.048}{\mathrm{Re}^{0.131}} \text{ for } a = b = 2.0 \quad (36)$$

and

$$\xi = \frac{1.522}{\mathrm{Re}^{0.146}} \text{ for } a = b = 1.5. \quad (37)$$

Klier used tube bundles with $n_R = 10$ and varied the Reynolds number in the range $2.0 \times 10^3 \leq \mathrm{Re} \leq 1.5 \times 10^4$ to develop Eqs. (34–37). The Reynolds number in the previous equations is formed – as in Sect. 1.1.2 – with the tube diameter d_o and the flow velocity in the narrowest cross section w_e.

2 Tube Bundles with Oval Tubes

Oval tubes with the major diameter parallel to the flow direction have a favorable fluid dynamic performance compared with circular tubes. As seen in Fig. 13, the point of separation of the boundary layer around an oval tube – under otherwise similar flow conditions – moves downwards in the flow direction; this leads to a smaller turbulent wake behind the oval tube and hence to a smaller loss of energy in comparison with that for the circular tube. The associated form pressure drop is thus smaller. However, the difference in pressure drop between a tube bundle with oval tubes and that with circular tubes is not as large as that for single tubes. Oval tubes are also more expensive in the production and their fixation in the tube sheets of a heat exchanger is difficult and more costly.

The number of parameters, that are required for geometrical similarity of bundles with oval tubes, is higher than that required for bundles with circular tubes. While three parameters (transverse pitch ratio, longitudinal pitch ratio, and tube arrangement, i.e., in-line or staggered) are sufficient for geometrical similarity of commonly used circular tube bundles, additional parameters as the ratio of major diameter to minor diameter, the form of the tube cross section, and the position of the major and minor diameters relative to the flow are required for geometrical similarity of oval tube bundles. General equations similar to those presented in Sect. 1.1.3 for circular tube bundles are not available for oval tube bundles. Nevertheless, many authors carried out experimental measurements and presented empirical correlations for predicting the pressure drop in oval tube bundles; it must however be emphasized that these correlations are only valid for the specific geometrical parameters and the operating conditions examined by the authors.

Brauer [20] uses the following equation to calculate the pressure drop Δp in a tube bundle with oval tubes:

$$\Delta p = \xi_B n_R \frac{\rho w_e^2}{2} \quad (38)$$

with w_e the fluid velocity in the narrowest cross section. Figures 14 and 15 show the position of the narrowest cross section in the tube bundle.

For the drag coefficient ξ_B, Brauer gives different equations for tube bundles with different geometrical ratios as follows:

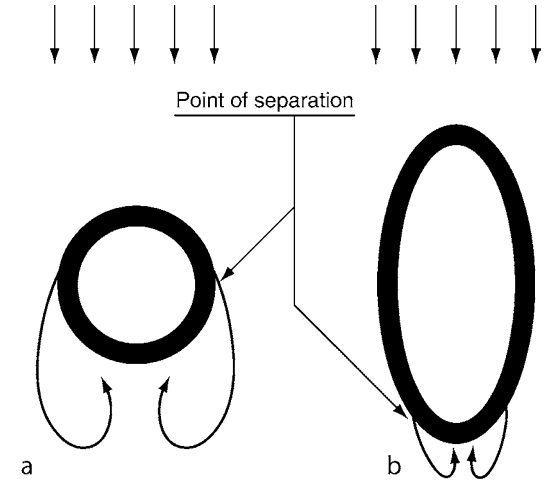
For the tube bundles No. 1, 2 in Table 2 (tube bundles with different dimensions but nearly geometrically similar)

$$\xi_B = \frac{12.4}{\mathrm{Re}_B^{0.24}} \text{ for } 5 \times 10^3 \leq \mathrm{Re}_B \leq 10^5 \quad (39)$$

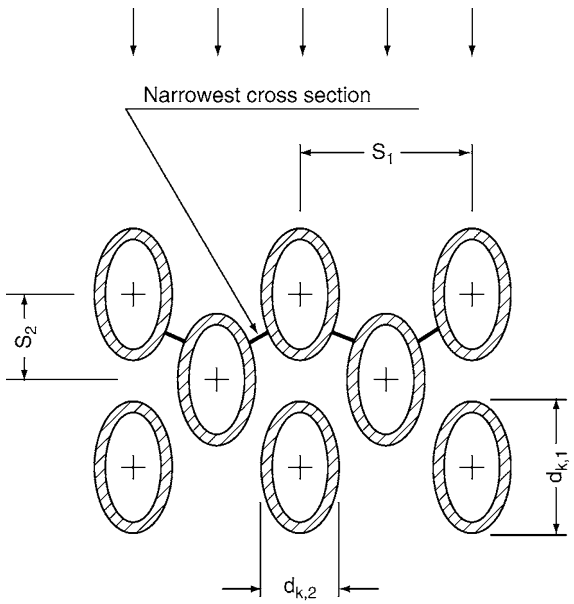
and for the tube bundle No. 3 in Table 2

$$\xi_B = \frac{36.8}{\mathrm{Re}_B^{0.27}} \text{ for } 5 \times 10^3 \leq \mathrm{Re}_B \leq 10^5. \quad (40)$$

The tube bundle No. 4 in Table 2 has oval tubes with a higher ratio of the major diameter to the minor diameter ($d_{k,1}/d_{k,2} = 2.57$) compared to that for the tube bundles No. 1 and No. 2 ($d_{k,1}/d_{k,2}$=1.84, 2.00 respectively); the transverse pitch ratio ($s_1/d_{k,2}$) and the longitudinal pitch ratio ($s_2/d_{k,1}$) are nearly the same for the three tube bundles. This tube bundle shows a higher drag coefficient in the range $6 \times 10^4 \leq \mathrm{Re}_B \leq 10^5$ and



L1.4. Fig. 13. Turbulent wake behind a tube: (**a**) a circular tube; (**b**) an oval tube with the major diameter parallel to the flow direction.

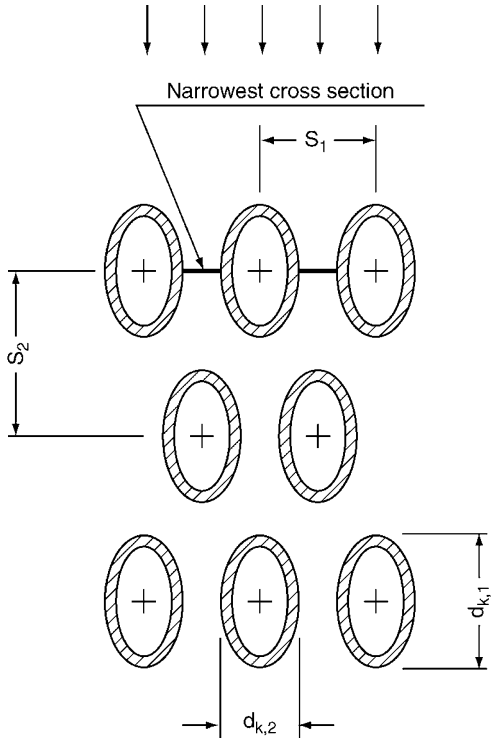


L1.4. Fig. 14. Arrangement of the tube bundles No.1, 2 and 4 in Table 2.

the inclination of the function $\xi_b = f(\mathrm{Re}_b)$ in a double logarithmic presentation is steeper. At a Reynolds number of about $\mathrm{Re} \approx 10^5$, the three tube bundles have almost the same drag coefficient.

The tube bundles No. 4 and 5 have the same dimensions of the tubes. However, the tubes have been arranged in tube bundle No. 5 – different to the commonly used arrangement – such that the main flow is parallel to the minor diameter. The pressure drop for tube bundle No. 5 is basically form pressure drop; experimental measurements yield for that bundle

$$\xi_{\mathbf{B}} = 0.53 \text{ for } 8 \times 10^3 \leq \mathrm{Re}_B \leq 5 \times 10^4. \tag{41}$$



L1.4. Fig. 15. Arrangement of the tube bundle No. 3 in Table 2.

The Reynolds number in Eqs. (39) and (40) is formed by

$$\mathrm{Re}_B = \frac{w_e d_{h,o} \rho}{\eta} \tag{42}$$

and the hydraulic diameter $d_{h,o}$ is given by

$$d_{h,o} = \frac{4F_R}{U} = \frac{4V_f}{A_{tot}}. \tag{43}$$

Figures 14 and 16 show schematically the arrangement of the tube bundles used in this investigation.

Merker and Hanke [21] give for an oval tube bundle the following equation (Fig. 17):

$$\Delta p = \xi_{M,H} n_R \frac{s_1^2 U}{s_e^3} \frac{\rho w_f^2}{2} = \xi_{\mathbf{M,H}} n_R \frac{U}{s_e} \frac{\rho w_e^2}{2} \tag{44}$$

with

$$s_e = 2s_{10} \text{ for } \frac{s_2}{d_{k,1}} = 1 \tag{45}$$

and

$$s_e = 2s_{20} \text{ for } \frac{s_2}{d_{k,1}} = 0.67. \tag{46}$$

According to Merker and Hanke, the drag coefficient $\xi_{\mathbf{M,H}}$ is independent of the transverse pitch ratio $s_1/d_{k,2}$ in the examined ranges; The following equation is recommended to calculate $\xi_{\mathbf{M,H}}$:

$$\xi_{\mathbf{M,H}} = \frac{K}{\mathrm{Re}_{\mathbf{M,H}}^m} \tag{47}$$

with

$$\mathrm{Re}_{\mathrm{M,H}} = \frac{w_e l \rho}{\eta} \tag{48}$$

and

$$l = \frac{U}{2}. \tag{49}$$

The constant K and the exponent m in Eq. (47) depend on the longitudinal pitch ratio $s_2/d_{k,1}$; their numerical values at different ranges of the Reynolds number $Re_{\mathrm{M,H}}$ are given in Table 3.

The measurements were made mostly with tube bundles with $n_R = 8$. Some measurements were made with a smaller number of tubes. The experimental results show that the flow after a few tube rows (between five and seven) is fully developed. The number of tube rows to achieve a fully developed flow depends on the longitudinal pitch ratio $s_2/d_{k,1}$. Tube bundles with a higher number of tube rows have a mean pressure drop per tube row, which practically does not depend on the number of the tube rows. The examined tube bundles had a major diameter $d_{k,1} = 30.2$ mm and a minor diameter $d_{k,2} = 7.6$ mm.

Ruth [22] examined three different tube bundles with tubes having an unconventional lenticular shape. The cross section of the tubes was formed from two circular arcs joined together as shown in Fig. 18. The following equation is given for calculating the pressure drop across the tube bundle:

$$\Delta p = \xi_{\mathrm{R}} \frac{S}{F} \frac{\rho w_e^2}{2} = \xi_{\mathrm{R}} n_{\mathrm{R}} \frac{U}{s_1} \frac{\rho w_e^2}{2}. \tag{50}$$

The examined lenticular tubes were made from segments of circular tubes with a chord $C = 51$ mm and a height $h = 6.4$ mm (h = half thickness of a lenticular tube); the tube bundles had in all cases distances $s_{10} = s_{20}$ and different ratios $s_{10}/h = s_{20}/h =$ 1.0, 1.91, and 3.5 (see, Fig. 18).

For the tube bundle with $s_{10}/h = s_{20}/h = 1.91$ and $n_{\mathrm{R}} = 5$, Ruth recommends for calculating the drag coefficient the following equation:

$$\xi_{\mathrm{R}} = \frac{0.56}{\mathrm{Re}_{\mathrm{R}}^{0.27}} \tag{51}$$

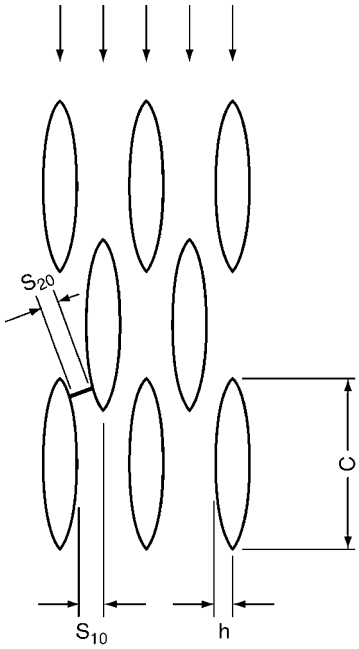
with the Reynolds number

$$\mathrm{Re}_{\mathrm{R}} = \frac{w_e (2 s_{10}) \rho}{\eta}. \tag{52}$$

The Reynolds number was varied in the range $2 \times 10^3 \leq \mathrm{Re}_{\mathrm{R}} \leq 5 \times 10^4$.

L1.4. Table 3. Values of K and m in Eq. (47)

$\frac{s_2}{d_{k,1}}$	K	m	Range of $Re_{M,H}$	Examined ratios $\frac{s_1}{d_{k,2}}$
1.00	1.668	0.479	$3.0 \times 10^3 \rightarrow 7.5 \times 10^3$	1.97, 2.26, 2.63, 3.16
	0.216	0.250	$7.5 \times 10^3 \rightarrow 3.0 \times 10^4$	
0.67	0.691	0.359	$4.0 \times 10^3 \rightarrow 1.0 \times 10^4$	2.63, 3.16
	0.251	0.250	$1.0 \times 10^4 \rightarrow 4.0 \times 10^4$	



L1.4. Fig. 18. Tube bundle with lenticular tubes examined by Ruth.

The Reynolds number of the other tube bundles was varied only in a narrow range; the drag coefficient was given in a tabular form [22]. For a tube bundle with five tube rows, the following equations are valid approximately:
For $s_{10}/h = s_{20}/h = 1.0$

$$\xi_R = 0.033(2.3 \times 10^4 \leq Re_R \leq 3.2 \times 10^4) \quad (53)$$

and for $s_{10}/h = s_{20}/h = 3.5$

$$\xi_R = 0.051(2.5 \times 10^4 \leq Re_R \leq 2.6 \times 10^4). \quad (54)$$

The deviations between the given mean values and the experimental measurements lie within ± 5 %. Drag coefficients for tube bundles with a number of tube rows less than five are also presented by Ruth [22].

L1.5 Pressure Drop in the Outer Shell of Heat Exchangers

Edward S. Gaddis
Technische Universität Clausthal, Clausthal-Zellerfeld, Germany

1 Shell-and-Tube Heat Exchangers with Segmental Baffles

1.1 Introduction

The flow in the shell-side of a shell-and-tube heat exchanger with segmental baffles is very complex. The segmental baffles lead to a main stream S_M inside the shell, as shown in Fig. 1, which is partly across and partly parallel to the tubes. Unavoidable gaps between the tubes and the holes in the baffles, and between the baffles and the heat exchanger shell cause leakage streams S_L, which may modify the main stream significantly. Since the tubes of the heat exchanger cannot be brought very close to the shell, bypass streams S_B may exist, which also influence the main stream. The flow direction of the main stream relative to the tubes is different in the window sections created by the baffle cuts from that in the cross flow sections existing between the segmental baffles. To calculate the pressure drop in the window sections different equations are needed than those used in the cross flow sections. The spacing between the heat exchanger sheets and the first and the last baffles, which is mostly dictated by the diameter of the inlet and outlet nozzles, differs in many cases from the spacing between two adjacent baffles and some of the aforementioned streams are not present in the first and the last heat exchanger sections. This adds to the complexity of the problem.

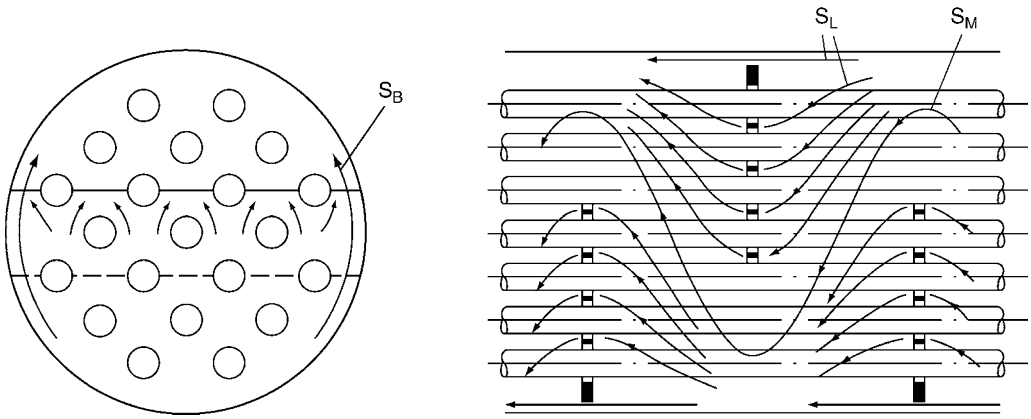
The procedure described in this chapter for calculating the shell-side pressure drop in shell-and-tube heat exchangers with segmental baffles is based principally on the Delaware method [1], in which the shell-side is divided into a number of sections. The pressure drop in the different sections is calculated separately and the total pressure drop in the heat exchanger is obtained as a summation of the individual pressure drops. The influence of leakage streams and bypass streams on the pressure drop is taken into consideration by means of correction factors. Unlike the Delaware method the pressure drop across the tube bundle is not obtained from diagrams, but from the equations presented in Subchap. L1.4. The modified calculation procedure is examined through a large number of experimental measurements available in the open literature [2].

1.2 Required Geometrical Data

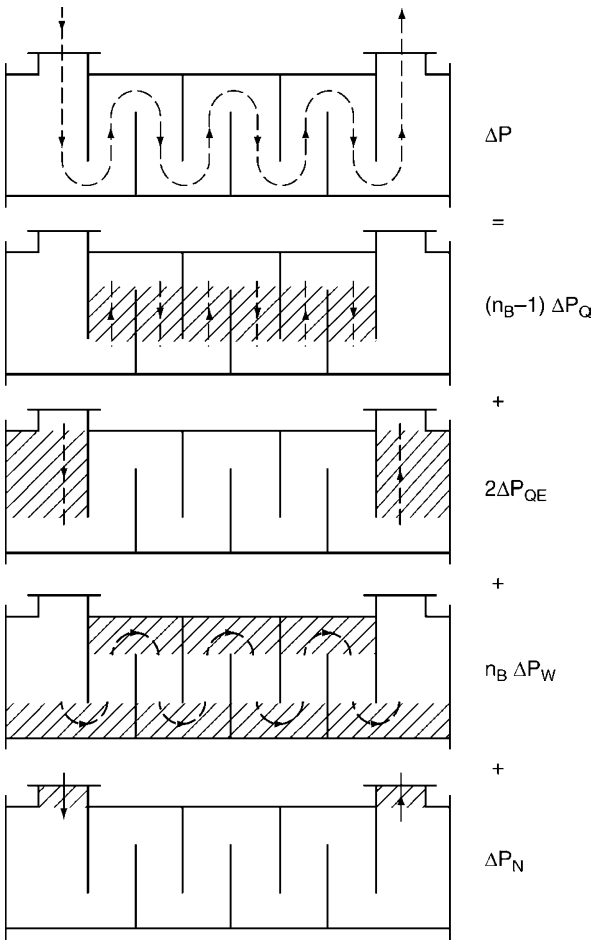
The following geometrical parameters are required for the calculation of the total pressure drop in a shell-and-tube heat exchanger with segmental baffles:

D_B,D_{BE}	Tube bundle diameters (in most cases $D_{BE} \approx D_B$)
D_i	Inside shell diameter
D_1	Baffle diameter
d_o	Outer diameter of tubes
d_B	Diameter of holes in baffles
d_N	Nozzle diameter
H	Height of baffle cut
L_E	Sum of the shortest connections e and e_1 (see Fig. 4,$L_E = 2e_1 + \Sigma e$)
n_T	Total number of tubes in heat exchanger including blind and support tubes
n_W	Number of tubes in both upper and lower windows (baffle cuts)
n_{RW}	Number of tube rows in a window section
n_S	Number of pairs of sealing strips
n_B	Number of baffles
n_{MR}	Number of main resistances in a central cross flow section
n_{MRE}	Number of main resistances in an end cross flow section
S	Baffle spacing between adjacent baffles
S_E	Baffle spacing between heat exchanger sheets and adjacent baffles (in many cases $S_E = S$)
s_1	Transverse pitch
s_2	Longitudinal pitch

Tube arrangement: in-line or staggered.



L1.5. Fig. 1. Fluid flow in the shell-side of a shell-and-tube heat exchanger with segmental baffles, S_M Main stream (partly across and partly parallel to the tubes), S_L Leakage stream, S_B Bypass stream.



L1.5. Fig. 2. Components of the shell-side pressure drop as given by Eq. (1).

1.3 Shell-Side Pressure Drop

The pressure drop Δp in the heat exchanger shell – as seen in Fig. 2 – may be calculated from the following equation:

$$\Delta p = (n_B - 1)\Delta p_Q + 2\Delta p_{QE} + n_B \Delta p_W + \Delta p_N, \qquad (1)$$

where

Δp_Q = pressure drop in a central cross flow section
Δp_{QE} = pressure drop in an end cross flow section
Δp_W = pressure drop in a window section
Δp_N = pressure drop in both nozzles

In Eq. (1), n_B is the number of baffles.

The difference in the pressure drop between end window sections and central window sections – as a result of a possible difference in the baffle spacing S and S_E – is ignored in Eq. (1).

Equation (1) gives the irreversible pressure drop due to friction and flow separation in the wake region behind the individual tubes in the shell-side of the heat exchanger. Other reversible components of pressure change, which may or may not be present, due to change in momentum flow rate (in case of gases with relatively high density change between the inlet and outlet of the heat exchanger) or due to change in hydrostatic pressure (in case of liquids with relatively high level difference between the inlet and outlet nozzles) are treated in Subchap. L1.4.

1.3.1 Pressure Drop in a Central Cross Flow Section

A central cross flow section is that part of the heat exchanger shell, which lies between two adjacent baffles and is bounded from the top and the bottom by the planes that touch the upper and lower edges of the baffle cuts. A heat exchanger with n_B baffles has $(n_B - 1)$ central cross flow sections. According to K. J. Bell [1], the pressure drop in a central cross flow section may be calculated from the following equation:

$$\Delta p_Q = \Delta p_{Q,0} f_L f_B, \qquad (2)$$

where

$\Delta p_{Q,0}$ = pressure drop in a tube bundle with cross flow under real operating conditions in the absence of leakage and bypass streams
f_L = correction factor to take in consideration the influence of leakage streams through the gaps between the tubes and the holes in the baffles and through the gaps between the baffles and the heat exchanger shell

f_B = correction factor to take in consideration the influence of bypass streams through the gaps between the outermost tubes in the bundle and the inside surface of the heat exchanger shell.

According to E. S. Gaddis and V. Gnielinski [3] (see also Subchap. L1.4), the pressure drop $\Delta p_{Q,0}$ may be calculated from

$$\Delta p_{Q,0} = \xi n_{MR} \frac{\rho w_e^2}{2}, \tag{3}$$

where

ξ = drag coefficient for the tube bundle
n_{MR} = number of main resistances in the path of the main flow in a cross flow section
ρ = fluid density
w_e = characteristic velocity

The number of main resistances n_{MR} in the path of the main flow in a cross flow section is equal to the number of the shortest connection lengths between the tubes, which has to be crossed by the main flow during its motion in a cross flow section from one edge of the segmental baffles to the other. For an in-line tube arrangement and a staggered tube arrangement having the shortest connection between adjacent tubes present in the same row, the number of main resistances n_{MR} is equal to the number of the tube rows n_R in a central cross flow section. For a staggered tube arrangement having the shortest connection between adjacent tubes present in two neighboring rows, the number of main resistances n_{MR} is equal to $(n_R - 1)$. Further, a main resistance that lies on the baffle edge marking the boundary between a central cross flow section and a window section counts only as a half resistance. In general, the drawings of the heat exchanger should be used in evaluating the number of the main resistances. Figure 3 illustrates the rules for evaluating n_{MR}.

The characteristic velocity w_e is the mean fluid velocity in the narrowest cross section measured in the tube row on or near to the shell diameter parallel to the edge of the baffle cuts and is calculated from

$$w_e = \frac{\dot{V}}{A_E}, \tag{4}$$

with $\dot{V}$ the fluid volumetric flow rate through the heat exchanger shell. The flow area A_E in Eq. (4) is given by

$$A_E = SL_E. \tag{5}$$

L_E is the sum of the shortest connections connecting neighboring tubes and the shortest connections between the outermost tubes and the shell measured in the tube row on or near the shell diameter parallel to the edge of the baffle cuts ($L_E = 2e_1 + \Sigma e$). For an in-line tube arrangement and for a staggered tube arrangement with the narrowest cross section between adjacent tubes in the same row (i.e.,$b \geq 0.5\sqrt{2a+1}e$ is calculated from $e = (a-1)d_o$ and for a staggered tube arrangement with the narrowest cross section in the diagonal (i.e.,$b < 0.5\sqrt{2a+1}e$ is calculated from $e = (c-1)d_o$. Equations (17–19) define a,b, and c. Figure 4 illustrates the definition of L_E,e, and e_1. Tie rods connecting the baffles together and fixing the baffle spacing, which influence the length L_E (and thus reducing the area A_E), should be considered in evaluating L_E.

The drag coefficient ξ is given by the following equations:
For in-line tube arrangement

$$\xi = \xi_{lam} f_{z,l} + \xi_{turb} f_{z,t} \left[1 - \exp\left(-\frac{Re + 1000}{2000}\right)\right] \tag{6}$$

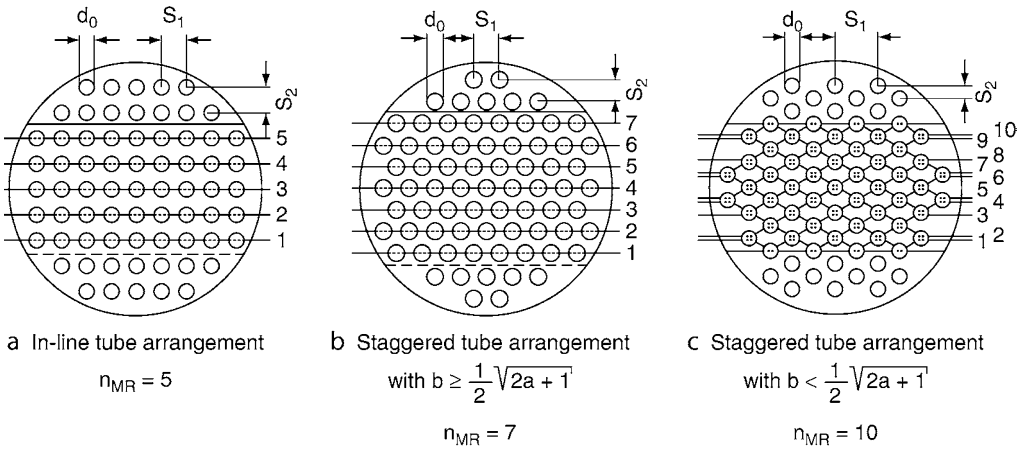
with

$$\xi_{lam} = \frac{f_{a,l,f}}{Re}, \tag{7}$$

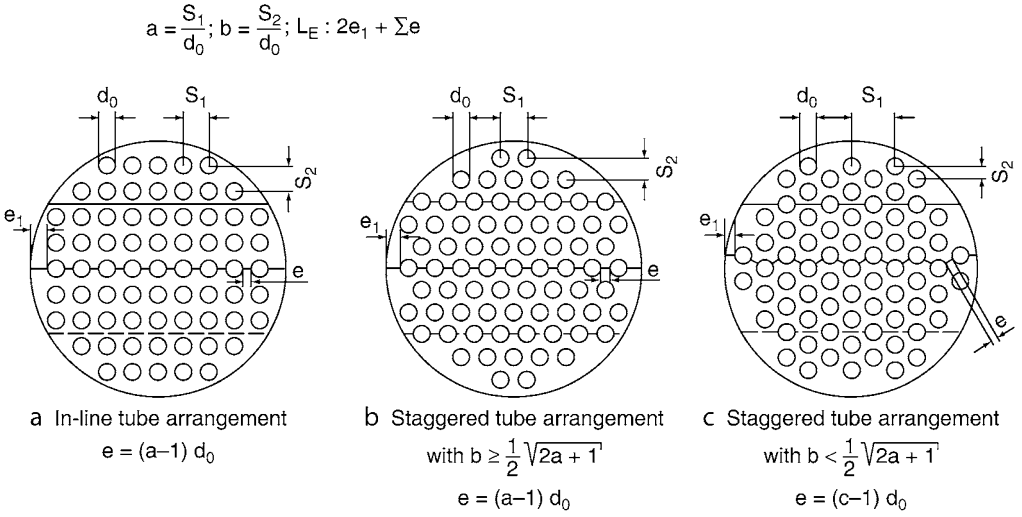
$$f_{a,l,f} = \frac{280\pi[(b^{0.5} - 0.6)^2 + 0.75]}{(4ab - \pi)a^{1.6}}, \tag{8}$$

$$\xi_{turb} = \frac{f_{a,t,f}}{Re^{0.1(b/a)}}, \tag{9}$$

$$f_{a,t,f} = \left[0.22 + 1.2\frac{\left(1 - \frac{0.94}{b}\right)^{0.6}}{(a - 0.85)^{1.3}}\right] \times 10^{0.47((b/a)-1.5)} + [0.03(a-1)(b-1)]. \tag{10}$$



L1.5. Fig. 3. Determination of the number of main resistances n_{MR}.



L1.5. Fig. 4. Definition of L_E,e and e_1.

For staggered tube arrangement:

$$\xi = \xi_{\text{lam}} f_{\text{z,l}} + \xi_{\text{turb}} f_{\text{z,t}} \left[1 - \exp\left(-\frac{\text{Re} + 200}{1000}\right)\right] \tag{11}$$

with

$$\xi_{\text{lam}} = \frac{f_{\text{a,l,v}}}{\text{Re}}, \tag{12}$$

$$f_{\text{a,l,v}} = \frac{280\pi\left[(b^{0.5} - 0.6)^2 + 0.75\right]}{(4ab - \pi)a^{1.6}} \quad \text{for } b \geq 0.5\sqrt{2a+1} \tag{13}$$

and

$$f_{\text{a,l,v}} = \frac{280\pi\left[(b^{0.5} - 0.6)^2 + 0.75\right]}{(4ab - \pi)c^{1.6}} \quad \text{for } b < 0.5\sqrt{2a+1}, \tag{14}$$

$$\xi_{\text{turb}} = \frac{f_{\text{a,t,v}}}{\text{Re}^{0.25}} \tag{15}$$

$$f_{\text{a,t,v}} = 2.5 + \left(\frac{1.2}{(a - 0.85)^{1.08}}\right) + 0.4\left(\frac{b}{a} - 1\right)^3 - 0.01\left(\frac{a}{b} - 1\right)^3, \tag{16}$$

$$a = \frac{s_1}{d_0} \text{ transverse pitch ratio}, \tag{17}$$

$$b = \frac{s_2}{d_0} \text{ longitudinal pitch ratio}, \tag{18}$$

$$c = \left((a/2)^2 + b^2\right)^{0.5} \text{ diagonal pitch ratio}. \tag{19}$$

The definition of the Reynolds number Re in the above equations is given by

$$\text{Re} = \frac{w_e d_o \rho}{\eta}. \tag{20}$$

The correction factors $f_{z,l}$ and $f_{z,t}$ for laminar and turbulent flow, respectively, take in consideration the influence of the change in the physical properties in the thermal layer adjacent to the tube surface due to heating or cooling of the shell-side fluid and are defined by

$$f_{\text{z,l}} = \left(\frac{\eta_w}{\eta}\right)^{\frac{0.57}{\left[\left(\frac{4ab}{\pi} - 1\right)\text{Re}\right]^{0.25}}}, \tag{21}$$

$$f_{\text{z,t}} = \left(\frac{\eta_w}{\eta}\right)^{0.14}. \tag{22}$$

A correction factor to take in consideration the influence of the number of tube rows on the pressure drop – as in the case of a tube bundle in a cross flow (see Subchap. L1.4) – is ignored because of the frequent change in the flow direction induced by the baffles. The dynamic viscosity η and the density ρ in the above equations are to be evaluated at the mean fluid temperature $\vartheta_m = (\vartheta_{in} + \vartheta_{out})/2$ and the dynamic viscosity η_w at the mean wall temperature ϑ_w. Moreover, for a gaseous medium with relatively high pressure drop, the gas density has to be evaluated at the mean gas pressure $p_m = (p_{in} + p_{out})/2$; since the gas pressure at the outlet of the heat exchanger is not known a priori, an iteration procedure is required.

The graphical presentations of the arrangement factors $f_{a,l,f}$, $f_{a,t,f}$, $f_{a,l,v}$, and $f_{a,t,v}$ in dependence on the transverse pitch ratio a and the longitudinal pitch ratio b, the dependence of the factors between square brackets in Eqs. (6) and (11) on the Reynolds number, the position of the shortest connections between tubes in tube bundles with staggered tube arrangement in dependence on a and b as well as the dependence of the drag coefficient ξ on the Reynolds number in case of isothermal flow for six customarily used tube bundles are given in Subchap. L1.4.

Leakage Correction Factor

According to J. Taborek [4], the leakage correction factor f_L may be calculated from

$$f_L = \exp\left[-1.33(1 + R_M)R_L^r\right] \tag{23}$$

with

$$r = [-0.15(1 + R_M) + 0.8], \tag{24}$$

$$R_M = \frac{A_{GSB}}{A_{SG}}, \tag{25}$$

$$R_L = \frac{A_{SG}}{A_E}. \tag{26}$$

A_{SG} is the sum of the areas of all gaps between the tubes and the holes in a baffle and between the shell and a baffle and is given by

$$A_{SG} = A_{GTB} + A_{GSB}. \tag{27}$$

The area A_{GTB} of all gaps between the tubes and the holes in a baffle is given by

$$A_{GTB} = \left(n_T - \frac{n_W}{2}\right)\frac{\pi\left(d_B^2 - d_o^2\right)}{4} \tag{28}$$

and the area A_{GSB} of the gap between the shell and a baffle is given by

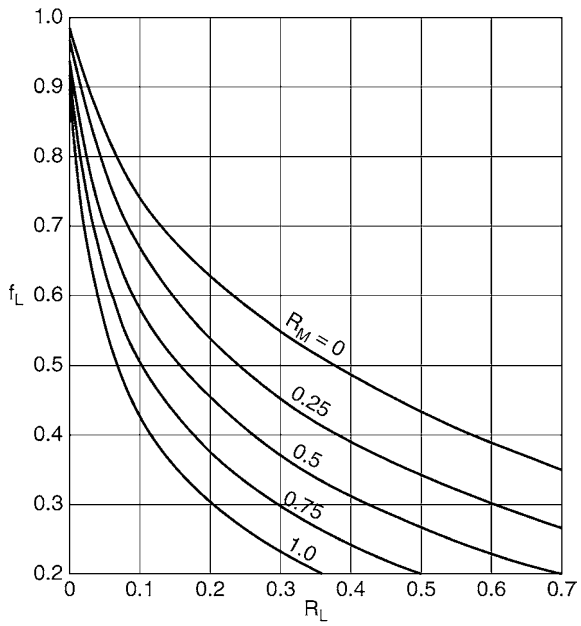
$$A_{GSB} = \frac{\pi}{4}\left(D_i^2 - D_1^2\right)\frac{360 - \gamma}{360}, \tag{29}$$

where γ is the central angle of a baffle cut (see Fig. 10) measured in degrees and is given by

$$\gamma = 2\cos^{-1}\left(1 - \frac{2H}{D_1}\right). \tag{30}$$

In counting the number of tubes n_W in both upper and lower windows, the tubes that lie on the edge of the baffles and are thus partly in a cross flow section and partly in a window section count as half tubes. The leakage correction factor f_L in dependence on R_L with R_M as a parameter is shown in Fig. 5.

Sedimentation and corrosion – if present during operation of the heat exchanger – might reduce the area of the gaps between the tubes and the holes in the baffles and between the shell and the baffles and might thus lead to an increase in the shell-side pressure drop with elapse of time. Depending on the expected amount of deposits during operation, the leakage correction factor f_L, calculated from Eq. (23), should be correspondingly modified.



L1.5. Fig. 5. Leakage correction factor as a function of R_L and R_M as given by Eq. (23).

Bypass Correction Factor

The bypass correction factor f_B is calculated from

$$f_B = \exp\left[-\beta R_B\left(1 - \sqrt[3]{2R_S}\right)\right] \text{ for } R_S < \frac{1}{2} \tag{31}$$

and

$$f_B = 1 \text{ for } R_S \geq \frac{1}{2}, \tag{32}$$

where

$$\beta = 4.5 \text{ for laminar flow } (\mathrm{Re} < 100) \tag{33}$$

and

$$\beta = 3.7 \text{ for the transition region and turbulent flow } (\mathrm{Re} \geq 100). \tag{34}$$

The ratios R_B and R_S are given by

$$R_B = \frac{A_B}{A_E}, \tag{35}$$

$$R_S = \frac{n_S}{n_{MR}}. \tag{36}$$

n_S is the number of pairs of sealing strips (in Fig. 6, $n_S = 2$). The area A_E in Eq. (35) is calculated from Eq. (5) and the flow cross sectional area A_B, which is responsible for the bypass streams, is given by

$$A_B = S(D_i - D_B - e) \text{ for } e < (D_i - D_B) \tag{37}$$

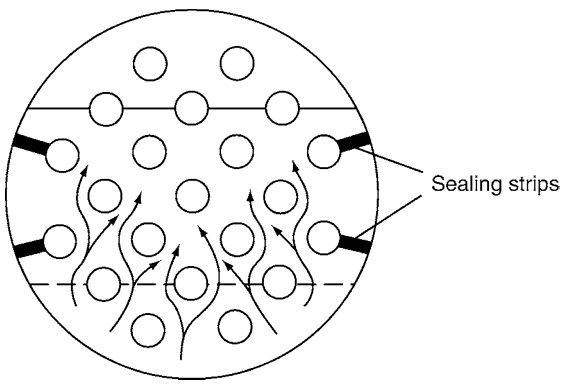
and

$$A_B = 0 \text{ for } e \geq (D_i - D_B). \tag{38}$$

The bundle diameter D_B is the diameter of a circle, which touches the outermost tubes in the space between the upper and lower edges of adjacent baffles (see Fig. 10). Figure 7 shows the dependence of the bypass correction factor f_B on R_B and R_S.

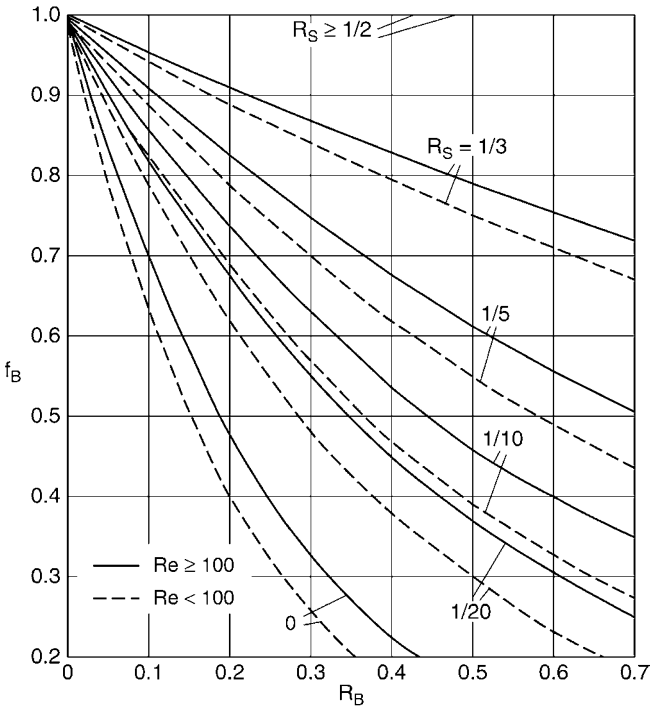
1.3.2 Pressure Drop in an End Cross Flow Section

An end cross flow section is that part of the heat exchanger shell, which lies between one of the tube sheets and the adjacent baffle, and is bounded at its outlet (for the inlet end cross flow section) or at its inlet (for the outlet end cross flow section) by



L1.5. Fig. 6. Arrangement for sealing strips n_S ($n_S = 2$ in the figure).

the plane that touches the edges of the baffle cuts. An inlet end cross flow section does not have leakage streams that flow in that section from a previous central cross flow section and an outlet end cross flow section does not have leakage streams that flow in a following central cross flow section. The influence of leakage on pressure drop in both end cross flow sections is thus ignored. Figure 8 shows the difference in the path of leakage streams between an end cross flow section and a central cross flow section.



L1.5. Fig. 7. Bypass correction factor f_B as a function of R_B and R_S as given by Eq. (31).

The pressure drop Δp_{QE} in an end cross flow section may be calculated from the following equation:

$$\Delta p_{QE} = \Delta p_{QE,0} f_B. \tag{39}$$

$\Delta p_{QE,0}$ is the pressure drop in an end cross flow section in the absence of bypass streams.

If the baffle spacing in an end cross flow section S_E is equal to the baffle spacing S in a central cross flow section, then

$$\Delta p_{QE,0} = \Delta p_{Q,0} \left(\frac{n_{MRE}}{n_{MR}} \right) \tag{40}$$

with n_{MRE} the number of main resistances in an end cross flow section (in Fig. 3a $n_{MRE} = 7$, in Fig. 3b $n_{MRE} = 9$, and in Fig. 3c $n_{MRE} = 13$). A main resistance that lies on the baffle edge marking the boundary between an end cross flow section and a window section counts only as a half resistance (see Example 1).

If $S_E \neq S$ then

$$\Delta p_{QE,0} = \xi n_{MRE} \frac{\rho w_{e,E}^2}{2}. \tag{41}$$

The velocity $w_{e,E}$ is calculated from

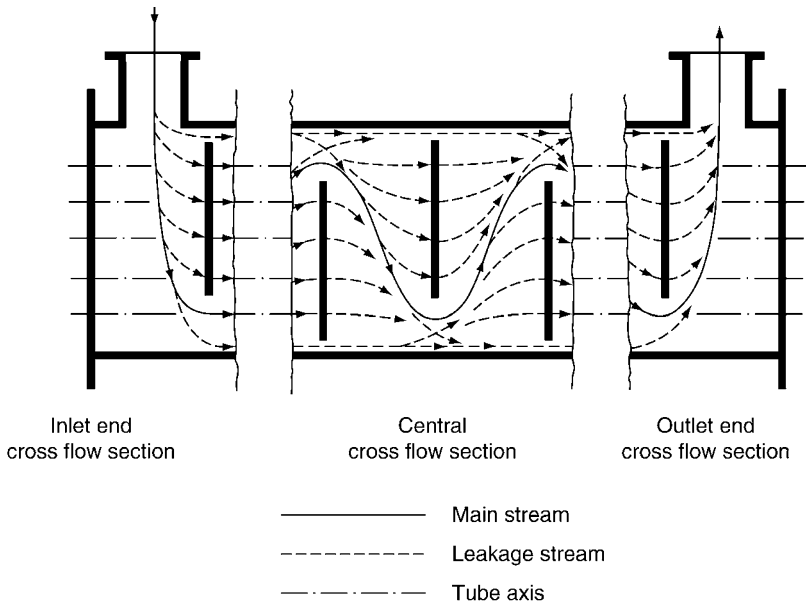
$$w_{e,E} = \frac{\dot{V}}{A_{E,E}} = w_e \frac{S}{S_E} \tag{42}$$

and

$$A_{E,E} = S_E L_E. \tag{43}$$

The drag coefficient ξ in Eq. (41) for an end cross flow section is calculated from Eq. (6) or (11); The Reynolds number Re in Eqs. (6, 7, 9, 11, 12, 15, 21) should be replaced by the Reynolds number in an end cross flow section Re_E, which is defined by

$$Re_E = Re \frac{S}{S_E}. \tag{44}$$



L1.5. Fig. 8. Difference in the path of leakage streams between an end cross flow section and a central cross flow section.

The bypass correction factor f_B is calculated from Eq. (31) or (32); the constant β in Eq. (31) is obtained from Eq. (33) or (34) depending on the numerical value of Re_E.

1.3.3 Pressure Drop in a Window Section

According to E. S. Gaddis and V. Gnielinski [2], the pressure drop Δp_W in a window section may be calculated from

$$\Delta p_W = \sqrt{\Delta p_{W,lam}^2 + \Delta p_{W,turb}^2} f_z f_L. \quad (45)$$

where

$$\Delta p_{W,lam} = \left[\frac{56}{\left(\frac{e w_z \rho}{\eta}\right)} n_{MRW} + \frac{52}{\left(\frac{d_g w_z \rho}{\eta}\right)} \left(\frac{S}{d_g}\right) + 2 \right] \left(\frac{\rho w_z^2}{2}\right) \quad (46)$$

and

$$\Delta p_{W,turb} = (0.6 n_{MRW} + 2) \left(\frac{\rho w_z^2}{2}\right). \quad (47)$$

n_{MRW} is the number of the effective main resistances in a window section. It is not essential that the numerical value of n_{MRW} is an integer; it can be calculated from

$$n_{MRW} = \frac{0.8H}{s_2}. \quad (48)$$

Equation (48) is valid when $n_{MRW} \le 2n_{RW}$, otherwise $n_{MRW} = 2n_{RW}$ (n_{RW} is the number of tube rows in a window section). d_g is the equivalent diameter of the flow area in a window section, which can be calculated from

$$d_g = \frac{4A_W}{U_W} \quad (49)$$

with A_W the cross-sectional flow area in a window section and U_W the wetted perimeter, calculated from the following equations:

$$A_W = A_{WT} - A_T \quad (50)$$

The cross-sectional area A_{WT} for a window section including the area of the window tubes is given by

$$A_{WT} = \frac{\pi}{4} D_i^2 \left(\frac{\gamma}{360}\right) - \frac{(D_1 - 2H) D_1}{4} \sin\left(\frac{\gamma}{2}\right) \quad (51)$$

and the area A_T of the window tubes is given by

$$A_T = \frac{\pi}{4} d_o^2 \left(\frac{n_W}{2}\right). \quad (52)$$

The wetted perimeter U_W is calculated from

$$U_W = \pi D_i \left(\frac{\gamma}{360}\right) + \pi d_o \left(\frac{n_W}{2}\right). \quad (53)$$

In evaluating the equivalent diameter d_g, the wetted area of the edge of the baffle has been ignored.

The characteristic velocity w_z in Eqs. (46) and (47) is evaluated from

$$w_z = (w_e w_p)^{1/2}. \quad (54)$$

w_e is given by Eq. (4) and w_p is calculated from

$$w_p = \frac{\dot{V}}{A_W}. \quad (55)$$

Equations for calculating the shortest connection e are given in Fig. (4). The correction factor f_z in Eq. (45) takes in consideration the dependence of the physical properties on temperature; it is given by

$$f_z = f_{z,l} \text{ for } Re < 100, \quad (56)$$

$$f_z = f_{z,t} \text{ for } Re \ge 100. \quad (57)$$

The correction factors $f_{z,l}$ and $f_{z,t}$ are calculated from Eqs. (21) and (22). The leakage correction factor f_L is given by Eq. (23). The influence of bypass streams in a window section has been ignored.

1.3.4 Pressure Drop in Inlet and Outlet Nozzles

The pressure drop Δp_N in both inlet and outlet nozzles may be calculated from

$$\Delta p_N = \xi_N \frac{\rho w_N^2}{2} \quad (58)$$

with ξ_N nozzle drag coefficient for both nozzles and w_N nozzle velocity given by

$$w_N = \frac{\dot{V}}{\frac{\pi}{4} d_N^2}. \quad (59)$$

It is assumed that both nozzles have the same nozzle diameter d_N and the same nozzle velocity w_N. According to V. Gnielinski [5], the drag coefficient ξ_N in the turbulent range, obtained from measurements with air and unbaffled shell-and-tube heat exchangers, may be correlated by

$$\xi_N = 5.79 \left(\frac{A_N}{A_F}\right)^{1.14} \left(\frac{d_N}{D_i}\right) \left(\frac{D_{BE}}{d_N}\right)^{2.4}. \quad (60)$$

The ratio of the cross-sectional area A_N of the nozzle to the free cross-sectional area A_F of the heat exchanger shell is given by

$$\frac{A_N}{A_F} = \frac{\frac{\pi}{4} d_N^2}{\frac{\pi}{4}\left(D_i^2 - n_T d_o^2\right)}. \quad (61)$$

The bundle diameter D_{BE} is the diameter of a circle, which touches the outermost tubes of all tubes in the shell of the heat exchanger (including the tubes in the window sections). In most heat exchanger layouts $D_{BE} \approx D_B$; however this is not essential in every case.

In some cases, the nozzle velocity w_N in the outlet nozzle differs from that in the inlet nozzle, for example, the case of a gas with a large density difference between the inlet and outlet of the heat exchanger. In such cases, it is recommended to use different drag coefficients $\xi_{N,in}$ and $\xi_{N,out}$ for inlet and outlet nozzles, respectively. According to V. Gnielinski [5]

$$\xi_{N,in} = 3.308 \left(\frac{A_N}{A_F}\right)^{1.14} \left(\frac{d_N}{D_i}\right) \left(\frac{D_{BE}}{d_N}\right)^{2.4}, \quad (62)$$

$$\xi_{N,out} = 2.482 \left(\frac{A_N}{A_F}\right)^{1.14} \left(\frac{d_N}{D_i}\right) \left(\frac{D_{BE}}{d_N}\right)^{2.4}. \quad (63)$$

Equation (58) can then be used to calculate the pressure drop in each nozzle separately using the corresponding drag coefficient and the corresponding nozzle velocity. In analogy, the same procedure may be used if (in seldom cases) the diameter of the outlet nozzle is different from that of the inlet nozzle. In such cases, different numerical values for the nozzle diameter d_N and the area ratio (A_N/A_F) have to be used.

According to V. Gnielinski [5], the nozzle drag coefficient is independent of the Reynolds number in the turbulent range. Previous estimation for the nozzle drag coefficient in the laminar and the turbulent ranges, based basically on sudden expansion of the flow at outlet of the inlet nozzle, was given by $\xi_N \approx 2$. Measurements made by V. Gnielinski [5] show that this value may be approached if the free cross-sectional area in the heat exchanger shell is relatively large (i.e., small ratio (A_N/A_F)). With decreasing free cross-sectional area in the shell (i.e., increasing number and diameter of the tubes in the shell), numerical values for ξ_N as high as 13 were measured experimentally. In the absence of a detailed experimental investigation in the laminar range similar to that made in the turbulent range [5], it may be safer to use Eq. (60) for both laminar and turbulent ranges provided that the calculated value $\xi_N \geq 2$; otherwise the value $\xi_N = 2$ should be used.

Mostly the nozzle pressure drop in a shell-and-tube heat exchanger with a large number of segmental baffles, compared with the total pressure drop, is small. However, the high negative exponent of the nozzle diameter in the equation for the nozzle pressure drop indicates that with decreasing nozzle diameter the nozzle pressure drop may contribute considerably to the total pressure drop (Eq. (58) gives $\Delta p_N \propto d_N^{-3.12}$ and the equation $\xi_N = 2$ gives $\Delta p_N \propto d_N^{-4}$).

Validity Ranges

The given equations for predicting the shell-side pressure drop may be used for heat exchangers having geometrical and operating parameters that lie within the following ranges:

$$1 < \mathrm{Re} < 5 \times 10^4$$

$$3 \leq \mathrm{Pr} \leq 10^3$$

$$0.2 \leq \frac{S}{D_i} \leq 1.0$$

$$0.15 \leq \frac{H}{D_i} \leq 0.4$$

$$R_B \leq 0.5$$

$$1.2 \leq \frac{t}{d_o} \leq 2.0$$

$$\frac{D_i}{d_o} > 10$$

$$f_L \geq 0.4$$

$$f_B \geq 0.4$$

The examined heat exchangers had tube bundles with equilateral triangular and staggered square tube arrangements [2]. The transverse pitch s_1 and the longitudinal pitch s_2 are related to the pitch t by the following relations:

For an equilateral triangular tube arrangement:

$$s_1 = t \tag{64a}$$

$$s_2 = 0.866t \tag{64b}$$

For a staggered square tube arrangement:

$$s_1 = 1.414t \tag{65a}$$

$$s_2 = 0.707t \tag{65b}$$

Measurements with in-line tube arrangement were not available. The fluids used were oil and water. The maximum deviations between measurements and predictions for the heat exchangers having geometrical and operating parameters within the ranges given above were about $\pm 35\%$. Heat exchangers with parameters highly outside the aforementioned ranges had much higher deviations. However, a small deviation from the mentioned geometrical and operating parameters did not lead immediately to much higher deviations.

It is worth mentioning that the validity ranges of the geometrical and operating parameters for the pressure drop equations given in this chapter are based on pressure drop measurements. On the other hand, the validity ranges of the same parameters for the heat transfer equations given in Chap. G8 are based on heat transfer measurements. It is not essential that the validity ranges of the parameters are the same in both cases. It is also important to emphasize that geometrical factors that lead to a reduction in the pressure drop have mostly a negative effect on the heat transfer performance of the heat exchanger; for example, increasing the area responsible for the bypass streams leads to a reduction in the pressure drop as well as in the heat transfer. This is also the case, when the gap area between the baffles and the exchanger shell is increased. On the other hand, increasing the gap area between the outer surface of the tubes and the holes in the baffles reduces the pressure drop but does not have the same adverse effect on the heat transfer as the gap area between the baffles and the shell, since leakage streams through the gap area between the tubes and the holes in the baffle contribute partly to heat transfer. All these factors have to be taken in consideration during dimensioning a shell-and-tube-heat exchanger with segmental baffles.

1.3.5 Simplified Equations for Certain Ranges of the Reynolds Numbers

The given equations for predicting the pressure drop in a central cross flow section, an end cross flow section, or a window section are formed by superimposing a laminar term and a turbulent term. Consequently, they cover a wide range of the Reynolds number. Equations of this form allow simple computer codes. However, if computations are made with a pocket calculator at very low or very high numerical values of the Reynolds number, the computational effort can be significantly reduced by eliminating some of the terms of the equations. The simplifications of the equations are as follows:

For calculating the pressure drop $\Delta p_{Q,0}$ in a central cross flow section:

Each of Eqs. (6) and (11) may be replaced by

For $Re \leq 10$:

$$\xi = \xi_{lam} f_{z,l}. \tag{66}$$

For $Re \geq 10^4$:

$$\xi = \xi_{turb} f_{z,t}. \tag{67}$$

The terms between square brackets in Eqs. (6) and (11) are effectively equal to unity in the range $Re \geq 10^4$.

For calculating the pressure drop $\Delta p_{QE,0}$ in an end cross flow section, when $S \neq S_E$:

Equation (41) may be replaced by

$$\Delta p_{QE,0} = \Delta p_{Q,0} \left(\frac{n_{MRE}}{n_{MR}}\right) \left(\frac{S}{S_E}\right)^{2-m}. \tag{68}$$

The exponent m is given by

For $Re \leq 10$ and $Re_E \leq 10$ simultaneously:

$$m = 1 \text{ for both in–line and staggered tube arrangements.} \tag{69}$$

For $Re \geq 10^4$ and $Re_E \geq 10^4$ simultaneously:

$$m = 0.1 \left(\frac{b}{a}\right) \text{ for in–line tube arrangement,} \tag{70}$$

$$m = 0.25 \text{ for staggered tube arrangement.} \tag{71}$$

In every case, m is the exponent of the Reynolds number in Eqs. (7), (9), (12), and (15).

For calculating the pressure drop Δp_W in a window section:

Equation (45) may be replaced by

For $Re \leq 10$:

$$\Delta p_W = \Delta p_{W,lam} f_{z,l} f_L. \tag{72}$$

For $Re \geq 10^4$:

$$\Delta p_W = \left[\sqrt{4 + (0.6 n_{MRW} + 2)^2} \left(\frac{\rho w_z^2}{2}\right)\right] f_{z,t} f_L. \tag{73}$$

Example 1

Figure 9 is a longitudinal and Fig. 10 is a transverse cross section of a shell-and-tube heat exchanger with two tube passes. Water at a flow rate of 60 $m^3\ h^{-1}$ is cooled in the heat exchanger shell from the inlet temperature $\vartheta_{in} = 68.5°C$ to the outlet temperature $\vartheta_{out} = 51.5\ °C$; the mean wall temperature amounts to 50°C. It is required to calculate the pressure drop through the heat exchanger shell due to friction and flow separation.

Given geometrical data:

Tube bundle diameter $D_B = 560$ mm

Inside shell diameter $D_i = 597$ mm

Baffle diameter $D_l = 590$ mm

Outer diameter of tubes $d_o = 25$ mm

Diameter of holes in baffles $d_B = 26$ mm

Nozzle diameter $d_N = 210$ mm

Height of baffle cut $H = 134.5$ mm

Total number of tubes in bundle $n_T = 258$

Number of tubes in both upper and lower windows $n_W = 82$

(Tubes that lie on the baffle edge, i.e., partly in a cross flow section and partly in a window section, count as half tubes (see Fig. 10).)

Number of tube rows in a window section $n_{RW} = 4.5$

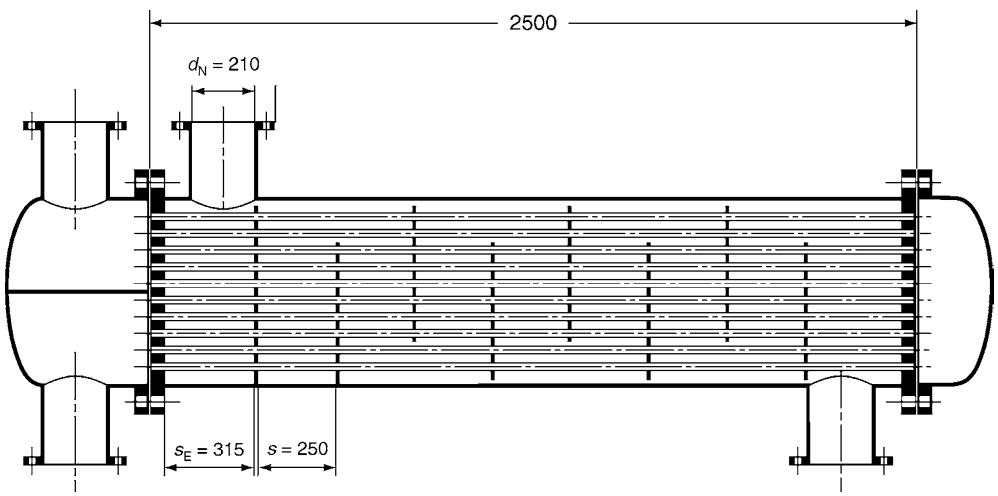
(A tube row that lies on the baffle edge, i.e., partly in a cross flow section and partly in a window section, counts as a half row (see Fig. 10).)

Number of pairs of sealing strips $n_S = 0$

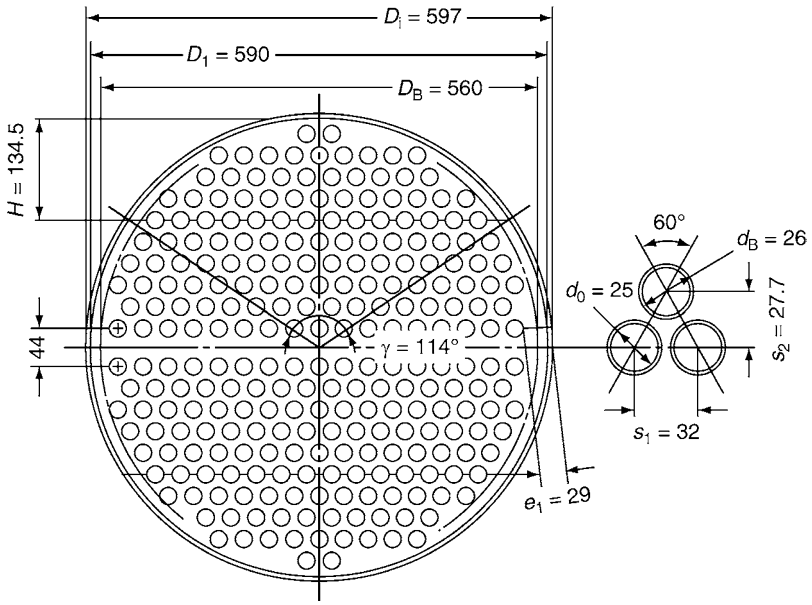
Number of baffles $n_B = 8$

Number of main resistances in a central cross flow section $n_{MR} = 11$

Number of main resistances in an end cross flow section $n_{MRE} = 15.5$



L1.5. Fig. 9. Longitudinal cross section in the heat exchanger of the example (dimensions in mm).



L1.5. Fig. 10. Transverse cross section in the heat exchanger of the example (dimensions in mm).

(A main resistance that lies on the baffle edge, i.e., partly in a cross flow section and partly in a window section, counts as a half main resistance in calculating n_{MR} and n_{MRE} (see Fig. 10).)

Baffle spacing between adjacent baffles $S = 250$ mm

Baffle spacing between the heat exchanger sheets and adjacent baffles $S_E = 315$ mm

Transverse pitch $s_1 = 32.0$ mm

Longitudinal pitch $s_2 = 27.7$ mm

Staggered tube arrangement

Further geometrical data are given in Figs. 9 and 10.

Physical properties of water:

$$\text{At a mean temperature } \vartheta_m = \frac{68.5 + 51.5}{2} = 60^\circ\text{C}$$

$$\text{Density } \rho = 983 \text{ kg m}^{-3}$$

$$\text{Dynamic viscosity } \eta = 467 \times 10^{-6} \text{ Pa s}$$

$$\text{At mean wall temperature } \vartheta_w = 50^\circ\text{C}$$

$$\text{Dynamic viscosity } \eta_w = 547 \times 10^{-6} \text{ Pa s}$$

Solution:

Calculation of the pressure drop Δp_Q in a central cross flow section:

$$a = \frac{s_1}{d_o} = \frac{32}{25} = 1.28$$

$$b = \frac{s_2}{d_o} = \frac{27.7}{25} = 1.11$$

Check: Is $b \geq \frac{1}{2}\sqrt{2a+1}$? (see Fig. 4) $\rightarrow 1.11\text{mm} \geq \frac{1}{2}\sqrt{2 \times 1.28 + 1} = 0.943\text{mm} \rightarrow$ yes

Thus, the shortest distance connecting adjacent tubes lies between tubes in the same row. Hence

$$e = (a-1)d_o = (1.28 - 1) \times 25 = 7 \text{ mm}$$

From Fig. 10 $\rightarrow e_1 = 29$ mm and the number of the shortest distances e is 16. Thus

$$L_E = 2e_1 + \Sigma e = 2 \times 29 + 16 \times 7 = 170 \text{ mm}$$

$$\text{Equation (5): } A_E = SL_E = 250 \times 170 = 42500 \text{ mm}^2$$

$$\text{Equation (4): } w_e = \frac{\dot{V}}{A_E} = \frac{\left(\frac{60}{3600}\right)}{42500 \times 10^{-6}} = 0.392 \text{ ms}^{-1}$$

$$\text{Equation (20): } \text{Re} = \frac{w_e d_o \rho}{\eta} = \frac{0.392 \times (25 \times 10^{-3}) \times 983}{467 \times 10^{-6}} = 2.06 \times 10^4$$

$$\text{Equation (16): } f_{a,t,v} = 2.5 + \left(\frac{1.2}{(a-0.85)^{1.08}}\right) + 0.4\left(\frac{b}{a} - 1\right)^3 - 0.01\left(\frac{a}{b} - 1\right)^3$$

$$= 2.5 + \left(\frac{1.2}{(1.28-0.85)^{1.08}}\right) + 0.4\left(\frac{1.11}{1.28} - 1\right)^3 - 0.01\left(\frac{1.28}{1.11} - 1\right)^3 = 5.48$$

The value of $f_{a,t,v}$ can also be obtained approximately from Fig. 9 in Subchap. L1.4.

$$\text{Equation (15): } \xi_{turb} = \frac{f_{a,t,v}}{\text{Re}^{0.25}} = \frac{5.48}{(2.06 \times 10^4)^{0.25}} = 0.457$$

$$\text{Equation (22): } f_{z,t} = \left(\frac{\eta_w}{\eta}\right)^{0.14} = \left(\frac{547 \times 10^{-6}}{467 \times 10^{-6}}\right)^{0.14} = 1.02 \text{ (turbulent flow)}$$

Since $\text{Re} > 10^4$, Eq. (67) can be used, or

$$\xi = \xi_{turb} f_{z,t} = 0.457 \times 1.02 = 0.466$$

If Eq. (11) is used instead of Eq. (67) to calculate ξ, a value $\xi = 0.477$ will be obtained.

$$\text{Equation (3): } \Delta p_{Q,0} = \xi n_{MR} \frac{\rho w_e^2}{2} = 0.466 \times 11 \times \left(\frac{983 \times 0.392^2}{2}\right) = 387 \text{ Pa}$$

Calculation of leakage correction factor f_L:

$$\text{Equation (28): } A_{GTB} = \left(n_T - \frac{n_W}{2}\right)\frac{\pi\left(d_B^2 - d_o^2\right)}{4} = \left(258 - \frac{82}{2}\right)\frac{\pi \times (26^2 - 25^2)}{4} = 8692\,\text{mm}^2$$

$$\text{Equation (30): } \gamma = 2\cos^{-1}\left(1 - \frac{2H}{D_1}\right) = 2\cos^{-1}\left(1 - \frac{2 \times 134.5}{590}\right) = 114^\circ$$

$$\text{Equation (29): } A_{GSB} = \frac{\pi}{4}\left(D_i^2 - D_1^2\right)\frac{360 - \gamma}{360} = \frac{\pi}{4}\left(597^2 - 590^2\right)\frac{360 - 114}{360} = 4459\,\text{mm}^2$$

$$\text{Equation (27): } A_{SG} = A_{GTB} + A_{GSB} = 8692 + 4459 = 13151\,\text{mm}^2$$

$$\text{Equation (25): } R_M = \frac{A_{GSB}}{A_{SG}} = \frac{4459}{13151} = 0.339$$

$$\text{Equation (26): } R_L = \frac{A_{SG}}{A_E} = \frac{13151}{42500} = 0.309$$

$$\text{Equation (24): } r = [-0.15(1 + R_M) + 0.8] = [-0.15 \times (1 + 0.339) + 0.8] = 0.599$$

$$\text{Equation (23): } f_L = \exp\left[-1.33(1 + R_M)R_L^r\right] = \exp[-1.33 \times (1 + 0.339) \times 0.309^{0.599}] = 0.414$$

Calculation of bypass correction factor f_B:

There are no sealing strips. Thus

$$\text{Equation (36): } R_S = \frac{n_S}{n_{MR}} = 0$$

$$\text{Equation (34): } \beta = 3.7 \text{ since Re} \geq 100$$

Check: $e = 7$ mm and $D_i - D_B = 597 - 560 = 37$ mm, i.e., $e < (D_i - D_B)$; thus Eq. (37) should be used.

$$\text{Equation (37): } A_B = S(D_i - D_B - e) = 250 \times (597 - 560 - 7) = 7500\,\text{mm}^2$$

$$\text{Equation (35): } R_B = \frac{A_B}{A_E} = \frac{7500}{42500} = 0.176$$

$$\text{Equation (31): } f_B = \exp\left[-\beta R_B\left(1 - \sqrt[3]{2R_S}\right)\right] = \exp\left[-3.7 \times 0.176 \times \left(1 - \sqrt[3]{2 \times 0}\right)\right] = 0.521 \text{ since } R_S = 0 \text{ (i.e., } < \frac{1}{2})$$

$$\text{Equation (2): } \Delta p_Q = \Delta p_{Q,0} f_L f_B = 387 \times 0.414 \times 0.521 = 83.5\,\text{Pa}$$

Calculation of the pressure drop Δp_{QE} in an end cross flow section:

$$\text{Equation (44): } \text{Re}_E = \text{Re}\frac{S}{S_E} = \left(2.06 \times 10^4\right) \times \frac{250}{315} = 1.63 \times 10^4$$

Since $S_E \neq S$, $\text{Re} > 10^4$ and $\text{Re}_E > 10^4$, Eq. (68) may be used with $m = 0.25$ (staggered tube arrangement, see Eq. (71)).

$$\text{Equation (68): } \Delta p_{QE,0} = \Delta p_{Q,0}\left(\frac{n_{MRE}}{n_{MR}}\right)\left(\frac{S}{S_E}\right)^{2-m} = 387 \times \left(\frac{15.5}{11}\right) \times \left(\frac{250}{315}\right)^{2-0.25} = 363.9\,\text{Pa}$$

If Eq. (41) and Eq. (11) are used instead of Eq. (68) to calculate $\Delta p_{QE,0}$, a value $\Delta p_{QE,0} = 374.7$ Pa will be obtained.

$$\text{Equation (39): } \Delta p_{QE} = \Delta p_{QE,0} f_B = 363.9 \times 0.521 = 189.6\,\text{Pa}$$

Calculation of the pressure drop Δp_W in a window section:

$$\text{Equation (51): } A_{WT} = \frac{\pi}{4}D_i^2\left(\frac{\gamma}{360}\right) - \frac{(D_1 - 2H)D_1}{4}\sin\left(\frac{\gamma}{2}\right) = \frac{\pi}{4} \times 597^2 \times \left(\frac{114}{360}\right) - \frac{(590 - 2 \times 134.5) \times 590}{4}\sin\left(\frac{114}{2}\right) = 48933\,\text{mm}^2$$

$$\text{Equation (52): } A_T = \frac{\pi}{4}d_o^2\left(\frac{n_W}{2}\right) = \frac{\pi}{4} \times 25^2 \times \left(\frac{82}{2}\right) = 20126\,\text{mm}^2$$

$$\text{Equation (50): } A_W = A_{WT} - A_T = 48933 - 20126 = 28807\,\text{mm}^2$$

$$\text{Equation (55): } w_p = \frac{\dot{V}}{A_W} = \frac{\left(\frac{60}{3600}\right)}{28807 \times 10^{-6}} = 0.579\,\text{ms}^{-1}$$

$$\text{Equation (54): } w_z = \left(w_e w_p\right)^{1/2} = (0.392 \times 0.579)^{1/2} = 0.476\,\text{ms}^{-1}$$

$$\text{Equation (48): } n_{MRW} = \frac{0.8H}{s_2} = \frac{0.8 \times 134.5}{27.7} = 3.88$$

The use of Eq. (48) is justified since $(n_{MRW} = 3.88) < (2n_{RW} = 2 \times 4.5 = 9)$.

Since $\text{Re} \geq 10^4$, Eq. (73) can be used

$$\text{Equation (73): } \Delta p_W = \left[\sqrt{4 + (0.6n_{MRW} + 2)^2}\left(\frac{\rho w_z^2}{2}\right)\right] f_{z,t} f_L = \left[\sqrt{4 + (0.6 \times 3.88 + 2)^2}\left(\frac{983 \times 0.476^2}{2}\right)\right] \times 1.02 \times 0.414 = 224.2\,\text{Pa}$$

If Eq. (45) is used instead of Eq. (73) to calculate Δp_W, a value $\Delta p_w = 225.1$ Pa will be obtained.

Calculation of the pressure drop Δp_N in inlet and outlet nozzles:

$$\text{Equation (59): } w_N = \frac{\dot{V}}{\frac{\pi}{4}d_N^2} = \frac{\left(\frac{60}{3600}\right)}{\frac{\pi}{4}\left(\frac{210}{1000}\right)^2} = 0.481\,\text{ms}^{-1}$$

$$\text{Equation (61): } \frac{A_N}{A_F} = \frac{\frac{\pi}{4}d_N^2}{\frac{\pi}{4}\left(D_i^2 - n_T d_o^2\right)} = \frac{\frac{\pi}{4}(210)^2}{\frac{\pi}{4}(597^2 - 258 \times 25^2)} = 0.226$$

$$\text{Equation (60): } \xi_N = 5.79\left(\frac{A_N}{A_F}\right)^{1.14}\left(\frac{d_N}{D_i}\right)\left(\frac{D_{BE}}{d_N}\right)^{2.4} = 5.79 \times (0.226)^{1.14} \times \left(\frac{210}{597}\right) \times \left(\frac{560}{210}\right)^{2.4} = 3.93$$

Equation (60) is used, since $\xi_N > 2$; it is assumed that $D_{BE} = D_B$.

$$\text{Equation (58): } \Delta p_N = \xi_N \frac{\rho w_N^2}{2} = 3.93 \times \frac{983 \times 0.481^2}{2} = 446.9\,\text{Pa}$$

Calculation of the shell-side pressure drop Δp:

$$\text{Equation (1): } \Delta p = (n_B - 1)\Delta p_Q + 2\Delta p_{QE} + n_B \Delta p_W + \Delta p_N = (8 - 1) \times 83.5 + 2 \times 189.6 + 8 \times 224.2 + 446.9 = 3204.2\,\text{Pa} = 3204.2 \times 10^{-5} = 0.032\,\text{bar}$$

2 Shell-and-Tube Heat Exchangers Without Baffles

Under otherwise identical operating conditions, the shell-side pressure drop in a shell-and-tube heat exchanger without baffles is much less than that in a baffled heat exchanger with a large number of baffles. For an approximate calculation of the total pressure drop Δp in a shell-and-tube heat exchangers without baffles, the concept of equivalent diameter may be used [6]:

$$\Delta p = \Delta p_p + \Delta p_N. \tag{74}$$

The pressure drop Δp_p in the shell for the flow parallel to the tubes is given by

$$\Delta p_p = \xi_p \left(\frac{L}{d_e}\right)\left(\frac{\rho w_{pa}^2}{2}\right), \tag{75}$$

the mean velocity w_{pa} in the shell is calculated from

$$w_{pa} = \frac{\dot{V}}{\frac{\pi}{4}\left(D_i^2 - n_T d_o^2\right)}, \tag{76}$$

and the equivalent diameter d_e is given by

$$d_e = \frac{D_i^2 - n_T d_o^2}{D_i + n_T d_o}. \tag{77}$$

The drag coefficient ξ_p may be calculated from

$$\xi_p = \frac{64}{Re_p} \text{ for } Re_p < 2300, \tag{78}$$

$$\xi_p = \frac{0.3164}{Re_p^{0.25}} \text{ for } 3 \times 10^3 \le Re_p \le 10^5. \tag{79}$$

The Reynolds number is defined by

$$Re_p = \frac{w_{pa} d_e \rho}{\eta}. \tag{80}$$

In Eq. (75), L is the length of the tubes between the heat exchanger sheets. Other notations are identical with those for baffled shell-and-tube heat exchangers. The nozzle pressure drop Δp_N is given by Eq. (58).

The use of Eq. (75) implies that the ratio $(L/D_i) > 10$ and that the tubes of the heat exchanger are uniformly distributed in the shell, such that no bypass currents exist in a part of the cross section where the fluid dynamic resistance to the flow is small in comparison with the rest of the free cross section.

L1.6 Pressure Drop in Fixed Beds

Karl-Ernst Wirth
Friedrich-Alexander-Universität Erlangen-Nürnberg, Erlangen, Germany

1 General

Fixed beds are solids accumulations consisting of single particles, which are passed through by a fluid (liquid, gas). They differ from packing materials, which normally are percolated by a two-phase mixture of liquids and gases. Unlike the single elements of a packing material, e.g., Raschig-rings and saddle body, which generally have a great surface per volume of the packed bed and low pressure drop, the particles in fixed beds are of compact shape and are often characterized as "spherical."

This chapter is about the pressure drop of fixed beds.

The pressure drop in fixed beds made of packing materials is described in Subchap. L2.6.

The pressure drop in fixed beds can be described by two different models:

- model of the hydraulic diameter,
- model of the flow around single particles.

The first model – the model of the hydraulic diameter – is older and leads to the relatively easy pressure drop equations like the Ergun equation [1]. The second model is newer and was firstly published by Molerus [2].

2 Pressure Drop Equation Based on the Model of the Hydraulic Diameter

The Ergun equation is based on the model that the real fixed bed can be replaced by parallel pipes for the flowing fluid and the pressure drop calculation is analog to the single-phase pipe flow, but with the hydraulic diameter of the fixed bed as a characteristic pipe dimension.

Evaluation of measurements yields the pressure drop equation for fixed beds using edged particles, the Ergun equation:

$$\frac{\Delta p}{\Delta L} = 150\frac{(1-\varepsilon)^2}{\varepsilon^3}\frac{\eta\nu}{\overline{d_\mathrm{p}}^2} + 1.75\frac{1-\varepsilon}{\varepsilon^3}\frac{\rho_\mathrm{f}\nu^2}{\overline{d_\mathrm{p}}}. \qquad (1)$$

The bulk material is characterized by the characteristic particle diameter, the Sauter-diameter $\overline{d}_\mathrm{p}$. It can be calculated from a measured particle size distribution:

$$\overline{d_\mathrm{p}} = \left[\sum_{i=1}^{n}\left(\frac{V_i}{V}\cdot\frac{1}{d_{\mathrm{p}i}}\right)\right]^{-1}. \qquad (2)$$

In Eq. (2), V_i/V is the volume of the ith-particle size fraction V_i referred to the total analyzed particle volume V and $d_{\mathrm{p}i}$ the average particle diameter of fraction i.

The constants in Eq. (1) depend on the shape and the porosity of the particles and thus has to be defined experimentally.

For the pressure drop in fixed beds, consisting of spherical particles, Brauer [3] found a correlation after analysis of measurements, which is similar to the Ergun equation:

$$\frac{\Delta p}{\Delta L} = 160\frac{(1-\varepsilon)^2}{\varepsilon^3}\frac{\eta\nu}{\overline{d_\mathrm{p}}^2} + 3.1\frac{1-\varepsilon}{\varepsilon^3}\frac{\rho_\mathrm{f}\nu^2}{\overline{d_\mathrm{p}}}\left[\frac{\eta\,(1-\varepsilon)}{\rho_\mathrm{f}\nu\overline{d_\mathrm{p}}}\right]^{0.1}. \qquad (3)$$

The Brauer equation is valid for fixed beds of monosized particles, i.e., consisting of equally sized spherical particles.

Using broad particle size distributions, the appropriate correction functions have to be considered in the pressure drop equations [3].

With pressure drop equations like the Ergun equation (1), the pressure drop in viscosity controlled ("laminar") flow is determined by the first part of the equation on the right side; the pressure drop in inertia-controlled ("turbulent") flow is determined by the second part of the equation on the right side.

In fact, there is a transition zone between both types of flow where the pressure drop is generated by the boundary layer formed by the fluid flow on the particle surface. The pressure drop caused by this flow pattern is not included in the fixed bed pressure drop equation of Ergun.

By modeling the void space in the fixed bed as parallel flow channels, the real flow paths are only insufficiently considered. This is shown among other things by the porosity dependence of the fixed bed pressure drop: it is not included correctly in the Ergun equation and hence both constants on the right side of Eqs. (1) and (3) are still functions of the fixed-bed porosity. This especially occurs for the broad particle size distributions of the fixed bed material.

The main disadvantage of the Ergun equation is that the model of the hydraulic diameter can only be applied to the

"turbulent" region, i.e., the inertia-controlled flow region, but it is not correct to use this model for the flow region where the flow is controlled by the fluid viscosity, thus on fixed beds consisting of fine grained solids (small particle Reynolds numbers) [2].

Up to now there have been no better pressure drop equations available for the technical important edged particles; the Ergun equation is wide spread. Hence, it is mentioned at this point.

The Carman–Kozeny equation is a special case of the Ergun equation. The Carman–Kozeny equation only applies to the Reynolds number region where the pressure drops are controlled by the fluid viscosity. With this, only the first part of the equation of the Ergun equation (1) is relevant.

Instead of the Sauter-diameter, the Carman–Kozeny equation contains as typical characteristic dimension of the particles the reciprocal value of the volume-related specific surface of the fixed-bed material.

Therewith, the Carman–Kozeny equation contains a changed proportional constant in comparison to the Ergun equation:

$$\frac{\Delta P}{\Delta L} = 4\frac{(1-\varepsilon)^2}{\varepsilon^3} S_v^2 \eta v. \tag{4}$$

Similar to the Ergun equation, the proportional constant in the Carman–Kozeny equation also depends on the particle shape, the width of the particle size distribution, and the fixed-bed porosity, and has to be determined experimentally. In general, the value 4 is used for the constant.

A generalized form of the Carman–Kozeny equation is the Darcy equation. In the Darcy equation, the properties of the fixed bed are summarized in a so-called permeability B:

$$\frac{\Delta P}{\Delta L} = \frac{1}{B}\eta v. \tag{5}$$

The permeability B has to be determined experimentally for each fixed bed.

3 Pressure Drop Equation Based on the Model of the Flow Around Single Particles

The pressure drop relation deduced by Molerus is based on the flow around single particles [2, 4]. During the flow around the particles, the fluid exerts a resistance W_1 on each particle. Depending on the number of particles z in the fixed bed, the resistance $z \cdot W_1$ is exerted on the fixed bed. This force is in equilibrium with the force caused by the pressure drop:

$$z \cdot W_1 = \Delta p \cdot F. \tag{6}$$

The number of particles in the fixed bed can be obtained from the solids mass balance. The number of particles equals to the ratio of solids volume in the fixed bed to the volume of a particle with the Sauter-diameter $\overline{d_p}$:

$$z = \frac{(1-\varepsilon)F\Delta L}{\overline{d_p^3}\frac{\pi}{6}}. \tag{7}$$

With Eqs. (6) and (7), the pressure drop can be described as

$$\frac{\Delta p}{\Delta L} \cdot \frac{\overline{d_p^3}\pi}{6} \cdot \frac{1}{1-\varepsilon} = W_1. \tag{8}$$

Referring Eq. (8) to the inertia force of the flowing fluid, the pressure drop is described in the dimensionless equation as

$$\mathrm{Eu} \equiv \frac{4}{3}\frac{\Delta p}{\rho_f v^2}\frac{\overline{d_p}}{\Delta L}\frac{\varepsilon^2}{1-\varepsilon} = \frac{W_1}{\frac{\rho_f}{2}\frac{\overline{d_p^2}\pi}{4}\left(\frac{v}{\varepsilon}\right)^2}. \tag{9}$$

With this, the Euler number Eu is defined similar to the drag coefficient of a single particle c_w. The Euler number is the dimensionless flow resistance W_1 of a single particle in the fixed bed, which is passed through with the average interstitial velocity v/ε.

The analysis of the flow around a single particle in a fixed bed with the help of the Navier–Stokes equation and evaluation of pressure drop measurements finally results in an equation for the Eu number. For spherical particles Molerus obtained:

$$\mathrm{Eu} \equiv \frac{24}{\mathrm{Re}}\left\{1 + 0.692\left[\frac{r_0}{\delta} + 0.5\left(\frac{r_0}{\delta}\right)^2\right]\right\} + \frac{4}{\sqrt{\mathrm{Re}}}\left[1 + 0.12\left(\frac{r_0}{\delta}\right)^{1.5}\right] + \left[0.4 + 0.891\frac{r_0}{\delta}\mathrm{Re}^{-0.1}\right], \tag{10}$$

with

$$\frac{r_0}{\delta} = \left[\frac{0.95}{\sqrt[3]{1-\varepsilon}} - 1\right]^{-1} \tag{11}$$

and the Reynolds number:

$$\mathrm{Re} \equiv \frac{\rho_f v \overline{d_p}}{\varepsilon\eta}. \tag{12}$$

Equation (11) describes the packing structure of the fixed bed and is valid for uniform random packing. For solid concentration $(1–\varepsilon) \to 0$, Eq. (10) turns into the equation for the drag coefficient of single particles, the Kaskas equation [3]

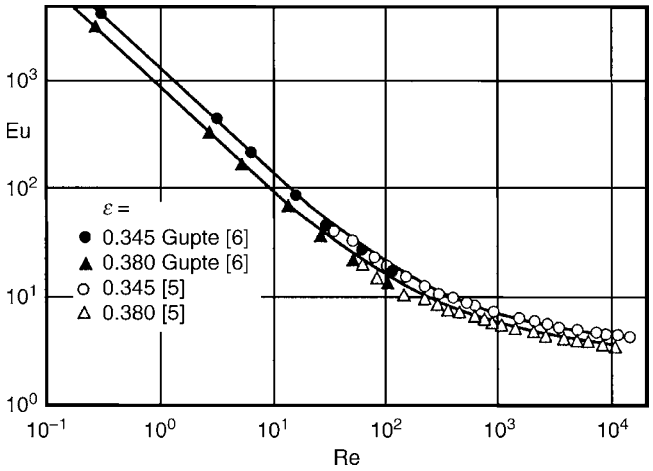
$$c_w = \frac{24}{\mathrm{Re}} + \frac{4}{\sqrt{\mathrm{Re}}} + 0.4. \tag{13}$$

This emphasizes the relevance of the Euler equation for the fixed bed percolation.

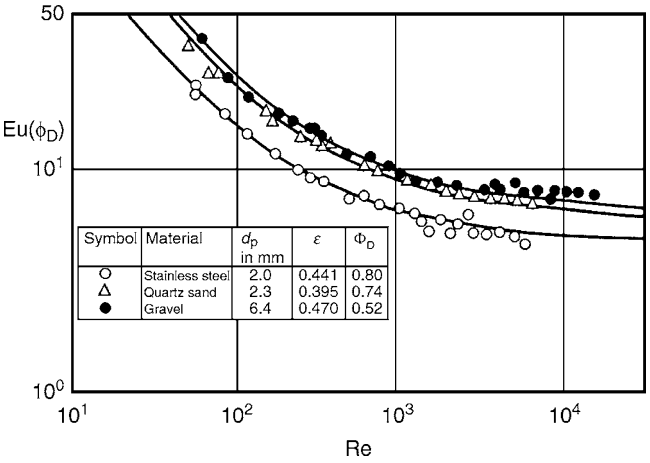
The first part of Eq. (10) describes the Stoke-flow around the particles. The middle part of the equation characterizes the flow resistance generated by the boundary layer of the fluid flow at the surface of the particles. The last part of the equation finally describes the separation characteristics of the fluid flow around the particles. A comparison of experimentally determined Euler-numbers and Euler-numbers calculated by Eqs. (10) and (11) is shown in Fig. 1.

In comparison to spherical particles there is a modified resistance in the fixed bed in the case of nonspherical particles. By introducing a pressure drop shape factor Φ_D, the resistance of nonspherical particles is related to that of spherical ones with the same Sauter diameter $\overline{d_p}$. In place of the Sauter diameter for spherical particles the equivalent diameter $\Phi_D\,\overline{d_p}$ of the nonspherical particles, i.e., the edged particles, is inserted in Eqs. (9) and (10).

According to evaluation of measurements, the following approximation function for the Euler number of nonspherical, edged particles Eu(Φ_D) results:



L1.6. Fig. 1. Comparison of experimental determined and calculated fixed-bed Euler number (plot calculated) for glass beads as test material.



L1.6. Fig. 2. Comparison of experimentally determined and calculated fixed-bed Euler numbers for nonspherical particles with different pressure loss shape factors.

$$\mathrm{Eu}(\Phi_D) = \frac{24}{\mathrm{Re}\Phi_D^2}\left\{1 + 0.685\left[\frac{r_0}{\delta} + 0.5\left(\frac{r_0}{\delta}\right)^2\right]\right\} + \frac{4}{\sqrt{\mathrm{Re}\Phi_D^{1,5}}}\left[1 + 0.289\left(\frac{r_0}{\delta}\right)^{1,5}\right] + \frac{1}{\Phi_D}\left[0.4 + 0.514\frac{r_0}{\delta}\right], \quad (14)$$

with

$$\mathrm{Eu}(\Phi_D) = \frac{4}{3}\frac{\Delta p}{\rho_f v^2}\frac{\overline{d_p}}{\Delta L}\frac{\varepsilon^2}{1-\varepsilon} \quad (15)$$

and r_0/δ according to Eq. (11) and Re according to Eq. (12).

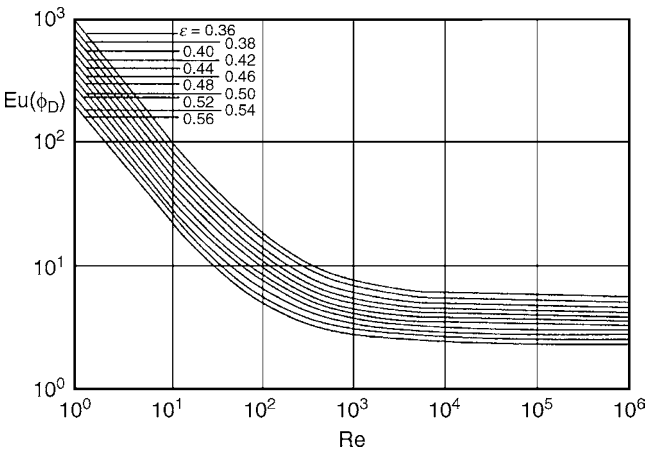
The Sauter diameter of nonspherical particles can in turn be calculated from a particle size analysis according to Eq. (2).

In Fig. 2 experimentally determined Euler numbers are compared with computed ones. The latter are depicted curvilinear.

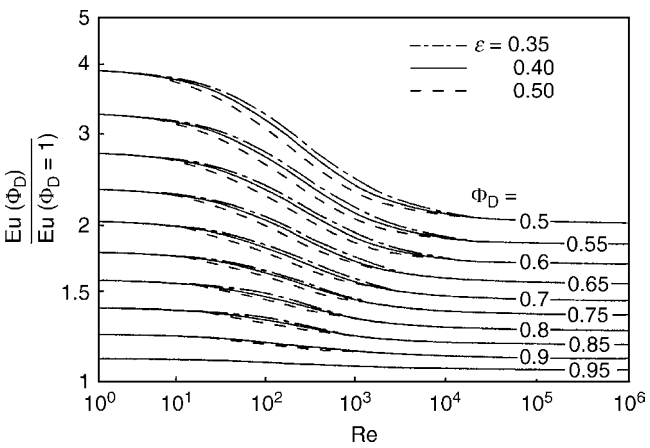
The pressure drop shape factor for nonspherical, edged particles can be determined by *one* pressure drop measurement using Eqs. (11), (14), and (15). Insertion of the measured data and of the material properties of the fluid in Eqs. (11), (14), and (15) provides the only unknown, the pressure drop shape factor, after an iteration process. Alternatively to the described arithmetical calculation Φ_D can also be determined graphically (Fig. 2).

Using Eqs. (11), (14), and (15) and for the pressure drop shape factor $\Phi_D = 1$ the associated Euler numbers are depicted in Fig. 3 depending on the fixed-bed porosity ε. The ratio of the Euler number of nonspherical particles $\mathrm{Eu}(\Phi_D)$ to that of a nonspherical particle with a pressure loss shape factor $\Phi_D = 1$ is depicted in Fig. 4 depending on the Reynolds number and the pressure drop shape factor.

The ratio plotted on the ordinate is identical to the multiple of the pressure drop of irregular formed, nonspherical particles in a fixed bed in comparison to the pressure drop in a bulk consisting of "spherical particles with coarse surface ($\Phi_D = 1$)" with the same average particle diameter at/as the identical Reynolds number, and the same bed porosity.



L1.6. Fig. 3. Diagram for determination of the Euler number for the "coarse" spheres ($\Phi_D = 1$) in fixed beds with different porosities (calculation of the curve according to Eq. (14)).



L1.6. Fig. 4. Diagram for determination of the pressure loss shape factor Φ_D from a measuring point (calculation of the curves according to Eq. (14)).

For a measuring point and using the operating parameter and the material properties, one can read off the Euler number for a "coarse sphere," $\mathrm{Eu}(\Phi_D = 1)$, from the ordinate of Fig. 3. With the measured pressure drop, the Euler number $\mathrm{Eu}(\Phi_D)$ can be calculated according to Eq. (15). The ratio of both Euler numbers has to be calculated and one has to read off from Fig. 4, the pressure drop shape factor of the applied bulk material Φ_D depending on the Reynolds number established, Eq. (12), and the fixed-bed porosity. Typical pressure drop shape factors are summarized in Table 1.

Example

A fixed bed reactor shall be operated at 150°C with spherical catalyst particles of a Sauter diameter of 3 mm and at a static pressure of 20 bar. As a reaction gas, a gas is applied which exhibits the same material data as air. The superficial gas velocity shall be 1 m/s. The fixed-bed porosity accounts for 0.4. To overcome the fluid pressure drop, there is a compressor available with a maximum pressure enhancement of 1 bar. Which length is the fixed bed reactor allowed to have?

At a static pressure of 20 bar, there is a pressure decrease of 1 bar. For practical purposes, the occurring density change can be neglected. For the material data of the fluid, one obtains therewith $\rho_f = 16.38\ \mathrm{kg/m^3}$ and $\nu = 14.8^{*}10^{-7}\ \mathrm{m^2/s}$.

For the Sauter diameter $\overline{d_p} = 3$ mm and the superficial gas velocity of 1 m/s, the particle Reynolds number results according to Eq. (12)

$$\mathrm{Re} = \frac{1\ \mathrm{m/s}^{*}3^{*}10^{-3}\ \mathrm{m}}{0.4^{*}14.8^{*}10^{-7}\ \mathrm{m^2/s}} = 5.07^{*}10^{3},$$

and for the aspect ratio r_0/δ one obtains with the porosity $\varepsilon = 0.4$ according to Eq. (11)

$$\frac{r_0}{\delta} = \left[\frac{0.95}{\sqrt[3]{0.6}} - 1\right]^{-1} = 7.91.$$

With $\mathrm{Re} = 5.07^{*}10^{3}$ and $r_0/\delta = 7.91$ the Euler number can at least be calculated according to Eq. (10) to $\mathrm{Eu} = 3.74$.

From the definition equation for the Euler number (Eq. (9)), one obtains for the length of the fixed bed

$$\begin{aligned}\Delta L &= \frac{4}{3}\frac{\Delta p}{\rho_f \nu^2}\overline{d_p}\frac{\varepsilon^2}{1-\varepsilon}\frac{1}{\mathrm{Eu}}\\ &= \frac{4}{3}\frac{10^5\ (\mathrm{kg/ms^2})}{16.38\ (\mathrm{kg/m^3})\ 1\ (\mathrm{m^2/s^2})}3^{*}10^{-3}\ \mathrm{m}\frac{0.4^2}{0.6}{*}\frac{1}{3.74}\\ &= 1.74\ \mathrm{m}.\end{aligned}$$

Which is the maximum length of the fixed bed if the spherical catalyst particles are replaced by coated quartz sand with the same Sauter diameter?

L1.6. Table 1. Pressure loss shape factors [5]

Material	Pressure loss shape factor Φ_D
Steel spheres (blasting material)	0.8
Clay granules	0.8
Quartz sand	0.74
Street chippings (broken edges)	0.63
Street chippings (sharp edged)	0.52

The Reynolds number as well as the aspect ratio has the same value for the coated nonspherical quartz sand as for the spherical catalyst. With both quantities and the pressure loss shape factor $\Phi_D = 0.74$ for quartz sand according to Table 1, one obtains the Euler number from the pressure drop equation for nonspherical particles (Eq. (14))

$$\mathrm{Eu}(\Phi_D) = 6.93.$$

With this a maximum length of the fixed bed for the nonspherical catalyst of

$$\begin{aligned}\Delta L &= \frac{4}{3}\frac{\Delta p}{\rho_f \nu^2}\overline{d_p}\frac{\varepsilon^2}{1-\varepsilon}\frac{1}{\mathrm{Eu}(\Phi_D)}\\ &= \frac{4}{3}\frac{10^5\ (\mathrm{kg/ms^2})}{16.38\ (\mathrm{kg/m^3})\ 1\ (\mathrm{m^2/s^2})}3^{*}10^{-3}\ \mathrm{m}\frac{0.4^2}{0.6}{*}\frac{1}{6.93}\\ &= 0.94\ \mathrm{m}\end{aligned}$$

can be calculated.

L1.7 Pressure Drop in Orifices and Column Trays

Johann Stichlmair
Technische Universität München, Garching, Germany

1 Fundamentals

A gas (or vapor) flowing through a mass transfer column (e.g., absorption column and distillation column) suffers a significant pressure drop (better pressure loss). This chapter describes in detail the dry pressure loss of tray columns.

The basic equation for calculating the pressure loss Δp of a fluid flowing through a perforated plate is:

$$\Delta p = \zeta \cdot \frac{\rho}{2} \cdot u_h^2 \tag{1}$$

The symbol u_h denotes the mean velocity of the fluid in the holes of the plate. Equation (1) is, in essence, just a definition of the orifice coefficient ζ. Thus, the problem of pressure loss calculation is the prediction of the orifice coefficient.

1.1 Theoretical Approach

A perforated plate is a system of parallel holes with identical flow conditions. Thus, the significant mechanisms can be studied by considering a single hole in the plate. As shown in Fig. 1, two different situations have to be considered:

- Thin plate with a large hole, $s/d_h \to 0$
- Thick plate with a small hole, $s/d_h >> 0$

Flowing through a hole in a plate the fluid always undergoes a flow contraction that is followed by a flow expansion (see Fig. 1). During flow contraction the flow velocity increases and, in turn, the static pressure decreases (Bernoulli). Thus, the fluid moves in the direction of falling pressure. Here, the potential energy is transformed into kinetic energy without any significant energy losses. No permanent pressure loss arises during flow contraction.

During flow expansion after passing through the hole, the flow velocity decreases and, in turn, the static pressure increases. Fluid flow in the direction of increasing pressure always results in a significant pressure loss. The permanent pressure loss Δp during flow expansion can be calculated from the first principles of fluid mechanics.

Equation of impulse momentum:

$$(p^* - p) \cdot A = A \cdot \rho \cdot u \cdot (u - u^*) \tag{2}$$

Bernoulli equation:

$$\frac{\rho}{2} \cdot u^* + p^* = \frac{\rho}{2} \cdot u^2 + p + \Delta p \tag{3}$$

Eliminating the term $(p^* - p)$ yields:

$$\rho \cdot u \cdot (u - u^*) = \frac{\rho}{2} \cdot (u^2 - u^{*2}) + \Delta p \tag{4}$$

Rearranging Eq. (4) delivers the Borda-Carnot equation:

$$\Delta p = \frac{\rho}{2} \cdot (u^* - u)^2 \tag{5}$$

Thus, the permanent pressure loss is proportional to the square of the velocity difference before and after flow expansion.

However, it has to be noted that the velocity u^* in the vena contracta differs from the velocity u_h in the geometrical cross section of a hole. Equation (5) is rewritten to give:

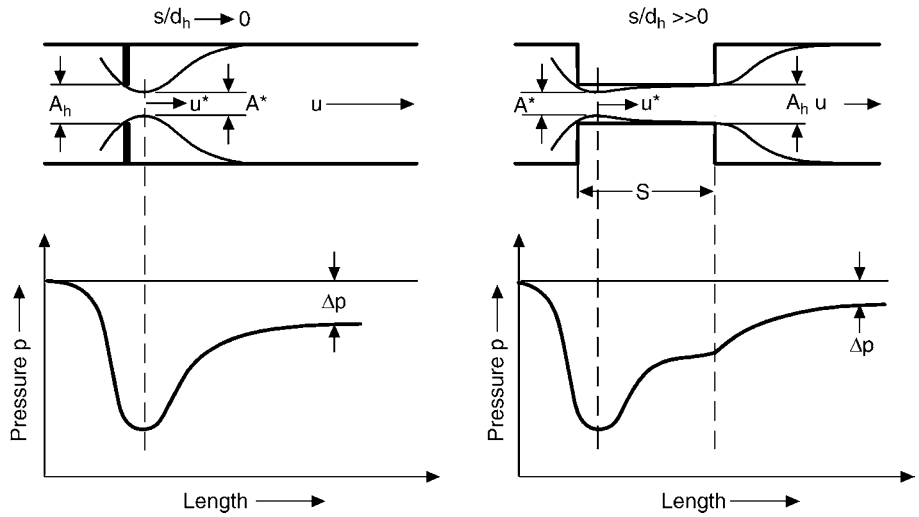
$$\Delta p = \frac{\rho}{2} \cdot u_h^2 \cdot \left(\frac{u^*}{u_h} - \frac{u}{u_h} \right)^2 \tag{6}$$

A comparison of Eq. (6) with (1) gives a relation for the orifice coefficient:

$$\zeta = \left(\frac{u^*}{u_h} - \frac{u}{u_h} \right)^2 \tag{7}$$

The decisive velocity ratios are easily calculated from the continuity equation.

As shown in Fig. 1, the flow in the hole contracts to the vena contracta A^*, which is significantly smaller than the open area A_h of the hole. The ratio A^*/A_h defines the orifice discharge coefficient α, i.e., $\alpha \equiv A^*/A_h$. With the continuity equation follows:



L1.7. Fig. 1. Fluid flow through a hole in a thin plate (*left*) and a thick plate (*right*).

$$\frac{u^*}{u_h} = \frac{1}{\alpha} \tag{8}$$

The ratio A_h/A is advantageously expressed by the relative free area φ, which is a geometrical quantity of the perforated plate, i.e., $\varphi \equiv A_h/A$. A combination with the continuity equation delivers:

$$\frac{u}{u_h} = \varphi \tag{9}$$

Equations (7)–(9) can be used for calculating the orifice coefficients of holes in thin and thick plates.

1.2 Orifice Coefficient of Holes in Thin Plates

In the special case of a large hole in a thin plate, the orifice coefficient results from Eqs. (7)–(9):

$$\zeta = (\frac{1}{\alpha} - \varphi)^2 \text{ for } s/d_h \to 0 \tag{10}$$

Equation (10) is the well-known orifice formula that describes the permanent pressure loss in nozzles used for flow rate measurements.

1.3 Orifice Coefficient of Holes in Thick Plates

In the special case of a small hole in a thick plate the flow expansion that causes the permanent pressure loss takes place in two steps. Firstly, from the vena contracta A^* to the hole area A_h and, secondly, from the hole area A_h to the column area A. The permanent pressure loss is the sum of the individual pressure losses of both expansions. The result is:

$$\zeta = \left(\frac{1}{\alpha} - 1\right)^2 + (1-\varphi)^2 \text{ for } s/d_h >> 0 \tag{11}$$

1.4 Orifice Discharge Coefficient

The evaluation of Eqs. (10) and (11) requires knowledge of the orifice discharge coefficient α. Generally, it depends on the Reynolds number in the hole and on the relative free area φ. However, at high Reynolds numbers and small values of the relative free area φ the following relation holds [1]:

$$\alpha = \frac{\pi}{\pi + 2} \approx 0.611 \tag{12}$$

For higher values of φ Eq. (13) is recommended:

$$\alpha = 0.6 + 0.4 \cdot \varphi^2 \tag{13}$$

1.5 Limiting Values of the Orifice Coefficient

The orifice coefficient of thin plates reaches its maximum value at large Reynolds numbers and low relative free areas. For $\varphi \to 0$ Eq. (10) becomes:

$$\zeta_o = \left(\frac{1}{0.611} - 0\right)^2 = 2.67 \text{ for } s/d_h \to 0 \text{ and } Re_h \geq Re_{crit} \tag{14}$$

The corresponding value of thick plates is:

$$\zeta_o = \left(\frac{1}{0.611} - 1\right)^2 + (1-0)^2 = 1.41 \quad \text{for } s/d_h >> 0 \text{ and } Re_h \geq Re_{crit} \tag{15}$$

It must be noted that thin plates have a higher pressure loss than thick plates since the flow expansion takes place in a single step. In thick plates, however, the expansion takes place in two smaller steps. In a diffuser, for instance, the expansion takes place in many very small steps that do not cause any significant pressure losses.

2 Dry Pressure Loss of Sieve Trays

Industrial sieve trays typically have values of s/d_h that are between the two special cases considered above. Additionally, the Reynolds number in the openings is often lower than the critical value Re_{crit} so that its influence on the orifice coefficient has to be considered also. The orifice coefficient cannot be rigorously modeled for these conditions. From a huge base of experimental data [2–9] an empirical correlation of the orifice coefficient ζ_o, for $\varphi \to 0$, has been developed [10, 11], which is shown in Fig. 2. As expected, the parameter lines of constant Reynolds numbers run between the theoretical limits of $\zeta_o = 2.67$ at $s/d_h \to 0$ and $\zeta_o = 1.41$ at $s/d_h >> 0$.

It must be noted that the influence of the Reynolds number on the orifice coefficient is opposite at thin and thick plates. In thin plates, the orifice coefficient ζ_o is inversely proportional to the orifice discharge coefficient α, which decreases with increasing Reynolds numbers. In thick plates, the friction of the fluid at the wall of the hole additionally contributes to the orifice coefficient. Wall friction decreases with increasing Reynolds numbers.

The correlation in Fig. 2 is valid for sharp-edged orifices with a very small relative free area, i.e., $\varphi \to 0$. In industrial columns the values of the relative free area are in the range $\varphi \leq 0.2$. The values $\zeta_o(\varphi \to 0)$ can be converted into the values $\zeta(\varphi > 0)$ by rewriting Eqs. (10) and (11), respectively:

$$\zeta(\varphi) = \zeta_o + \varphi^2 - 2 \cdot \varphi \cdot \sqrt{\zeta_o} \quad \text{for } s/d_h \to 0 \qquad (16)$$

And:

$$\zeta(\varphi) = \zeta_o + \varphi^2 - 2 \cdot \varphi \quad \text{for } s/d_h >> 0 \qquad (17)$$

In most cases the differences of the results of Eqs. (16) and (17) are very small for industrial sieve trays since the values of φ normally do not exceed 0.15 or 0.20.

3 Dry Pressure Loss of Bubble Cap and Valve Trays

Many different tray designs are used in industrial separation columns. Important examples are sieve trays, bubble cap trays, and valve trays. The dry pressure loss of sieve trays can be calculated from the correlation developed in Sect. 2.

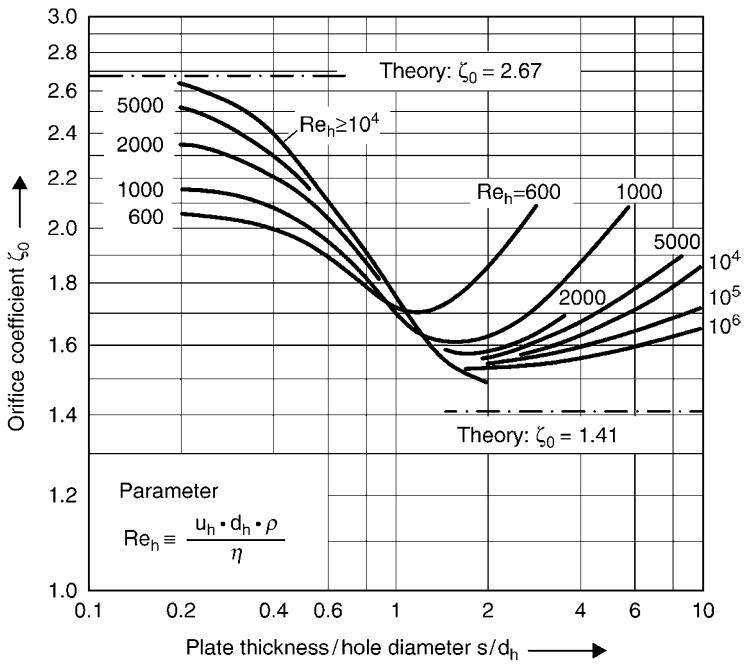
For the calculation of the pressure loss of bubble cap trays and valve trays a slightly different approach is recommended [10, 11]. The orifice coefficient is not related to the velocity in the smallest geometrical area of the open area but to the whole active area of the tray. The reason for this different approach is that the quality of tray design depends not only on the pressure loss of a single element but also on the number of elements on a tray, i.e., the relative free area φ'. The following definition implies both quantities:

$$\Delta p = \zeta_t' \cdot \frac{\rho}{2} \cdot u^2 \qquad (18)$$

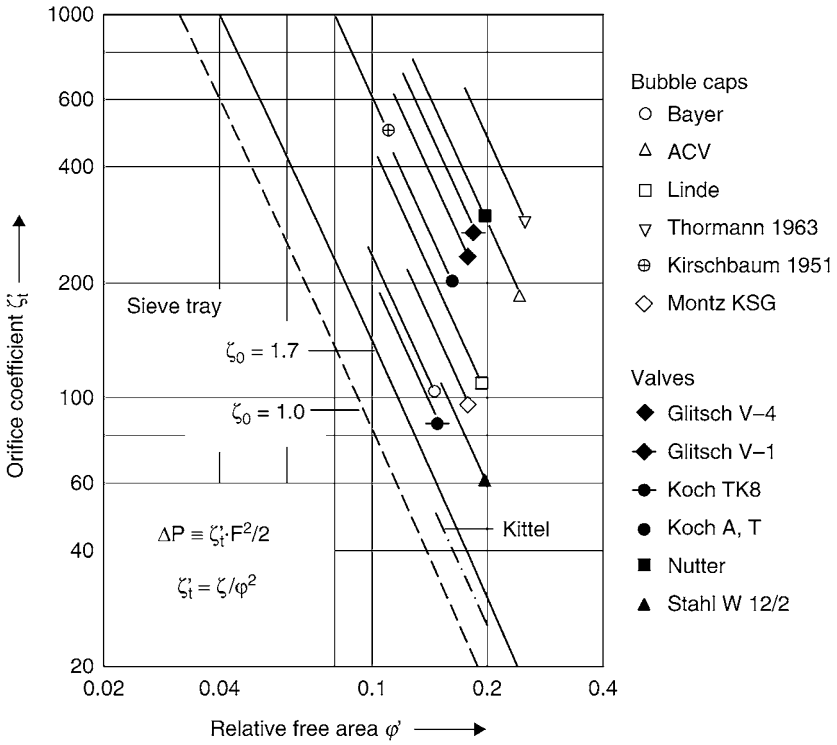
Thus, this relation between ζ and ζ_t' holds:

$$\zeta_t' = \zeta/\varphi^2 \qquad (19)$$

In Eq. (18) the symbol u denotes the superficial velocity of the fluid. More precisely, the volume flow of the fluid relates to the active area of the tray, i.e., the cross section of the column minus two times the area of the down comer. In a standard tray design



L1.7. Fig. 2. Correlation of the orifice coefficient ζ_o of sieve trays.



L1.7. Fig. 3. Correlation of the orifice coefficient ζ'_t of bubble cap and valve trays.

with a weir length of 70% of the column diameter, the active area of the tray is about 80% of the column cross section.

Bubble caps and valves are very complex elements with a multitude of geometrical parameters. Therefore, the pressure loss cannot be modeled rigorously. Since these elements are produced in large numbers it is advisable to determine the pressure drop experimentally. Most vendors provide such data of their products.

In Fig. 3a compilation of the orifice coefficients ζ'_t is presented for different tray designs. The symbols are plotted for the recommended number of elements per tray area. The parameter lines show the orifice coefficients ζ'_t when less elements are installed. Such a modification is often necessary for geometrical reasons.

The abscissa in Fig. 3 is the smallest relative free area φ' that is, for instance, either the slots or the chimney of a bubble cap. For comparisons sake, the orifice coefficient ζ'_t of a sieve tray with $\zeta_o = 1.7$ is also plotted in Fig. 3. The quality of a tray design is determined by the distance of the relevant parameter line from the line of a sieve tray with $\zeta_o = 1$, which is the theoretical minimum of a sieve tray with rounded edges.

4 Symbols

A area (m^2)
A^* area in the vena contracta (m^2)
A_{ac} active area of a column tray (m^2)
A_h area of the hole (m^2)
d_h hole diameter (m)
p pressure (N/m^2)
p^* pressure in the vena contracta (N/m^2)
s plate thickness (m)
u velocity of the fluid, superficial velocity in a column (m/s)
u^* velocity in the vena contracta (m/s)
u_h velocity in the hole (m/s)
α orifice discharge coefficient
Δp pressure loss (N/m^2)
φ relative free area of the plate
φ' relative free area of bubble cap and valve trays
ζ orifice coefficient, see Eq. (1)
ζ_o orifice coefficient for $\varphi \to 0$
ζ'_t orifice coefficient of a tray, see Eq. (18)
η dynamic viscosity of the fluid (kg/(m · s))
π circular constant, $\pi = 3.14159$
ρ density of the fluid (kg/m^3)
Re_h Reynolds number in the hole, $Re_h \equiv u_h \cdot d_h \cdot \rho/\eta$

L2.1 Prediction of Void Fraction

Holger Schmidt
Areva NP GmbH, Erlangen, Germany

1 Introduction

The method by which the pressure drop of a gas–liquid flow is calculated differs significantly to that of a single-phase flow. This is primarily due to the interaction of the two phases, which can be accounted for by applying the void fraction to the equations of mass, momentum, and energy conservation. Fields in which this methodology is applied include the evaluation of pressure drops, the analysis of expansion characteristics, or the processes involving phase change. In the following section are described the definition of the void fraction and the difference in the procedure applicable to a single-phase flow by considering the void fraction in the conservation equations. As the void fraction is in relation to the single phase flow an additional parameter that depends upon the way, in which the phases are distributed, it is also described how these parameter can be calculated.

2 Flow Pattern

Because of the interaction between the phases, their cross-sectional distributions vary in accordance with the flow conditions. Furthermore, the cross-sectional distribution of the phases is also influenced by the orientation of the tube as illustrated by the flow patterns in Fig. 1. In the following, the characteristics of these typical types of adiabatic tube flows are named and described according to their labeling in Fig. 1 (A–E and a–e, respectively).

- For upwards flow through vertical tubes

(A) Bubble flow

Bubble flow is characterized by a large quantity of bubbles that appear to be mixed almost homogeneously throughout the liquid. The liquid phase nevertheless wets the tube wall.

(B) Slug flow

In slug flow, very large bubbles form and can be several times the tube diameter in length. There are also small bubbles.

(C) Chaotic flow or churn flow

In chaotic flow, there are large and small bubbles that appear to be randomly distributed.

(D) Wispy annular flow

In this type of flow, the liquid is predominantly distributed around the tube wall. The gas phase is present in the tube core, mixed with swarms of droplets that can form strands.

(E) Annular flow

The liquid is almost entirely distributed around the tube wall with few droplets suspended in the gas phase.

- For horizontal flow

(a) Bubble flow

The gas phase is present in the form of small bubbles that, under the influence of gravitation, are mainly distributed in the upper part of the tube.

(b) Stratified flow

The gas phase is above the liquid phase, with no waves at the phase boundary.

(c) Wavy flow

The gas phase lies above the liquid phase. In this case, there are waves present at the phase boundary.

(d) Slug flow (Intermittent flow)

The liquid and gas phases are separate. The waves are so intense that they occasionally occupy the whole cross section of the tube. In these areas, there is an increased occurrence of bubbles in the liquid phase and droplets in the gas phase.

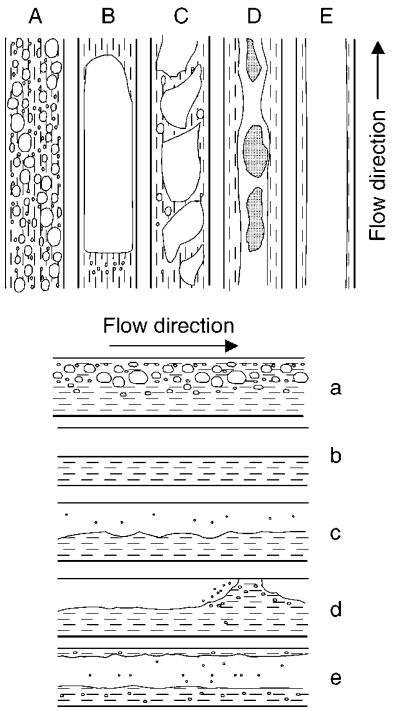
(e) Annular flow

The gas flows in the middle of the tube. The tube wall is wetted by the liquid phase. There are droplets in the gas phase. Although the tube wall is completely wetted, the majority of the liquid flows at the bottom of the tube.

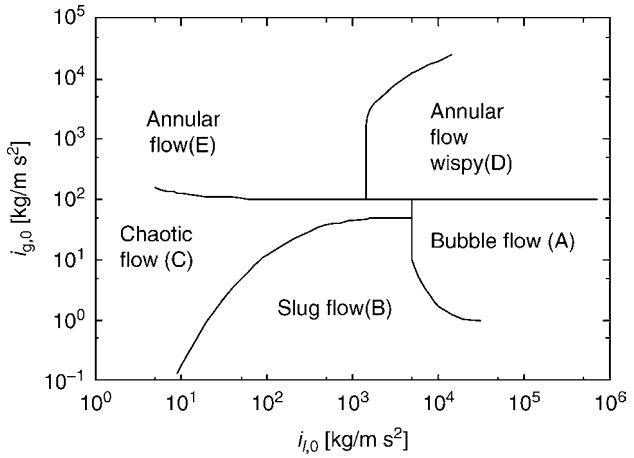
It can sometimes be of practical significance to predict the flow pattern that will occur. For instance, in slug flow, the differences between the liquid and gas phases can sometimes be so great that damages to the piping system can occur with changes in the flow direction. The flow pattern charts shown in Figs. 2 and 3 give an indication of the type of flow that will establish itself under certain undisturbed conditions.

For vertical upwards flow, the flow pattern map according to Hewitt and Roberts [1] is recommended. By means of the momentum fluxes $i_{g,0}$ and $i_{l,0}$, the types of flow to be expected can be determined. The momentum fluxes are:

VDI-GVC (ed.), *VDI Heat Atlas*, DOI 10.1007/978-3-540-77877-6_47,



L2.1. Fig. 1. Types of flow pattern.



L2.1. Fig. 2. Flow pattern map according to Hewitt and Roberts [1] for vertically upwards flow in tubes.

$$i_{g,0} = (\dot{m} \cdot \dot{x})^2 / \rho_g \tag{1}$$

$$i_{l,0} = (\dot{m} \cdot (1 - \dot{x}))^2 / \rho_l \tag{2}$$

with the two relevant quantities for the description of gas–liquid flows, i.e., the steam quality $\dot{x}$ and the mass flux $\dot{m}$ given by:

$$\dot{x} = \dot{M}_g / (\dot{M}_l + \dot{M}_g) \tag{3}$$

$$\dot{m} = (\dot{M}_g + \dot{M}_l) / A \tag{4}$$

For horizontal flow, the flow pattern map developed by Taitel and Dukler [2] is recommended. In this case, various dimensionless quantities are used to estimate which type of flow pattern will occur. For the abscissa, the Lockhart-Martinelli parameter

$$X = \left(\left(\frac{\Delta p_R}{\Delta x} \right)_l \Big/ \left(\frac{\Delta p_R}{\Delta x} \right)_g \right)^{0,5} \tag{5}$$

must be evaluated. Here, the two frictional pressure losses are each equal to that which would occur if each phase occupies the entire cross section.

For the ordinate, three values are to be determined for the following boundary conditions:

- The boundary between bubble and slug flows

$$T_D = \left(\left(\frac{\Delta p_R}{\Delta x} \right)_l \Big/ \left(\left(\rho_l - \rho_g \right) \cdot g \right) \right)^{0,5} \tag{6}$$

- The boundary between annular and wavy flows and

$$F_D = \frac{\dot{m} \cdot \dot{x}}{\left(\left(\rho_l - \rho_g \right) \cdot \rho_g \cdot d \cdot g \right)^{0,5}} \tag{7}$$

- The boundary between wavy and stratified flows

$$K_D = \frac{\dot{m}^3 \cdot \dot{x}^2 \cdot (1 - \dot{x})}{\left(\rho_l - \rho_g \right) \cdot \rho_g \cdot g \cdot \eta_l} \tag{8}$$

3 Modeling

It becomes clear from the above-mentioned flow types that a gas–liquid flow is, in part, discontinuous. The flow conditions at a point, e.g., the density, can change abruptly. It is therefore usual in practical calculations to use simplified models of the complex and discontinuous flow behavior, treating the flow as if it is continuous. The most widely used modeling approaches are:

- The heterogeneous model
- The homogeneous model
- The drift flow model and
- The two-fluid model

Both the drift flow and the two-fluid models are so complex that they are only used in complex program systems such as RELAP [3], RETRAN [4], ATHLET [19], or for calculations involving phase separation processes. However, the heterogeneous and homogeneous models can be used with reasonable effort in practical calculations.

An important quantity that is used in nearly all modeling approaches to describe a gas–liquid flow is the void fraction ε. This is defined in Eq. (9) such that the discontinuities in the fluctuating flow may be treated as continuous by time-averaging over the interval $\Delta\tau$. To this end, the function R is introduced for which:

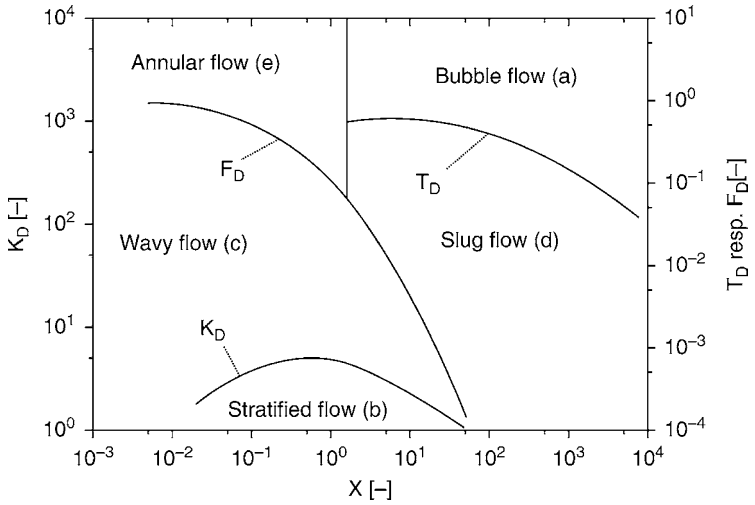
$R = 1$ if gas is present, and

$R = 0$ if liquid is present.

$$\varepsilon_{g,B} = \frac{\int_B \int_0^{\Delta\tau} R \; \mathrm{d}t \; \mathrm{d}B}{B \cdot \Delta\tau} \tag{9}$$

In the literature, there are various ranges of B over which the integration is carried out (e.g., point, line, surface, or volume). The most practically meaningful of these is that over the cross-sectional area. In the following, the quantity so defined will be referred to as the void fraction ε.

$$\varepsilon = \frac{\int_A \int_0^{\Delta\tau} R \; \mathrm{d}t \; \mathrm{d}A}{A \cdot \Delta\tau} \tag{10}$$



L2.1. Fig. 3. Flow pattern map according to Taitel and Dunkler [2] for horizontal flow in tubes.

In line with the general definition of the void fraction, a liquid fraction $\varepsilon_{l,B}$ can also be evaluated which denotes the fraction of the flow field occupied by the liquid phase:

$$\varepsilon_{l,B} = 1 - \varepsilon_{g,B} \tag{11}$$

3.1 Heterogeneous Model

In the heterogeneous model, the velocity of each phase is constant over the cross section and can be calculated using the void fraction according to Eq. (12) or (13).

$$u_g = \frac{\dot{M} \cdot \dot{x}}{\rho_g \cdot A \cdot \varepsilon} \tag{12}$$

$$u_l = \frac{\dot{M} \cdot (1 - \dot{x})}{\rho_l \cdot A \cdot (1 - \varepsilon)} \tag{13}$$

For the average density of a particular cross section, the following applies in accordance with the definition of the void fraction:

$$\bar{\rho} = \varepsilon \cdot \rho_g + (1 - \varepsilon) \cdot \rho_l \tag{14}$$

The slip ratio $s = u_g / u_l$, which is a frequently used quantity for the characterization of gas–liquid flows can be expressed in terms of the void fraction ε:

$$s = \frac{\dot{x}}{1 - \dot{x}} \cdot \frac{1 - \varepsilon}{\varepsilon} \cdot \frac{\rho_l}{\rho_g} \tag{15}$$

3.2 Homogeneous Model

The homogeneous model differs from the heterogeneous model in that the slip ratio, $s = 1$. This leads to a void fraction for the homogeneous model ε_{hom} of:

$$\varepsilon_{\text{hom}} = \frac{\rho_l \cdot \dot{x}}{\rho_l \cdot \dot{x} + \rho_g \cdot (1 - \dot{x})} \tag{16}$$

or the homogeneous density ρ_{hom} and the homogeneous velocity u_{hom}:

$$\rho_{\text{hom}} = \left(\frac{\dot{x}}{\rho_g} + \frac{1 - \dot{x}}{\rho_l} \right)^{-1} \tag{17}$$

$$u_{\text{hom}} = \frac{\dot{M}}{\rho_{\text{hom}} \cdot A} = u_g = u_l \tag{18}$$

Although the homogeneous model is very simple, it can nevertheless be used to construct very good descriptions of gas–liquid flows if:

- The phases are well mixed, as is for example the case downstream of fittings or
- The differences between the phases are small, as is the case at high pressures

3.3 Pressure Drop and Conservation Equations

The pressure drop along a piping system or vessel is determined through the evaluation of a momentum balance. This is viewed as one-dimensional in the direction of the flow path L. It is generally the case that the change in the momentum of a flow is equal to the sum of the intervening forces. In the steady state case, this means that the difference between the entry and exit momentum flows $\Delta \dot{I}$ is equal to the sum of the gravitational force F_G, the frictional force F_R, and the force resulting from the pressure difference F_p. For practical calculations, the forces or momentum flows are represented as pressure differences, where for constant flow cross sections:

$$\Delta p = \Delta p_A + \Delta p_G + \Delta p_R \tag{19}$$

with the total change in pressure Δp:

$$\Delta p = p_{\text{in}} - p_{\text{out}} = F_P / A \tag{20}$$

the frictional pressure drop Δp_R:

$$\Delta p_R = -F_R / A \tag{21}$$

the acceleration pressure drop Δp_A according to the heterogeneous model:

$$\Delta p_A = \Delta \dot{I}/A = \left(u_g^2 \cdot \rho_g \cdot \varepsilon + u_l^2 \cdot \rho_l \cdot (1-\varepsilon)\right)_{out} - \left(u_g^2 \cdot \rho_g \cdot \varepsilon + u_l^2 \cdot \rho_l \cdot (1-\varepsilon)\right)_{in} \quad (22)$$

and the geodetic pressure drop according to the heterogeneous model, where φ is the angle of inclination away from to the horizontal:

$$\Delta p_G = -F_G/A = \int_0^L (\varepsilon \cdot \rho_g + (1-\varepsilon) \cdot \rho_l) \cdot \sin(\varphi) \cdot g \; \mathrm{d}x \quad (23)$$

The contribution of the acceleration pressure drop term is equal to zero in the calculation of single-phase and incompressible pressure drops and does not influence the momentum balance. On the other hand, it is in precisely the case of evaporation processes that this contribution is to be accounted for, as the mass flow is accelerated from the slower moving liquid phase to the faster moving gas phase.

Unlike the calculation procedure for single-phase or incompressible geodetic pressure drops, in the case of a gas–liquid flow the integration must be carried out along the flow path insofar as the void fraction and the densities do not remain constant. In many practical applications, there is a phase change along the flow path and the void fraction changes. This phase change is caused by expansion evaporation (flashing) due to the pressure drop or the input or extraction of heat. For this reason, pressure drop calculations for a gas–liquid flow can often only be carried out in conjunction with an energy balance.

In line with the energy balance, the sum of the heat and power inputs, $\dot{Q}$ and P respectively, is equal to the sum of the changes in the kinetic energy of the flow $\dot{E}_T$, the flow enthalpy $\Delta \dot{H}$ and the power required to overcome the gravitational field $\dot{E}_G$ such that:

$$P + \dot{Q} = \Delta \dot{H} + \dot{E}_G + \dot{E}_T \quad (24)$$

with the change in enthalpy:

$$\Delta \dot{H} = \dot{M} \cdot (h_{out} - h_{in}) \quad (25)$$

the power required to overcome the gravitational field:

$$\dot{E}_G = \dot{M} \cdot g \cdot L \cdot \sin(\varphi) \quad (26)$$

and the change in the kinetic energy of the flow according to the heterogeneous model:

$$\dot{E}_T = \frac{1}{2} \cdot A \cdot \left(\left(u_g^3 \cdot \rho_g \cdot \varepsilon + u_l^3 \cdot \rho_l \cdot (1-\varepsilon)\right)_{out} - \left(u_g^3 \cdot \rho_g \cdot \varepsilon + u_l^3 \cdot \rho_l \cdot (1-\varepsilon)\right)_{in} \right) \quad (27)$$

For this reason, it is common practice to calculate the pressure drop in steps along the flow path L. It is assumed that the integrand in Eq. (23) and the frictional pressure drop are constant over a step of width Δx. The pressure and enthalpy after step Δx can then be determined using Eqs. (19–27) giving the input conditions for the next step.

The total mass of a gas–liquid mixture in a piping system according to the heterogeneous approach is given by integrating the product of the cross-sectional area and the average density along the flow path according to Eq. (14):

$$M = \int_0^L (\varepsilon \cdot \rho_g + (1-\varepsilon) \cdot \rho_l) \cdot A \; \mathrm{d}x \quad (28)$$

Knowledge of the total content of a vessel or piping system is of interest, for example, in determining the dimensions of expansion vessels.

4 Calculation of the Void Fraction

According to Eqs. (22), (23), (27), and (28), the void fraction is to be taken into account in all conservation equations for calculations involving gas–liquid flows. This quantity has therefore been intensively investigated. Many calculation algorithms for the void fraction are based upon the drift-flux model according to Zuber and Findly [5]. According to this model, the void fraction is given by:

$$\varepsilon = \left(\frac{C_0}{\varepsilon_{hom}} + \frac{\rho_g \cdot u_{gj}}{\dot{x} \cdot \dot{m}} \right)^{-1} \quad (29)$$

Here, the distribution factor C_0 and the weighted average drift velocity u_{gj} are to be determined from measured void fractions. Mayinger [6] and Chexal et al. [7] give an overview of a number measuring methods for determining the void fraction. These methods are based upon, for example:

- Gamma or neutron beam measurements, where the reduction of the beam intensity due to the fluid can be used to calculate the void fraction
- Traversable needle probes, which emit a signal that can be transferred to a time dependent signal of R, depending on the status at the end of the needle (according to Eq. (2))
- Impedance measurement, whereby more local or cross-section averaged void fractions can be measured depending of the positioning and geometry of the electrodes
- Weight or volume expansion measurements, which are volume averaged void fraction measurements over an entire system and
- Total pressure drop, where the void fraction can be calculated based upon correlations of the frictional pressure drop

A number of relationships for C_0 and u_{gj} are given in Table 1. There are other relationships for the calculation of the void factor in tubes or similar duct geometries than those according to Rouhani [8], such as those by Melber [9], Hughmark [10], or Nabizadeh [11]. Comparative studies by Friedel [12] or Woldesmayat and Ghajar [13] show that these models can be used with similar success. It must be pointed out that with small mass flow densities, downwards flow, counter-flow, or large flow

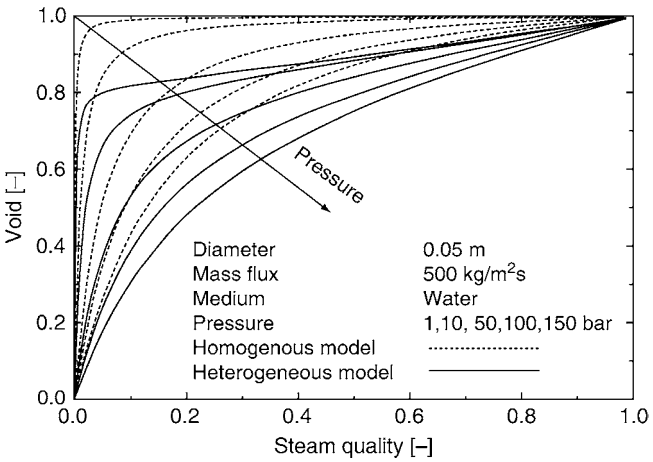
cross sections it is advantageous to use the Chexal-Lellouche correlation [7] which is valid not only over a very wide range of parameters but also requires a great deal of programming.

If the flow channel differs significantly from a cylinder, various effects including separation or homogenization influence the results of these calculations. For this reason, specific values for C_0 and u_{gj} must be determined for such geometries. Some guideline values are given in Table 1.

An ideal homogenization, as can be assumed to occur downstream of a fitting is synonymous with $C_0 = 1$ and $u_{gj} = 0$. Figure 4 shows the difference between a homogenized and fully formed flow for which the void fractions were determined using the approach by Rouhani [8]. From Fig. 4, it is also clear that the difference between the homogeneous and heterogeneous calculations becomes smaller with increasing pressure and is particularly large for low steam qualities.

There is no relationship that accounts for the influence of the gravitational force on the void fraction. Results from Elkow and Rezkallah [17] indicate that the void fraction in a very small gravitational field can differ by up to 25% from that which would occur under comparable conditions on Earth. In this respect, a summary representation by Ohta [18] shows that the void fraction for small volumetric flow rates is greater, and for large volume flows less, than that present due to the gravitational field on Earth.



L2.1. Fig. 4. Void fraction ε as a function of the steam quality $\dot{x}$.

5 Examples

The following examples demonstrate the various ways in which the conservation equations can be solved. In each case, it is assumed that the frictional pressure drop is negligible, which at low mass fluxes is a plausible simplification by the model. The following chapters contain information concerning the prediction of the frictional pressure drop.

Example 1:

The pressure drop is to be determined in the vertical riser of a pool cleaner. The riser lifts water from the bottom of a pool to the top, carrying with it some mud. The pool cleaner is driven by blowing air into the riser. Given are:

The diameter $d = 0.02$ m, the lifting height $L = 0.5$ m, the water density $\rho_l = 998.21$ kg/m^3, the gas density $\rho_g = 1.188$ kg/m^3, the surface tension $\sigma = 0.01$ N/m, the air mass flow $\dot{M}_g = 0.001$ kg/s, and the water mass flow $\dot{M}_l = 0.1$ kg/s.
The values of the friction and acceleration pressure drops in the riser are neglected so that the total pressure drop is equal to the geodetic pressure drop given by Eq. (23). Since the properties of air and water can be considered constant, ε, ε_{hom}, C_0, and u_{gj} can be determined as follows using Eqs. (16) and (29) and Table 1 and with

$$\dot{x} = \dot{M}_g / (\dot{M}_g + \dot{M}_l) = 0.001/(0.001 + 0.1) = 0.0099$$

and

$$\dot{m} = \frac{(\dot{M}_g + M_l) \cdot 4}{\pi \cdot d^2} = \frac{(0.001 + 0.1) \cdot 4}{\pi \cdot 0.02^2} = 321.5 \frac{\text{kg}}{\text{m}^2\text{s}}$$

-:

$$\begin{aligned} u_{gj} &= 1.18 \cdot (g \cdot \sigma \cdot (\rho_l - \rho_g))^{0,25} \cdot (1 - \dot{x}) / \sqrt{\rho_l} \\ &= 1.18 \cdot (9.81 \cdot 0.01 \cdot (998.21 - 1.188))^{0,25} \cdot \\ &\quad (1 - 0.0099) / \sqrt{998.21} \\ &= 0.12 \ \text{m/s} \end{aligned}$$

$$C_0 = 1 + 0.2 \cdot (1 - \dot{x}) \cdot \frac{(g \cdot d_h)^{0.25} \cdot \rho_l^{0.5}}{\dot{m}^{0.5}}$$
$$= 1 + 0.2 \cdot (1 - 0.0099) \cdot \frac{(9.81 \cdot 0.02)^{0.25} \cdot 998.21^{0.5}}{321.5^{0,5}} = 1.23$$
$$\varepsilon_{\text{hom}} = \frac{\rho_l \cdot \dot{x}}{\rho_l \cdot \dot{x} + \rho_g \cdot (1 - \dot{x})}$$
$$= \frac{998.21 \cdot 0.0099}{998.21 \cdot 0,0099 + 1.188 \cdot (1 - 0.0099)} = 0.894$$
$$\varepsilon = \left(\frac{C_0}{\varepsilon_{\text{hom}}} + \frac{\rho_g \cdot u_{gj}}{\dot{x} \cdot \dot{m}} \right)^{-1} = \left(\frac{1.23}{0.894} + \frac{1.188 \cdot 0.12}{0.0099 \cdot 321.5} \right)^{-1} = 0.7.$$

Therefore, for the pressure drop:

$$\Delta p \approx \Delta p_{\text{G}} = \int_0^L (\varepsilon \cdot \rho_g + (1 - \varepsilon) \cdot \rho_l)_l \cdot \sin(\varphi) \cdot g \ \ \text{d}x$$
$$= (0.7 \cdot 1.188 + (1 - 0.7) \cdot 998.21) \cdot$$
$$\sin(90^\circ) \cdot 9.81 \cdot 0.5 = 1,473 \text{ Pa}$$

Example 2:
The pressure drop and the mass in a 10-m-long vertical evaporator of a natural circulation steam generator are to be determined. The inlet temperature of 360°C is equal to the saturation temperature. Due to the low mass flow density of 350 kg/m²/s, the frictional pressure drop can be neglected. The following values apply:

$$p_i = 528.3 \text{ kg/m}^3, \ p_g = 143.467 \text{ kg/m}^3.$$

Since the pressure of 186.7 bar is close to the critical pressure of 220.64 bar, the homogeneous model will be used as an approximation. The heat flow density is constant along the flow path and the steam quality at the outlet is 0.3. Consequently, the steam quality rises approximately linearly in the direction of flow. Thus, for the steam content at point x:

$$\dot{x} = x \cdot (\dot{x}_{\text{out}} - \dot{x}_{\text{in}})/L = x \cdot 0,3/10 \ \ \text{m}$$

and together with Eqs. (16) and (23), the following can be written for the geodetic pressure drop according to the homogeneous model:

$$\Delta p_{\text{G}} = \int_{\dot{x}_{\text{in}}}^{\dot{x}_{\text{out}}} \frac{\rho_l \cdot g \cdot L/(\dot{x}_{\text{out}} - \dot{x}_{\text{in}})}{\dot{x} \cdot (\rho_l - \rho_g)/\rho_g + 1} \cdot \sin(\varphi) \ \ \text{d}\dot{x}$$

or, after integrating:

$$\Delta p_{\text{G}} = \frac{\rho_l \cdot \rho_g \cdot g \cdot L \cdot \sin(\varphi)}{(\dot{x}_{\text{out}} - \dot{x}_{\text{in}}) \cdot (\rho_l - \rho_g)} \cdot \left[\ln \left(\frac{\dot{x} \cdot (\rho_l - \rho_g)}{\rho_g} + 1 \right) \right]_{\dot{x}_{\text{in}}}^{\dot{x}_{\text{out}}}$$

or, for $\dot{x}_{\text{in}} = 0$:

$$\Delta p_{\text{G}} = \frac{\rho_l \cdot \rho_g \cdot g \cdot L \cdot \sin(\varphi)}{x_{\text{out}} \cdot (\rho_l - \rho_g)} \cdot \ln \left(\frac{\dot{x}_{\text{out}} \cdot (\rho_l - \rho_g)}{\rho_g} + 1 \right)$$

and inserting the values:

$$\Delta p_{\text{G}} = \frac{528.3 \cdot 143.467 \cdot 9.81 \cdot 10 \cdot \sin(90^\circ)}{0.3 \cdot (528.3 - 143.467)} \cdot$$
$$\ln \left(\frac{0.3 \cdot (528.3 - 143.467)}{143.467} + 1 \right) = 38,024 \text{ Pa} = 0,38 \text{ bar}.$$

The acceleration pressure drop can be found using Eqs. (22) and (16) from the homogeneous model:

$$\Delta p_{\text{A}} = \dot{m}^2 \cdot \left(\rho_{\text{hom,out}}^{-1} - \rho_{\text{hom,in}}^{-1} \right)$$

or for $\dot{x}_{\text{in}} = 0$

$$\Delta p_A = \dot{m}^2 \cdot \dot{x}_{\text{out}} \left(\rho_g^{-1} - \rho_l^{-1} \right)$$

and inserting the values:

$$\Delta p_{\text{A}} = 350^2 \cdot 0,3 \cdot \left(143.467^{-1} - 528.3^{-1} \right)$$
$$= 187 \text{ Pa} = 0,00187 \text{ bar}.$$

For the total pressure drop, the approximation $\Delta p_{\text{R}} = 0$ is applied according to Eq. (19):

$$\Delta p = \Delta p_{\text{A}} + \Delta p_{\text{G}} + \Delta p_{\text{R}} = 187 + 38,024 + 0$$
$$= 38,211 \text{ Pa} = 0.38 \text{ bar}.$$

The mass of water within the evaporator tube is given by Eqs. (16) and (28). As for the calculation of the geodetic pressure drop, the integral is to be solved as follows:

$$M = \int_{\dot{x}_{\text{in}}}^{\dot{x}_{\text{out}}} \frac{\rho_l \cdot L/(\dot{x}_{\text{out}} - \dot{x}_{\text{in}}) \cdot A}{\dot{x} \cdot (\rho_l - \rho_g)/\rho_g + 1} \cdot \text{d}\dot{x}$$

or, after integrating:

$$M = \frac{\rho_l \cdot \rho_g \cdot L \cdot A}{(x_{\text{out}} - x_{\text{in}}) \cdot (\rho_l - \rho_g)} \cdot \left[\ln \left(\frac{\dot{x} \cdot (\rho_l - \rho_g)}{\rho_g} + 1 \right) \right]_{\dot{x}_{\text{in}}}^{\dot{x}_{\text{out}}}$$

and for $\dot{x}_{\text{in}} = 0$:

$$M = \frac{\rho_l \cdot \rho_g \cdot L \cdot A}{x_{\text{out}} \cdot (\rho_l - \rho_g)} \cdot \ln \left(\frac{\dot{x}_{\text{out}} \cdot (\rho_l - \rho_g)}{\rho_g} + 1 \right)$$

and inserting the values for an inner diameter of 0.05 m:

$$M = \frac{528.3 \cdot 143.467 \cdot 10 \cdot 0.05^2 \cdot 3.14}{0,3 \cdot (528.3 - 143.467) \cdot 4} \cdot$$
$$\ln \left(\frac{0.3 \cdot (528.3 - 143.467)}{143.467} + 1 \right) = 7,6 \text{ kg}.$$

Example 3:
The pressure drop along a vertically orientated evaporator tubes is to be calculated. In the calculation, variations in fluid properties due to changes in pressure are to be accounted for and the heterogeneous model has been applied. The conditions are as follows:

(a) As in Example 2, but with a heat flux of 93 kW/m² through the inner wall of the tube. The material parameters for water are determined by linear interpolation between the following values:

t	p	ρ_g	ρ_l	σ	h_g	h_l
°C	bar	kg/m³	kg/m³	10^{-3} N/m	kJ/kg	kJ/kg
360	186.7	143.5	528.3	1.89	2485.4	1764.2
350	165.4	113.4	574.5	3.68	2576.4	1671.9

(b) As in Example 3a, but with a heat flux of 21 kW/m^2 through the inner wall of the tube. Also, neon is used as the working fluid with an inlet temperature of 41 K. The material properties are determined by linear interpolation between the following values:

T	p	ρ_g	ρ_l	σ	h_g	h_l
K	bar	kg/m^3	kg/m^3	10^{-3} N/m	kJ/kg	kJ/kg
41	16.88	164.5	859	0.65	86.58	38.67
39	12.6	115.3	932	1.15	89.93	32.93

To account for the change in material properties and the flow of kinetic energy, the following steps are required:

1. Division of the flow path into elements with a step-length of Δx and with a heat flow of $\dot{Q}/\Delta x$ per element. Steps 2 to 11 are to be completed for each element as follows:
2. $\dot{E}_G$ according to Eq. (26).
3. $\dot{E}_T$ according to Eq. (27), $\dot{E}_T = 0$ for the first iteration.
4. $\Delta\dot{H}$ according to Eq. (24).
5. h_{out} according to Eq. (25) at the outlet of the element.
6. $\rho_{g,out}$, $\rho_{l,out}$, $h_{g,out}$, $h_{l,out}$, and σ_{out}at the outlet of the element in question as a function of the corresponding pressure p_{out}, $p_{out} = p_{in}$ for the first iteration.
7. $\dot{x}_{out}$ with $\dot{x}_{out} = (h_{out} - h_{g,out})/(h_{l,out} - h_{g,out})$.
8. ε_{out} according to Eq. (29) and Table 1.
9. Δp_A according to Eq. (22).
10. Δp_G by, for example, the following simplification of Eq.(23)
11. $$\Delta p_G = \left(\begin{matrix} \left(\varepsilon \cdot \rho_g + (1-\varepsilon)\cdot \rho_l\right)_{in} + \\ \left(\varepsilon \cdot \rho_g + (1-\varepsilon)\cdot \rho_l\right)_{out} \end{matrix} \right) \cdot 0,5 \cdot g \cdot \sin(\varphi) \cdot \Delta x\,.$$
12. Δp according to Eq. (19) and $p_{out} = p_{in} - \Delta p$.
13. Decision whether the repetition of steps 2 to 11 is necessary. At least one repetition must be completed in order to determine $\dot{E}_T$. As a criterion for stopping the iteration sequence, the change in the outlet pressure of an element is checked each time to see whether it is less than, say 1%. At the end of this iterative procedure, the outlet values become the inlet values for the next element.

Using this calculation procedure, Examples 3a and 3b were each calculated with 200 elements. The outlet values for the first and last elements are listed below.

	Example 3a		Example 3b	
Element	1	200	1	200
Δx [m]	0.05	0.05	0.05	0.05
$\dot{Q}$ [kW]	0.73	0.73	0.165	0.165
$\dot{E}_G$ [kW]	0.0003	0.0003	0.0003	0.0003
$\dot{E}_T$ [kW]	0.001	0.0018	0.0018	0.0136
$\Delta\dot{H}$ [kW]	0.729	0.727	0.1626	0.1508
h_{out} [kJ/kg]	1765.3	1976.3	38.90	84.47
$\rho_{g,out}$ [kg/m^3]	143.5	142.9	164.45	159.95
$\rho_{l,out}$ [kg/m^3]	528.3	529.2	859.07	865.75
$h_{g,out}$ [kJ/kg]	2485.4	2487.1	86.58	86.88
$h_{l,out}$ [kJ/kg]	1764.2	1762.4	38.66	38.14
σ_{out} [10^{-3} N/m]	1.89	1.92	0.65	0.70
$\dot{x}_{out}$ [-]	0.0014	0.295	0.005	0.95
ε_{out} [-]	0.0041	0.508	0.018	0.976
Δp_A [Pa]	0.72	0.79	2.23	3.89
Δp_G [Pa]	258.7	163.3	418.21	87.03
Δp [Pa]	259.5	164.13	420.44	90.93
i_{out} [bar]	186.74	186.33	16.87	16.48
$\sum_1^{200} \Delta p$ [bar]		0.408		0.397

L2.2 Pressure Drop in Tubes, Valves, and Fittings

Anton Wellenhofer · Sebastian Muschelknautz
Linde AG, Pullach, Germany

1 Introduction

Two-phase flow (gas–liquid) in tubes, valves, and fittings is fundamentally different from single-phase flow. The pressure drop in single-phase flow is characterized by the level of turbulence and the wall roughness. The two-phase pressure drop, by contrast, is linked to the momentum exchange between the two phases and is characterized by the two-phase flow pattern.

This chapter is limited to adiabatic gas–liquid flow. Usually, adiabatic conditions are considered in process piping of chemical and petrochemical plants and cooling systems.

Two-phase flow under influence of an external heat source is characterized by phase transfer in the boundary layer. This task is described in Subchap. H3.2.

To evaluate the pressure drop in complex pipe systems, also taking fittings, valves, and other internals into account, the use of commercially available computer-based calculation tools may be considered. The software programs are mainly based on empirical or semi-empirical methods. Analytical, computer-based methods undergo a sharp development and gain more and more importance for specific tasks. For ubiquitous use, these methods are not fully matured.

The experimentally confirmed empirical and semi-empirical methods have not lost their value. These methods are further used for everyday sizing of tubes and equipment in two-phase service – by hand or as the base of the software tools used.

2 Pressure Drop in Straight Tubes

2.1 Introduction

As explained in Subchap. L2.1, the pressure drop in an adiabatic gas–liquid mixture Δp in straight tubes having the same diameter is composed of a pressure drop due to acceleration based on phase change of the mixture Δp_A, a hydrostatic part Δp_g due to level change, and pressure drop due to friction Δp_R:

$$\Delta p_{2ph} = \Delta p_A + \Delta p_g + \Delta p_R. \tag{1}$$

The frictional pressure drop Δp_A between the two locations (a) and (b) of a tube is calculated assuming momentum equilibrium (reference is made to Subchap. L2.1):

$$\Delta p_A = \frac{\dot{M}_G(b)\cdot u_G(b) + \dot{M}_f(b)\cdot u_f(b) - \dot{M}_g(a)\cdot u_g(a) - \dot{M}_f(a)\cdot u_f(a)}{(\pi/4)d^2} \tag{2}$$

Δp_A must be considered when a notable part of the mixture, e.g., a saturated mixture, is vaporized due to pressure loss in the tube. The increase of overall volume flow from (a) to (b) leads to an increased flow speed, resulting in an increased pressure drop.

The hydrostatic pressure drop is calculated as

$$\Delta p_g = \bar{\rho}\cdot g\cdot \Delta x, \tag{3}$$

where g is the acceleration of gravity, Δx is the vertical level difference, and $\bar{\rho}$ is the mean mixture density. The mean mixture density is defined as follows:

$$\bar{\rho} = (1 - \varepsilon) \cdot \rho_l + \varepsilon \cdot \rho_g. \tag{4}$$

To calculate the mean void fraction ε, reference is made to Subchap. L2.1.

2.2 Friction Pressure Drop

Two-phase flow in tubes results in different flow patterns. Considering the widely used flow pattern map by Hewitt and Roberts [1], for *vertical tubes* low gas flow results in either bubbly flow, bubbly slug flow, or churn turbulent flow, depending on the liquid volume flow. High gas flows lead either to n annular or a wispy annular flow pattern.

For *horizontal* two-phase flow, the flow pattern map by Taitel und Dukler [2] is commonly used. Dependent on the coefficients T_D, F_D, and K_D and the Lockhart–Martinelli parameter X, different flow types – bubbly flow, stratified flow, wavy flow, slug flow, and even annular flow – are predicted.

The two-phase pressure drop in straight tubes is the subject of numerous publications. The introduced methods to calculate the pressure drop are based on empirical correlations.

Most empirical methods are based on a two-phase multiplier which was introduced already in 1948 by Martinelli and Nelson [3]. The fundamental idea behind this is to calculate the pressure drop of one phase, either gas or liquid $\Delta p_{L,G}$, first. To evaluate the two-phase pressure drop Δp_R, the single-phase pressure drop is then multiplied with a two-phase multiplier $\Phi^2_{L,G}$ to consider the influence of the second phase

$$\Delta p_R = \Delta p_{L,G} \cdot \Phi^2_{L,G}. \tag{5}$$

Chisholm [4] used the liquid phase as the base phase:

$$\Delta p_R = \Delta p_L \cdot \Phi^2_L, \tag{6}$$

where

$$\Phi^2_L = 1 + (\Gamma^2 - 1)\left[\frac{21}{\Gamma} \cdot \dot{x}^{0.9}(1 - \dot{x})^{0.9} + \dot{x}^{1.8}\right], \tag{7}$$

$$\Gamma = \left(\frac{\rho_L}{\rho_G}\right)^{0.5} \cdot \left(\frac{\eta_G}{\eta_L}\right)^{0.1} \tag{8}$$

Δp_L is calculated assuming the liquid phase as the only phase in the tube, completely covering the tube cross section.

Friedel [5] developed a method which is valid for *horizontal and vertical upward flows*. The method is based on experimental data of freon-operated cooling cycles and gives acceptable predictions for ammonia, oil–gas mixtures, and liquid metals.

The single-phase pressure drop is calculated such that the overall mass flow is again considered liquid, covering the complete cross section of the tube.

$$\Phi^2_L = (1 - \dot{x})^2 + \dot{x}^2 \frac{\zeta_G}{\zeta_L} \cdot \frac{\rho_L}{\rho_G} + 3.43 \cdot \dot{x}^{0.69}(1 - \dot{x})^{0.24} \cdot \left(\frac{\rho_L}{\rho_G}\right)^{0.8} \cdot \left(\frac{\eta_G}{\eta_L}\right)^{0.22} \cdot \left(1 - \frac{\eta_G}{\eta_L}\right)^{0.89} \cdot \mathrm{Fr}_L^{-0.047} \cdot \mathrm{We}_L^{-0.033} \tag{9}$$

which is valid for viscosity ratios of $\eta_f/\eta_g \leq 1{,}500$ [5].

The friction factor for single-phase gas flow ζ_G and that for single-phase liquid flow ζ_L are calculated neglecting the wall friction (Techo [6]):

$$\zeta_{L,G} = \frac{64}{\mathrm{Re}} \tag{10}$$

and

$$\zeta_{L,G} = \left(0.86859 \cdot \ln\left[\frac{\mathrm{Re}_{L,G}}{1.964 \cdot \ln(\mathrm{Re}_{L,G}) - 3.825}\right]\right)^{-2}, \tag{11}$$

where $\mathrm{Re}_{G,L} > 1{,}055$.

For Eq. (9), Froude and Weber numbers are calculated as follows:

$$\mathrm{Fr}_L = \frac{16 \cdot \dot{M}^2_F}{g \cdot \rho^2_L \cdot \pi^2 \cdot d^5} \tag{12}$$

and

$$\mathrm{We}_L = \frac{16 \cdot \dot{M}^2_F}{\sigma \cdot \rho_L \cdot \pi^2 \cdot d^5}. \tag{13}$$

The pressure drop is then calculated as

$$\Delta p_R = \Delta p_L \cdot \Phi^2_L. \tag{14}$$

For horizontal tubes, Garcia et al. [6] derived an empirical equation based on a comprehensive set of measured data.

The influence of the tube roughness is neglected. For an unknown flow pattern, the following equation may be used:

$$f_m = 0.0925\mathrm{Re}^{-0.2534} + \frac{13.98\mathrm{Re}^{-0.9501} - 0.0925\mathrm{Re}^{-0.2534}}{\left(1 + \left(\frac{\mathrm{Re}}{293}\right)^{4.864}\right)^{0.1972}} \tag{15}$$

and

$$f_m = \frac{(\Delta p/x)D}{2\rho_m w^2_m}. \tag{16}$$

The pressure drop is calculated using Eqs. (15) and (16):

$$\Delta p = \frac{x \cdot 2\rho_m w^2_m}{D} \left(0.0925\mathrm{Re}^{-0.2534} + \frac{13.98\mathrm{Re}^{-0.9501} - 0.0925\mathrm{Re}^{-0.2534}}{\left(1 + \left(\frac{\mathrm{Re}}{293}\right)^{4.864}\right)^{0.1972}}\right), \tag{17}$$

where

$$\rho_m = \rho_L \lambda_L + \rho_G(1 - \lambda_L), \tag{18}$$

$$\lambda_L = \frac{\dot{V}_L}{\dot{V}_L + \dot{V}_G}, \tag{19}$$

$$w_M = w_G + w_L, \tag{20}$$

the superficial gas velocity

$$w_G = \frac{\dot{V}_G}{A} \tag{21}$$

the superficial liquid velocity

$$w_F = \frac{\dot{V}_L}{A} \tag{22}$$

and the mixture Reynolds number Re,

$$\mathrm{Re} = \frac{w_M \cdot D \cdot \rho_L}{\eta_L}. \tag{23}$$

The Reynolds number of the mixture is calculated using the viscosity of the liquid only. This definition acknowledges that the frictional resistance of the mixture is mainly due to the liquid phase.

The mean error for Eq. (15) has been calculated to 20.27%. A comparison of predicted versus calculated data is given in Fig. 1.

With known flow pattern, the following equation with a higher accuracy can be used:

$$f_M = F_2 + a_2 \cdot \mathrm{Re}^{b2} + \frac{\left(a_1 \cdot \mathrm{Re}^{b1} - a_2 \cdot \mathrm{Re}^{b2}\right)}{\left(1 + \left(\frac{\mathrm{Re}}{t}\right)^{c}\right)^{d}}. \tag{24}$$

The parameters for Eq. (23) are summed up in Table 1 [1].

Friedel [7] systematically compared the accuracy of different pressure drop calculation methods, and recommends the methods of Baroczy [8], Chisholm [4], and Lombardi and Pedrocchi [9] for practical use.

Current correlations to predict the pressure drop in horizontal tubes for diabatic and adiabatic flows were compared by Mauro et al. [10]. He compared the accuracy of the methods with experimental data of different refrigerants and different flow regimes. Highest accuracy is expected by the method by Quiben and Thome [11, 12] and Grönnerud [13]. Still the method by Friedel [5] yielded accurate results.

For vertical upward and horizontal flows, Storek et al. [14] developed an empirical model by systematically evaluating a comprehensive data base. He used the approach of a homogeneous equilibrium flow, extended by empirical correction functions. His model considered wall friction.

The pressure drop in inclining and declining tubes can be calculated with equations by Breggs and Brill [15], based on empirical data.

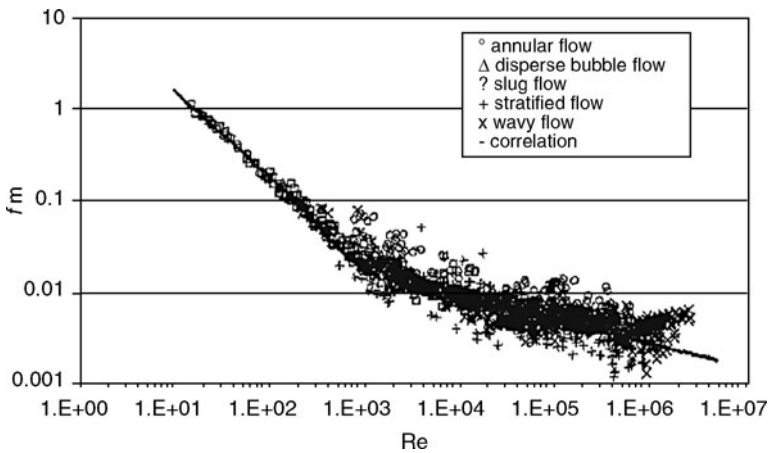
Kadambi [16] and Akai et al. [17, 18] measured the pressure drop in stratified flow pattern and horizontal tubes. The results can be confirmed using the two-phase multiplier by Lockart and Martinelli.

A model described in [19] can be utilized to calculate the pressure drop of water–steam mixtures in horizontal pipelines of geothermal plants.

Herrn-Stapelberg and Mewes [20] examined the slug flow in horizontal and slightly declined tubes. The developed model can be used to give information on the buildup and length of liquid slugs in offshore crude-oil pipelines.

A comprehensive overview is given by Friedel [7] and Mayinger [21].

Special attention shall be paid to the intersections from horizontal to vertical tubes as liquid may accumulate there. Considering sufficient gas velocity, the liquid may finally be entrained through the vertical tube. The increased liquid holdup in the horizontal tube shall be considered in calculating the (increased) pressure drop and the flow pattern.



L2.2. Fig. 1. Correlation and measured data for different flow patterns [6].

L2.2. Table 1. Parameter of the gas–liquid friction factor correlations for different flow patterns [6]

Parameter	a_1	b_1	a_2	b_2	c	d	t
Slug flow	13.98	−0.9501	0.1067	−0.2629	3.577	0.2029	293
Disperse bubble flow	13.98	−0.9501	0.1067	−0.2629	2.948	0.2236	304
Stratified flow	13.98	−0.9501	0.0445	−0.1874	9.275	0.0324	300
Annular flow	3.671	0.6257	0.0270	−0.1225	2.191	0.2072	10,000

Example 1: Vertical tube

A cooling cycle is operated with freon 12. In a 10-m insulated tube DN150 located downstream of the expansion nozzle, a two-phase mixture flows under the following conditions:
$p = 1.5$ bar.a, $T = -20°C$

$$\dot{M}_F = 13 \text{ kg/s},\ \dot{m}_F = \frac{13 \text{ kg/s}}{\frac{\pi}{4} \cdot 0.15^2 \text{ m}^2} = 736 \text{ kg/m}^2\text{s},$$
$$\dot{x} = 0.02,$$
$$\dot{M}_L = 12.75 \text{ kg/s},\ \dot{M}_G = 0.25 \text{ kg/s},$$
$$\rho_L = 1{,}460 \text{ kg/m}^3,\ \rho_G = 9.1 \text{ kg/m}^3,$$
$$\eta_L = 0.3 \times 10^{-3} \text{ Pa} \cdot \text{s},\ \eta_G = 9.3 \times 10^{-6} \text{ Pa} \cdot \text{s},$$
$$c_{pf} = 0.94 \text{ kJ/kg K},\ \Delta H = 162 \text{ kJ/kg}.$$

The slip s, the void gas fraction ε, the phase velocities w_G and w_L of the gas and liquid, respectively, and the pressure drop $\Delta p_{2\text{ ph}}$ over the tube length shall be calculated.

According to Ahmad [22], the slip can be calculated by

$$s = \left(\frac{\rho_L}{\rho_G}\right)^{0.205} \cdot \left(\frac{\dot{m} \cdot d}{\eta_L}\right)^{-0.016} = \left(\frac{1{,}460}{9.1}\right)^{0.205} \cdot \left(\frac{736 \times 0.15}{0.3 \times 10^{-3}}\right)^{-0.016} = 2.3. \quad (25)$$

The void fraction is then calculated according to Subchap. L2.1:

$$\varepsilon = \frac{1}{1 + \frac{1 - 0.02}{0.02} \cdot 2.3 \cdot \frac{9.1}{1460}} = 0.59 \quad (26)$$

the gas velocity can then be calculated using the continuity equation:

$$w_G = \frac{\dot{M}_G}{\rho_G \cdot \varepsilon \cdot \frac{\pi}{4} \cdot d^2} = \frac{0.25}{9.1 \times 0.59 \cdot \frac{\pi}{4} \cdot 0.15^2} = 2.63 \text{ m/s} \quad (27)$$

and with the slip s the liquid velocity is calculated as

$$w_L = \frac{w_g}{s} = \frac{2.63}{2.3} = 1.14 \text{ m/s}. \quad (28)$$

Using the flow pattern map by Hewitt and Roberts [1], for vertical flow (reference is made to Subchap. L2.1) with the value for the abscissa

$$\frac{\dot{m}_F^2 \cdot (1 - x)^2}{\rho_L} = \frac{736^2 \cdot (1 - 0.02)^2}{1{,}460} = 356 \quad (29)$$

and the value for the ordinate

$$\frac{\dot{m}_F^2 \cdot x^2}{\rho_G} = \frac{736^2 \times 0.02^2}{9.1} = 2.4 \quad (30)$$

plug flow is expected. Accounting for the supervelocity of the bubbles compared to the liquid velocity in this flow regime, the calculated slip $s = 2.4$ seems reasonable.

The mixture mean density may be calculated with Eq. (4):

$$\bar{\rho} = (1 - 0.59) \cdot 1{,}460 + 0.59 \times 9.1 = 604 \text{ kg/m}^3 \quad (31)$$

the hydrostatic pressure drop is then calculated with Eq. (3) and a level difference of 10 m, the length of the vertical tube:

$$\Delta p_g = \bar{\rho} \cdot g \cdot \Delta x = 604 \times 9.81 \times 10 = 59{,}250 \text{ Pa}. \quad (32)$$

The two-phase friction pressure drop Δp_R is then calculated by Chisholm [4].

In the first step the superficial liquid velocity, assuming that the liquid fraction completely covers the tube cross section, is calculated as

$$w_L = \frac{\dot{M}_L}{\rho_L \cdot \frac{\pi}{4} \cdot d^2} = \frac{12.75}{1{,}460 \cdot \frac{\pi}{4} \cdot 0.15^2} = 0.5 \text{ m/s} \quad (33)$$

Δp_L is calculated (Subchap. L2.1) to be $\Delta p_L = 240$ Pa.

Next step is the calculation of the two-phase multiplier (according to [4]):

$$\Phi_L^2 = 1 + (\Gamma^2 - 1)\left[\frac{21}{\Gamma} \cdot \dot{x}^{0.9}(1 - \dot{x})^{0.9} + \dot{x}^{1.8}\right] = 1 + (\Gamma^2 - 1)\left[\frac{21}{\Gamma} \cdot 0.02^{0.9}(1 - 0.02)^{0.9} + 0.02^{1.8}\right] = 6.46, \quad (34)$$

where

$$\Gamma = \left(\frac{p_L}{p_G}\right)^{0.5} \cdot \left(\frac{\eta_G}{\eta_L}\right)^{0.1} = \left(\frac{1{,}460}{9.1}\right)^{0.5} \cdot \left(\frac{9.3 \times 10^{-6}}{0.3 \times 10^{-3}}\right)^{0.1} = 8.95, \quad (35)$$

$$\Delta p_R = 240 \times 6.46 = 1{,}550 \text{ Pa}.$$

The overall pressure drop is the sum of Δp_R and Δp_G: 59,250 + 1,550 = 60,800 Pa.

The pressure at the outlet of the vertical tube is now 1.5 bar.a – 0.608 bar.a = 0.892 bar.a.

The saturation temperature is reduced from −20 to approximately −30°C. Due to flashing of the liquid phase, an additional gas fraction is formed as follows:
Annotation: The heat transfer through the insulated tube is neglected.

$$\Delta \dot{M}_G = \frac{c_{p,L} \cdot \dot{M}_L \cdot \Delta T}{\Delta H} = \frac{0.94 \times 12.75 \times 10}{162} = 0.75 \text{ kg/s}. \quad (36)$$

The gas flow changes at the outlet of the tube to $M_G = 0.25 + 0.75 = 1$ kg/s and a liquid flow to $M_F = 12$ kg/s. With the new mass flow quality = 1/13 = 0.077, the void fraction is $\varepsilon = 0.85$.

The gas velocity at the outlet of the tube is now

$$w_G = \frac{1}{9.1 \cdot 0.85 \cdot \frac{\pi}{4} \cdot 0.15^2} = 7.3 \text{ m/s} \quad (37)$$

and the liquid velocity changes to $w_L = 7.3/2.4 = 3.0$ m/s.

With Eq. (1) the pressure drop by acceleration Δp_A is calculated as

$$\Delta p_A = \frac{1 \times 7.3 + 12 \times 3.2 - 0.25 \times 2.63 - 12.75 \times 1.14}{\frac{\pi}{4} 0.15^2} = 1{,}726 \text{ Pa}. \quad (38)$$

The overall pressure drop is summed to

$$\Delta p_{2ph} = \Delta p_A + \Delta p_g + \Delta p_R = 1{,}726 + 59{,}250 + 1{,}550 = 62{,}526 \text{ Pa}. \quad (39)$$

The hydrostatic pressure drop Δp_g is no pressure loss but a reversible pressure reduction by reducing height. The pressure drop due to acceleration Δp_A can be considered nonreversible because the liquid phase, in contrast to the gas phase, only marginally gains back pressure during deceleration of the gas–liquid mixture.

The accuracy of the calculation can be improved by using average property data between the inlet and outlet – in this case a more demanding iterative procedure is inevitable.

Example 2: Horizontal tube

The pressure drop in a horizontal tube DN150 of 10 m length shall be calculated:

$$p = 1.5\,\text{bar.a},\ T = -20^\circ\text{C},$$
$$\dot{x} = 0.02,$$
$$\dot{M}_L = 12.75\,\text{kg/s},\ \dot{M}_G = 0.25\,\text{kg/s},$$
$$\rho_L = 1{,}460\,\text{kg/m}^3,\ \rho_G = 9.1\,\text{kg/m}^3,$$
$$\eta_L = 0.3 \times 10^{-3}\,\text{Pa}\cdot\text{s},\ \eta_G = 9.3 \times 10^{-6}\,\text{Pa}\cdot\text{s},$$
$$\dot{M}_F = 13\,\text{kg/s},\ \dot{m} = \frac{13\,\text{kg/s}}{\frac{\pi}{4}\cdot 0.15^2\,\text{m}^2} = 736\,\text{kg/m}^2\text{s}. \quad (40)$$

The superficial gas velocity and the superficial liquid velocity are calculated as

$$w_{G,l} = \frac{\dot{V}_G}{A} = \frac{\dot{M}_G/\rho_G}{\pi\cdot\frac{D^2}{4}} = \frac{(0.25\,\text{kg/s})/(9.1\,\text{kg/m}^3)}{\frac{\pi}{4}\cdot 0.15^2\,\text{m}^2} = 1.55\,\text{m/s}, \quad (41)$$

$$w_{L,l} = \frac{\dot{V}_L}{A} = \frac{\dot{M}_L/\rho_L}{\pi\cdot\frac{D^2}{4}} = \frac{(12.75\,\text{kg/s})/(1{,}460\,\text{kg/m}^3)}{\frac{\pi}{4}\cdot 0.15^2\,\text{m}^2} = 0.49\,\text{m/s}, \quad (42)$$

The mean two-phase density is then calculated as

$$w_m = w_{G,l} + w_{F,l} = 1.55\ \text{m/s} + 0.49\ \text{m/s} = 2.04\ \text{m/s}, \quad (43)$$

where

$$\lambda_L = \frac{\dot{V}_L}{\dot{V}_L + \dot{V}_G} = \frac{\dot{M}_L/\rho_L}{\dot{M}_L/\rho_L + \dot{M}_G/\rho_G} = \frac{(12.75\ \text{kg/s})/(1{,}460\ \text{kg/m}^3)}{(12.75\ \text{kg/s})/(1{,}460\ \text{kg/m}^3) + (0.25\ \text{kg/s})/(9.1\ \text{kg/m}^3)} = 0.24. \quad (44)$$

Now the Reynolds number can be calculated as

$$\text{Re} = \frac{w_m\cdot D}{\eta_L/\rho_L} = \frac{2.04\ \text{m/s}\times 0.15\ \text{m}}{\frac{0.3\times 10^{-3}\text{Pa}\cdot\text{s}}{1{,}460\ \text{kg/m}^3}} = 1.48\times 10^6 \quad (45)$$

and without considering the flow pattern the pressure drop is calculated as

$$\Delta p_{2ph} = f_m\cdot\frac{2\rho_m w_m^2\cdot x}{D} = 0.00253\cdot\frac{2\times 357\ \text{kg/m}^3\cdot(2.04\ \text{m/s})^2\cdot 10\ \text{m}}{0.15\ \text{m}} = 501\ \text{Pa}, \quad (46)$$

where

$$f_m = 0.0925\text{Re}^{-0.2534} + \frac{13.98\text{Re}^{-0.9501} - 0.0925\text{Re}^{-0.2534}}{\left(1+\left(\frac{\text{Re}}{293}\right)^{4.864}\right)^{0.1972}} = 0.00253. \quad (47)$$

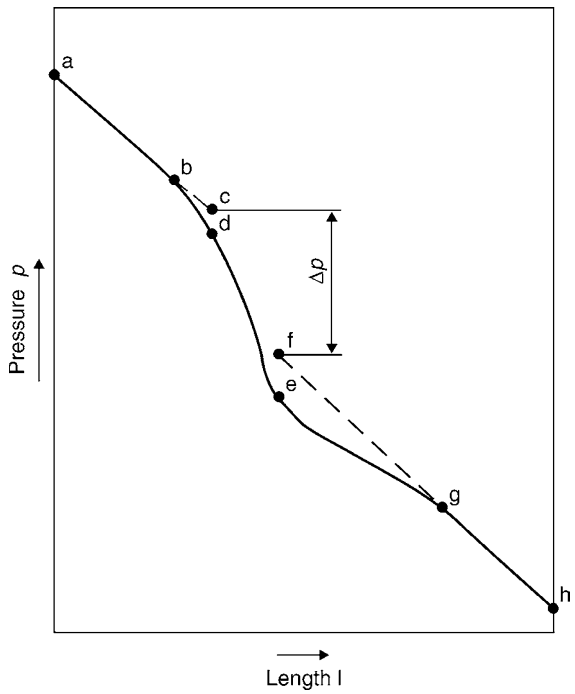
3 Pressure Drop in Bends

3.1 Introduction

When a fluid flows through a bend, the curvature causes a centrifugal force directed from the center of curvature to the outer wall. This force together with the adhesive forces at the wall (fluid adhesion, friction) is the reason for the formation of ideally two identical eddies in the bend. The eddies together with vortex generation and boundary layer detachment in the bend are responsible for the increased pressure drop through bends.

In Fig. 2 the gradient of the static pressure of the bended tube in flow direction is visualized for single-phase flow. The inlet of the bend is labeled "d" and the outlet, "e." The irreversible pressure drop Δp is the pressure drop between the labels "c" and "f." The dashed line expresses the pressure drop due to wall friction. The high pressure loss between "b" and "d" is denoted as the flow interruption in the inlet. The pressure gain between "e" and "g" is the result of the smoothening of the asymmetric velocity profile at the outlet of the bend.

The pressure loss of a two-phase mixture flowing through a bend is, in addition to the single-phase pressure loss, also



L2.2. Fig. 2. Schematic pressure drop in a 90° bend [23].

dependent on the plane and the outlet direction of the bend. An additional pressure loss occurs at the outlet of the bend, with ascending gas content. The lower velocity liquid fraction is accelerated by the gas flow and the gas looses its momentum.

Due to the vorticity of the fluid in the bend, a certain homogenization of the flow at the bend outlet is expected, which results in a homogenized flow pattern.

Two-phase flow studies for bends are not as numerous as for flow in straight tubes. The influence of the plane and outlet direction is considered, and correlations for the different planes and outlet directions are published. However, an elaborate and conclusive work is not available.

3.2 Pressure Drop for Single-Phase Flow

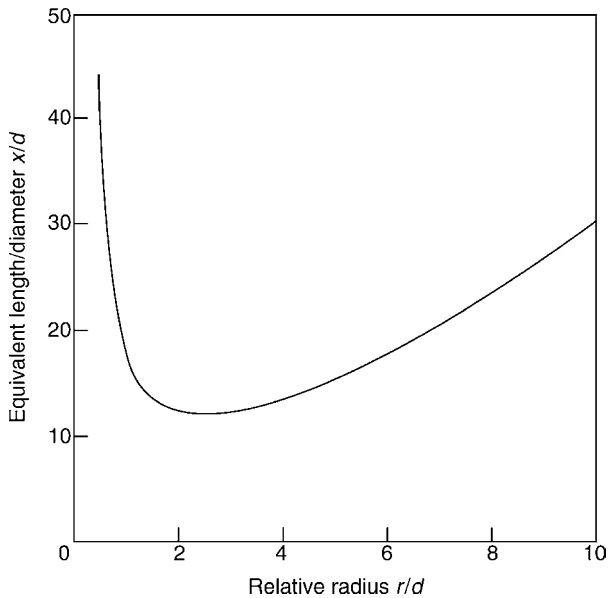
To calculate the two-phase pressure drop with the assistance of a two-phase multiplier, the single-phase pressure drop of the considered phase must be known.

One method to determine the single-phase pressure drop of the bend is to compare the bend with a straight tube of the same diameter with an equivalent length of x/d. According to Fig. 3, the equivalent length is dependent on the ratio bend radius and tube diameter, r/d. Figure 3 is valid for 90° bends.

The single-phase pressure drop is then calculated as given below:

$$\Delta p = \frac{\zeta}{2\rho} \cdot \frac{x}{d} \cdot \left(\frac{\dot{M}}{\frac{\pi}{4} \cdot d^2} \right)^2 . \tag{48}$$

The Darcy friction factor ζ may be evaluated as shown in Subchap. L1.1.



L2.2. Fig. 3. Ratio of the equivalent length and the tube diameter with the same pressure drop as that of a 90° bend [23].

3.3 Calculation of the Two-Phase Multiplier

A well-known correlation to calculate the two-phase multiplier for two-phase flow through 90° bends is presented by Chisholm [24] – the B-type equation. The two-phase multiplier Φ^2 is related to the liquid flow pressure drop Δp_f:

$$\Delta p_{2ph} = \Delta p_L \cdot \Phi_L^2 \tag{49}$$

Δp_{2ph}: two-phase pressure drop, where

$$\Delta p_L = \frac{\zeta}{2\rho_L} \cdot \frac{\dot{x}}{d} \cdot \left(\frac{\dot{M}_F}{\frac{\pi}{4} \cdot d^2} \right)^2 . \tag{50}$$

Assuming the friction factor ζ as independent of the Reynolds number, the two-phase multiplier Φ^2 is calculated as

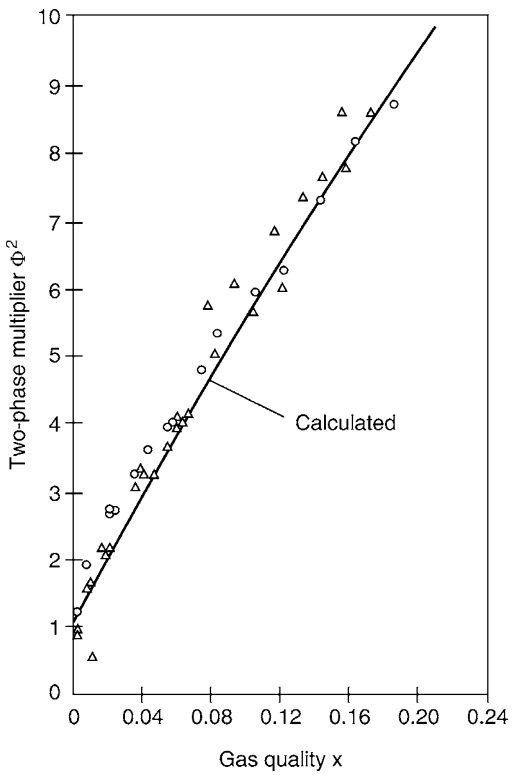
$$\Phi_L^2 = 1 + \left(\frac{\rho_L}{\rho_G} - 1 \right) \left[B \cdot \dot{x} \cdot (1 - \dot{x}) + \dot{x}^2 \right], \tag{51}$$

where

$$B = 1 + \frac{2.2}{\zeta \cdot \frac{x}{d} \left(2 + \frac{r}{d} \right)} . \tag{52}$$

In Fig. 4 data measured by Fitzsimmons [25] is compared to the predictions calculated with Eq. (21).

In the area of a low void fraction, the calculated and measured data are consistent. At higher void fractions, a higher deviation is expected as the relation to the single-phase liquid



L2.2. Fig. 4. Measured and calculated [23] two-phase multiplier Φ^2 over gas quality.

pressure drop is not given any more. The two-phase pressure drop is expected to equalize to the vapor pressure drop under the influence of a rough surface. The rough surface is the result of the wavy liquid wall film. The free diameter is reduced accordingly by the liquid wall film thickness. Considering high gas velocities the pressure drop is further increased by the acceleration of the liquid by the gas stream.

For bends from 90° to 180° the coefficient B [24] is calculated as

$$B = 1 + \frac{2.2}{\zeta \cdot \frac{x_{90°}}{d}\left(2 + \frac{r}{d}\right)} \cdot \frac{x_{90°}}{x}. \tag{53}$$

Bends with $\alpha < 90°$ are conservatively considered 90° bends following Eq. (52).

Freeston et al. [26] studied water–steam mixtures in a 90° bend. He also studied the interaction of multiple bends attached in short distance between each other.

The influence of the wall friction in horizontal 180° bends was studied by Shimizu et al. [27], while Usui et al. [28] concentrated on upward and downward flows in vertical 180° bends.

Azzi et al. [29] evaluated different correlations and favored the Chisholm B-equation. For 90° upward bends, Azzi and Friedel [52] presented a more accurate correlation.

Example 3: Pressure drop in bends

A propene gas–liquid mixture flows through a bend ($d = 45$ mm, $a = 90°$, $r = 90$ mm) at a pressure of $p = 20$ bar ($\rho_L = 530$ kg/m^3, $\rho_G = 14.8$ kg/m^3, $\eta_L = 8 \times 10^{-5}$ Pa s), the total mass flow $\dot{M}_F = 0.6$ kg/s, and the vapor quality

$$\dot{x} = \frac{\dot{M}_g}{\dot{M}_g + \dot{M}_f} = 0.2. \tag{54}$$

The pressure drop shall be calculated.

Mass flow:

$$\dot{M}_G = \dot{x} \cdot \dot{M}_F = 0.2 \times 0.6 = 0.12 \text{ kg/s} \quad \text{(gas)}, \tag{55}$$

$$\dot{M}_L = (1 - x) \cdot \dot{M}_F = (1 - 0.2) \cdot 0.6 = 0.48 \text{ kg/s} \quad \text{(liquid)}. \tag{56}$$

The superficial liquid velocity is, therefore,

$$w_L = \frac{\dot{M}_L}{\rho_L \cdot \frac{\pi}{4} \cdot d^2} = \frac{0.48}{530 \cdot \frac{\pi}{4} \cdot 0.045^2} = 0.57 \text{ m/s} \tag{57}$$

and the Reynolds number $Re_{L,1}$ (for liquid at the superficial liquid velocity)

$$Re_L = \frac{w_L \cdot d \cdot \rho_L}{\eta_L} = \frac{0.57 \times 0.045}{8 \times 10^{-5}} = 170{,}000. \tag{58}$$

The Darcy friction factor of a hydraulic smooth tube at $Re_f = 170{,}000$ Reynolds–Zahl is considered with $\zeta = 0.017$ (reference is made to Subchap. L1.1).

With the relative radius r/d

$$\frac{r}{d} = \frac{90}{45} = 2 \qquad \text{(relative radius)}$$

the equivalent length can be determined by Fig. 3:

$$\frac{x}{d} = 12 \qquad \text{(equivalent length according to Fig. 3)}.$$

The equivalent pressure drop of the liquid phase is then calculated with Eq. (16):

$$\Delta p_L = \frac{\zeta}{2\rho_L} \cdot \frac{x}{d} \cdot \left(\frac{\dot{M}_F}{\frac{\pi}{4} \cdot d^2}\right)^2 = \frac{0.017 \times 12}{2 \times 530} \cdot \left(\frac{0.6}{\frac{\pi}{4} \cdot 0.045^2}\right)^2 \tag{59}$$

$$= 27 \text{ Pa},$$

where with Eq. (52)

$$B = 1 + \frac{2.2}{\zeta \cdot \frac{x}{d}\left(2 + \frac{r}{d}\right)} = 1 + \frac{2.2}{0.017 \times 12 \cdot \left(2 + \frac{90}{45}\right)} = 3.75 \tag{60}$$

and the two-phase multiplier with Eq. (51)

$$\Phi_L^2 = 1 + \left(\frac{\rho_{Lf}}{\rho_G} - 1\right)\left[B \cdot \dot{x} \cdot (1 - \dot{x}) + \dot{x}^2\right]$$

$$= 1 + \left(\frac{530}{14.8} - 1\right)\left[3.75 \times 0.2 \cdot (1 - 0.2) + 0.2^2\right] \tag{61}$$

$$= 23.3.$$

The two-phase pressure drop can be found with Eq. (49)

$$\Delta p_{2ph} = \Delta p_L \cdot \Phi_L^2 = 23.3 \times 27 = 629 \text{ Pa}. \tag{62}$$

4 Pressure Drop in Expansions, Reducers, and T-Pieces

4.1 Diffusers, Expansions, Reducers, and Contractions

The two-phase flow through reducers and expansions is fundamentally different from single-phase flow. The single-phase flow in a nozzle is considered a homogeneous acceleration without significant losses. The pressure drop in an expanding tube (diffuser) is dependent on the degree of boundary layer detachment due to pressure increase in the boundary layer by reduced velocity. In case of boundary layer detachment, the pressure drop as a result of dissipation (built up of vortices) is rather high. The overall pressure drop of a system without boundary layer detachment is reduced to the pressure drop due to wall friction.

If the flow pattern of a gas–liquid mixture consists of a liquid wall film and dispersed liquid droplets in the core gas, the momentum forces from the gas to the liquid determine the overall pressure drop.

In a nozzle the droplets are accelerated by the accelerating gas flow (momentum transfer from the gas to the liquid droplets). The loss of kinetic energy is considerable. This results in an exceptional high pressure drop, which significantly exceeds the pressure drop of a single-phase gas flow of a similar mean density as the two-phase mixture.

In the expansions the inertia of the dispersed liquid droplets leads to a supervelocity of the liquid droplets compared to the gas flow. This results in a momentum transfer from the liquid droplets to the gas, however, only a minor amount of kinetic energy is transferred to the gas. In addition, the supervelocity of the liquid promotes the detachment of the boundary layer.

In case of *bubbly flow* with small bubble size, the two-phase flow can be considered a homogenous mixture, with a behavior

L2.2. Table 2. Various models to calculate the density of a two-phase mixture [31]

Momentum density	$\frac{1}{\rho_{\mathrm{I}}} = \frac{\dot{x}^2}{\rho_{\mathrm{G}} \cdot \varepsilon} + \frac{(1-\dot{x})^2}{\rho_{\mathrm{L}} \cdot (1-\varepsilon)}$
Homogeneous density	$\frac{1}{\rho_{\mathrm{hom}}} = \frac{\dot{x}}{\rho_{\mathrm{G}}} + \frac{1-\dot{x}}{\rho_{\mathrm{L}} \cdot (1-\varepsilon)}$
Energy density	$\frac{1}{\rho_{\mathrm{E}}} = \left(\frac{\dot{x}}{\rho_{\mathrm{G}}} + \frac{1-\dot{x}}{\rho_{\mathrm{L}} \cdot (1-\varepsilon)}\right)^{-1} \cdot \left(\frac{\dot{x}^3}{\rho_{\mathrm{G}}^2 \cdot \varepsilon^2} + \frac{(1-\dot{x}^3)}{\rho_{\mathrm{L}}^2 \cdot (1-\varepsilon)^2}\right)$
Void density	$\frac{1}{\rho_{\mathrm{void}}} = \frac{\dot{x}^2}{\rho_{\mathrm{G}}} + \frac{(1-\dot{x})^2}{\rho_{\mathrm{L}}}$

comparable to a single-phase flow. Therefore, the predictions for single-phase flow may be used.

The pressure increase through a sudden expansion is often calculated with the model by Rouhani [30]. Best results are expected using the mean momentum mixture density (25% deviation, values calculated too low). The mean mixture density is essential for predicting the quality of the calculations. An overview of the different definitions based on mass, energy, or momentum conservation is given in Table 2.

The pressure drop in sudden contraction is preferably calculated using the mean density definition by mass [32, 33]. In every diameter a homogeneous mass distribution is considered. With this definition, the pressure drop can be calculated with an accuracy of ~20%.

In the throat area of a contraction, the gas is accelerated significantly faster than the liquid fraction, as long as there is a density difference between the gas and liquid phases. Based on this insight, Schmidt [31] developed a model to predict the pressure drop in horizontal and vertical expansions and contractions. The model differentiates between the liquid wall flow and the gas core flow with droplets. Momentum balance is then used to account for the change in diameter.

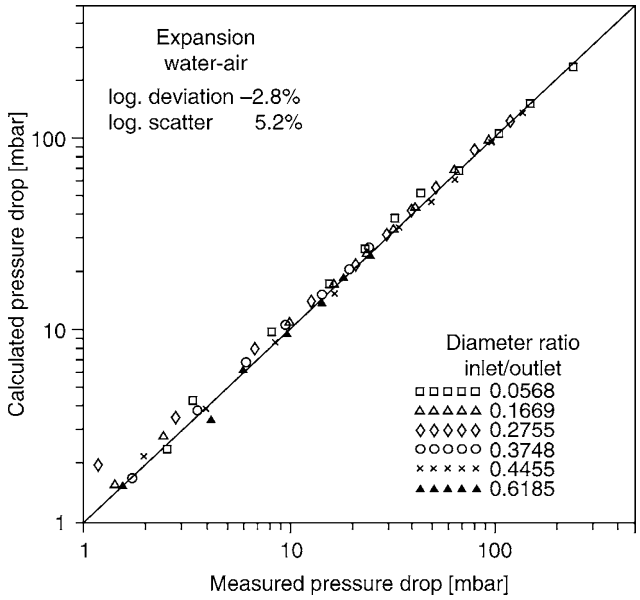
The prediction quality of the model is shown for air–water mixtures in Fig. 5 for expansions and in Fig. 6 for contractions.

The pressure increase in expansion is calculated as follows:

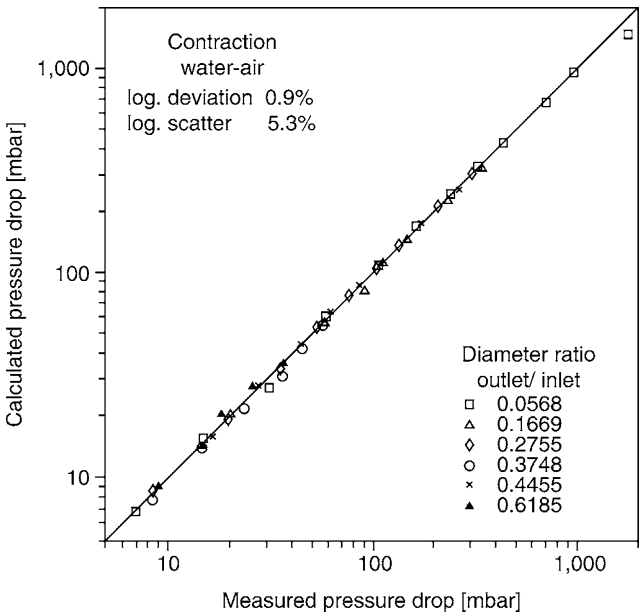
Indices

1. Fully developed flow upstream
2. Transient expansion or contraction
3. Fully developed flow downstream

$$\Delta p_{\mathrm{Erw}} = \frac{\dot{m}_2^2 \cdot \left[\frac{K_{1,2}\sigma_{2,3}}{\rho_{\mathrm{eff},2}} - \frac{K_{1,3}\sigma_{2,3}^2}{\rho_{\mathrm{eff},3}} - f^*_{\mathrm{Erw}} \cdot \rho_{\mathrm{eff},2}\left(\frac{\dot{x}}{\varepsilon_2 \rho_{\mathrm{g},2}} - \frac{(1-\dot{x})}{(1-\varepsilon_2)\rho_{\mathrm{fl}}}\right)^2 \left(1 - \sqrt{\frac{d_2^2}{d_3^2}}\right)^2\right]}{1 - \Gamma_{\mathrm{Erw}}\left(1 - \frac{d_2^2}{d_3^2}\right)} + \frac{\left(\frac{1}{2}\left(1 - \frac{d_2^2}{d_3^2}\right)(\rho_{\mathrm{eff},3} + \rho_{\mathrm{eff},2}) - \rho_{\mathrm{eff},3}\right) g \Delta z \sin\psi}{1 - \Gamma_{\mathrm{Erw}}\left(1 - \frac{d_2^2}{d_3^2}\right)} \tag{63}$$



L2.2. Fig. 5. Comparison of the measured and predicted pressure increases of expansions with two-phase flow [31].



L2.2. Fig. 6. Comparison measured and predicted pressure drops of contractions with two-phase flow [31].

$K_1 \equiv 1$, turbulent flow (Re > 2,300), $K_1 \equiv 1.33$, laminar flow, ψ = angle: 0° = horizontal, 90° = vertical upward flow,

$$\varepsilon = 1 - \frac{(1-\dot{x})^2 \cdot 2}{1 - 2\dot{x} + \sqrt{1 + 4\dot{x}(1-\dot{x}) \cdot \left(\frac{\rho_{\mathrm{f}}}{\rho_{\mathrm{g}}} - 1\right)}}, \tag{64}$$

$$\frac{1}{\rho_{\text{eff}}} = \frac{\dot{x}^2}{\rho_G \varepsilon} + \frac{(1-\dot{x})^2}{\rho_L(1-\varepsilon)} + \rho_L(1-\varepsilon)\left(\frac{\varepsilon_K}{1-\varepsilon_K}\right)\left[\frac{\dot{x}}{\rho_G \varepsilon} - \frac{(1-\dot{x})}{(1-\varepsilon)\rho_L}\right]^2, \quad (65)$$

$$\varepsilon_K = \frac{1}{s}\left[1 - \frac{(1-\dot{x})}{1-\dot{x}+\dot{x}\cdot \text{We}^{0.27}\cdot \text{Re}^{0.05}}\right], \quad (66)$$

$$s = \frac{\dot{x}}{1-\dot{x}}\frac{1-\varepsilon}{\varepsilon}\frac{\rho_L}{\rho_G}, \quad (67)$$

$$\text{We} = \frac{\dot{m}^2\dot{x}^2}{\rho_G}\frac{d}{\sigma}\frac{(\rho_L-\rho_G)}{\rho_G}, \quad (68)$$

$$\text{Re} = \frac{\dot{m}^2(1-\dot{x})d}{\eta_L}, \quad (69)$$

where the friction factor:

$$f^*_{\text{Erw}} = 0.0049\dot{x}^2(1-\dot{x})^2\left(\frac{\eta_{L,2}}{\eta_{G,2}}\right)^{0.7}, \quad (70)$$

$$\Gamma_{\text{Erw}} = 1 - \left(\frac{d_2^2}{d_3^2}\right)^{0.25}. \quad (71)$$

The pressure loss in contraction is calculated as follows:

$$\Delta P_{\text{Kon}} = \frac{\dot{m}_3^2\left[\frac{K_{I,3}}{\rho_{\text{eff},3}} - \frac{K_{I,1}\sigma_{3,1}}{\rho_{\text{eff},1}} + f^*_{\text{Kon}}\cdot\rho_{\text{eff},3}\left(\frac{\dot{x}}{\varepsilon_3\rho_{G,3}} - \frac{1-\dot{x}}{(1-\varepsilon_3)\rho_L}\right)^2\left(1-\sqrt{\frac{d_3^2}{d_1^2}}\right)^2\right]}{1+\Gamma_{\text{Kon}}\left(\frac{\frac{1}{d_3^2}}{\frac{1}{d_1^2}}-1\right)}, \quad (72)$$

$$\varepsilon = 1 - \frac{(1-\dot{x})^2\cdot 2}{1-2\dot{x}+\sqrt{1+4\dot{x}(1-\dot{x})\cdot\left(\frac{\rho_L}{\rho_G}-1\right)}}, \quad (73)$$

$$\frac{1}{\rho_{\text{eff}}} = \frac{\dot{x}^2}{\rho_G\varepsilon} + \frac{(1-\dot{x})^2}{\rho_L(1-\varepsilon)} + \rho_L(1-\varepsilon)\left(\frac{\varepsilon_K}{1-\varepsilon_K}\right)\left[\frac{\dot{x}}{\rho_G\varepsilon} - \frac{(1-\dot{x})}{(1-\varepsilon)\cdot\rho_L}\right]^2, \quad (74)$$

$$\varepsilon_K = \frac{1}{s}\left[1 - \frac{(1-\dot{x})}{1-\dot{x}+\dot{x}0.18\text{We}^{0.12}\text{Re}^{0.50}}\right], \quad (75)$$

$$s = \frac{\dot{x}}{1-\dot{x}}\frac{1-\varepsilon}{\varepsilon}\frac{\rho_L}{\rho_G}, \quad (76)$$

$$\text{We} = \frac{\dot{m}^2\dot{x}^2}{\rho_G}\frac{d}{\sigma}\frac{(\rho_L-\rho_G)}{\rho_G}, \quad (77)$$

$$\text{Re} = \frac{\dot{m}(1-\dot{x})d}{\eta_L}, \quad (78)$$

$$f^*_{\text{Kon}} = 5.2\times 10^{-3}\dot{x}^{0.1}(1-\dot{x})\left(\left(\frac{d_3^2}{d_1^2}\right)\cdot\frac{\eta_L}{\eta_{G,3}}\right)^{0.8}, \quad (79)$$

$$\Gamma_{\text{Kon}} = 0.77\cdot\frac{d_3^2}{d_1^2}\cdot\left(1-\left(\frac{d_3^2}{d_1^2}\right)^{0.306}\right). \quad (80)$$

As the change of state of the two-phase media is essential to the calculation, an iterative approach is proposed.

In the first step, the media is considered incompressible. The density in the upstream, transient (2), and downstream areas (3) is considered the same.

In the ongoing iterative steps, the density in (3) is corrected considering the calculated pressured drop. A good accuracy can be expected after two calculation runs.

Example 4: Pressure increase through a sudden expansion

The pressure change of a water–air mixture flowing through a horizontal expansion shall be calculated.

The upstream pipe diameter is 0.0296 m (d_2), and the downstream pipe diameter is 0.0443 m (d_3).

p = 4.901 bar.a,

$$\dot{M}_F = 0.5692\ \text{kg/s},\ \dot{m} = \frac{0.5692\ /\text{s}}{\frac{\pi}{4}\cdot 0.0269^2\ \text{m}^2} = 1001.6\ \text{kg/m}^2\text{s}, \quad (81)$$

$$\dot{x} = 0.348,\ \rho_L = 997.41\ \text{kg/m}^3,\ \rho_{G,2} = 5.73\ \text{kg/m}^3,$$

$$\eta_L = 0.8961\times 10^{-3}\ \text{Pa}\cdot\text{s},\ \eta_G = 0.1825\times 10^{-4}\ \text{Pa}\cdot\text{s},$$

$$\sigma = 0.0719061\ \text{N/m},\ \psi = 0°.$$

The iterative approach is proposed, as the mixture is compressible:

Step 1: Incompressible flow through expansion considered

$$\rho_{G,2} = \rho_{G,3} = 5.73\,\text{kg/m}^3,$$

the mean volumetric void fraction in the upstream tube (1–2):

$$\varepsilon_2 = 1 - \frac{(1-\dot{x})^2\cdot 2}{1-2\dot{x}+\sqrt{1+4\dot{x}(1-\dot{x})\cdot\left(\frac{\rho_L}{\rho_G}-1\right)}} = 1 - \frac{(1-0.348)^2\cdot 2}{1-2\times 0.348+\sqrt{1+4\times 0.348(1-0.348)\cdot\left(\frac{997.41\,\text{kg/m}^3}{5.73\,\text{kg/m}^3}-1\right)}} = 0.934 \quad (82)$$

the dimensionless numbers:

$$\text{We}_2 = \frac{\dot{m}^2\dot{x}^2}{\rho_G}\frac{d}{\sigma*}\frac{(\rho_L-\rho_G)}{\rho_G} = \frac{(1001.6\,\text{kg/m}^3)^2\cdot 0.0348^2}{5.73\,\text{kg/m}^3}\frac{0.0296\,\text{m}}{0.0719\,\text{N/m}}\cdot\frac{(997.41\,\text{kg/m}^3 - 5.73\,\text{kg/m}^3)}{5.73\,\text{kg/m}^3} = 1.511\times 10^6, \quad (83)$$

$$\text{Re}_2 = \frac{\dot{m}^2(1-\dot{x})d}{\eta_L} = \frac{(1001.6\ \text{kg/m}^3)^2(1-0.348)\cdot 0.0269\ \text{m}}{0.8961\times 10^{-3}\text{Pa}\cdot\text{s}} = 2.157\times 10^4, \quad (84)$$

$$s_2 = \frac{\dot{x}}{1-\dot{x}}\frac{1-\varepsilon_2}{\varepsilon_2}\frac{\rho_L}{\rho_G} = \frac{x0.348}{1-\dot{x}}\frac{1-0.934}{0.934}\frac{997.41\ \text{kg/m}^3}{5.73\ \text{kg/m}^3} = 6.565, \quad (85)$$

$$\varepsilon_{K,2} = \frac{1}{s_2}\left[1 - \frac{(1-\dot{x})}{1-\dot{x}+\dot{x}\cdot \mathrm{We}_2^{0.27}\cdot \mathrm{Re}_2^{0.05}}\right]$$
$$= \frac{1}{6.565} \cdot \left[1 - \frac{(1-0.348)}{1-0.348+0.348\cdot(1.511\times10^6)^{0.27}\cdot(2.157\times10^4)^{0.05}}\right]$$
$$= 0.102. \quad (86)$$

With this result, the effective density of the two-phase mixture in the upstream tube can be calculated as

$$\frac{1}{\rho_{\mathrm{eff}}} = \frac{\dot{x}^2}{\rho_G\varepsilon_2} + \frac{(1-\dot{x})^2}{\rho_L(1-\varepsilon_2)} + \rho_L(1-\varepsilon_2)\left(\frac{\varepsilon_{K,2}}{1-\varepsilon_{K,2}}\right) \cdot \left[\frac{\dot{x}}{\rho_G\varepsilon_2} - \frac{(1-\dot{x})}{(1-\varepsilon)\cdot\rho_L}\right]^2$$
$$= \frac{0.348^2}{5.73\ \mathrm{kg/m^3}\times 0.934} + \frac{(1-0.348)^2}{997.41\ \mathrm{kg/m^3}\cdot(1-0.934)} + 997.41\ \mathrm{kg/m}\times(1-0.934)\cdot\left(\frac{0.102}{1-0.102_K}\right) \cdot \left[\frac{0.348}{5.73\ \mathrm{kg/m^3}\cdot 0.934} - \frac{(1-0.348)}{(1-0.934)\cdot 887.34\ \mathrm{kg/m^3}}\right]^2$$
$$= 0.0518\ \mathrm{m^3/kg}, \quad (87)$$

$$f^*_{\mathrm{Erw}} = 0.0049\cdot\dot{x}^2(1-\dot{x})^2\left(\frac{\eta_{L,2}}{\eta_{G,2}}\right)^{0.7}$$
$$= 0.0049\times 0.348^2(1-0.348)^2\left(\frac{0.8961\times10^{-3}\ \mathrm{Pa\cdot s}}{0.1825\times10^{-4}\ \mathrm{Pa\cdot s}}\right)^{0,7}$$
$$= 3.851\times10^{-3}, \quad (88)$$

$$\Gamma_{\mathrm{Erw}} = 1-\sigma_{2.3}^{0.25} = 1-0.4486^{0.25} = 0.1816. \quad (89)$$

The incompressible pressure drop is now calculated as

$$\Delta P_{\mathrm{Erw}} = 132.96\ \mathrm{mbar}. \quad (90)$$

Step 2: Calculation of a new density in the outlet tube (3)

Horizontal flow means no influence of gravitational forces. Also, the density changes of the water are neglected. The density change of the air is considered by the ideal gas law.

$$\rho_{G,3} = \frac{p_3}{R\cdot T_3} \rightarrow \rho_{G,3} = \rho_{G,2}\frac{p_2+\Delta P_{\mathrm{Erw}}}{p_3} = 5.89\ \mathrm{kg/m^3}. \quad (91)$$

With the new density the calculation steps are repeated

$$\varepsilon_3 = 0.934,$$
$$\varepsilon_{k,3} = 0.092,$$
$$\mathrm{We}_3 = 4.2835\times10^{56},$$
$$\mathrm{Re}_3 = 21.445\times10^4,$$
$$\rho_{\mathrm{eff}} = 21.1\ \mathrm{kg/m^3}.$$

The pressure drop is now calculated as

$$\Delta P_{\mathrm{Erw}} = 152.8\ \mathrm{mbar}. \quad (92)$$

An additional calculation step will not enhance the result significantly.

4.2 T-pieces

Upon dividing a gas–liquid flow in an asymmetric T-piece (straight tube with a branch), a new distribution of gas and liquid occurs. The void fractions of the resulting flows are not identical, as the inertia allocates the liquid in a straight direction.

Zetzmann [34] studied, using an air–water mixture, the phase distribution in vertically orientated T-pieces with the flow direction from bottom to top and with branch angles of 45° and 90°. He found a linear correlation between the inlet and outlet void fractions. The phase separation is amplified with a smaller branch diameter compared to the main tube diameter.

The results were basically supported by Honan et al. [35]. He detected in the normal case a substantial phase separation of the gas and liquid by the T-piece. Surprisingly, the phase separation was dependent neither on the angle of the branch nor on the inlet overall mass flow.

Whalley et al. [36] studied T-pieces with vertical and horizontal 90° branch. They concluded that the liquid routed to the branch is mainly the liquid of the wall film. The liquid in the gas core flow primarily follows the straight tube. The liquid mass flow was found proportional to the gas flow through the branch. For horizontal T-pieces with a small branch, Henry [37] developed a simple correlation, which is assured by air–water mixture experiments (deviation calculation and experiment: $<\pm20\%$) under atmospheric pressure and ambient temperature. Again the linear correlation of the gas and the liquid flows in the branch was confirmed.

With air–water mixtures Kubie et al. [38] modeled the behavior of steam–water mixtures in Y-branch pipes.

A model to calculate the fluid distribution in T-pieces, based on momentum equilibrium, was introduced by Skorek and Domanski [39]. The model accounts for most flow patterns and different angles of the branch.

5 Fittings and Valves

5.1 Pressure Release Valves and Pressure Safety Valves

Emergency release valves or pressure release valves for vessels are normally located in the gas area of the vessel in such a way that even under the transient conditions of a release action only the gas flows through the valve. While protecting a chemical reactor against excessive overpressure by a pressure safety valve, in many cases, two-phase flow release must be considered.

During pressure release, boil-up due to evaporation by pressure loss or the release of dissolved gases is expected. Also mixtures tending to build foam further assist the generation of a two-phase mixture in the system.

For this case the pressure release devices must be dimensioned, considering the two-phase release scenario.

A comprehensive presentation of the methods used to size pressure relief valves would exceed the framework of this compendium. An abstract of a set of well-known methods is given.

Different methods are used to calculate the two-phase mass flow through these valves. A well-known method is the ω

(Omega)-method by Leung [40]. This method considers the flow as homogeneous. An advantage of this method is the straightforward calculation without iterative steps and that only one set of property data at the release condition is required.

This method is recommended by the API, API 520 RP [41]. Herein, an elaborate explanation, guidelines, and examples for the ω-method are given.

Based on Leung's ω-method, the HNE-DS method was developed. This method is an extension of the ω-method by a nonequilibrium factor which characterizes the boiling delay of saturated mixtures flowing through the throat of the valve. This extension leads to a higher accuracy of this method. The ISO 4126-10, currently under standardization, proposes the HNE-DS method to size two-phase pressure safety valves. An explanation and a guideline are given by Schmidt [42] for initially subcooled flow and by Diener and Schmidt [43] for two-phase flow.

For sizing pressure safety valve for viscous media, the method by Wieczorek und Friedel (also based on the ω-method) may be used [44, 45]. For this method an overestimation of the pressure safety valve on an average by 29% is expected [44].

5.2 Valves and Orifices

The flow of a saturated two-phase mixture through a valve, if not considered properly, may lead to the failure of the internals by cavitations or vibration. Controlling a constant mass flow or a constant pressure drop by a two-phase operated valve is hardly possible. For that reason single-phase flow into the valve is preferred. Technically, the two-phase mixture is subcooled or pressurized by, e.g., level height.

In common the two-phase flow through tube internals with contraction–expansion characteristics cannot be neglected. Therefore, methods to calculate the pressure drop through such devices are presented herein.

To calculate the mass flow through *globe valves*, a method based on IEC 60534-2-1 seems reasonable. So all the methods are based on the coefficient of single-phase pressure drop. The pressure loss by wall friction is neglected as the flow length in the device is small compared to the length of the tube.

A physical consistent model was presented by Diener [46]. The mean logarithmic deviation for a measured data is given as <15% but the method is rather complicated. Therefore, Diener et al. modified the method customizing the well-known ω-method [40]. With this simplification the mean logarithmic deviation between measured and calculated values is 17% and therefore, getting close to the accuracy of the physical correct model [47, 48].

Fitzsimmons [25] compared the measured two-phase pressure drop also of *gate valves* to the homogeneous flow model and found the homogeneous model to be a conservative assumption.

Lex examined the fluid dynamics and the pressure drop of *ball valves* and presented a pressure drop, taking the valve dihedral angle into account [49].

McNeil developed a hybrid model, located between a homogeneous and two separate flow model, which is valid for two-phase compressible and incompressible media [50]. This iterative model was later simplified. The simplified model considers the gas as ideal and isentropic, the liquid as isothermal, and the slip as known [51].

It is evident that the two-phase pressure drop in *orifices* can also be calculated by modifying Leung's ω-method. Diener et al. proposed an approach in conjunction with their method to calculate the pressure drop of control valves [48].

6 Symbols

d	(inner) tube diameter (m)
f_m	Fannings friction factor (–)
f, f^*	Darcy friction factor = 4 * f_m (–)
ΔH	enthalpy of vaporization (kJ/kg)
K	friction coefficient, expansions, and contractions (–)
p	Pressure (Pa)
Δp	pressure drop (Pa)
s	slip
w	Velocity (m/s)
α	angle (°)
ψ	angle 0° = horizontal, 90° = vertical upwards (°)
$\dot{x}$	*vapor quality* ($\dot{x} = \dot{M}_g/(\dot{M}_f + \dot{M}_g)$) (–)
ε	volumetric void fraction (–)
ε_K	mean volumetric void fraction in the core flow (–)
Φ^2	two-phase multiplier (–)
ζ	Darcy friction factor (–)
Γ	pressure multiplier (–)

Indices

g	hydrostatic
2 ph	two-phase
m	mean
l	superficial
Erw	expansion
Kon	reduction
1	fully developed flow upstream
2	transient expansion or contraction
3	fully developed flow downstream

L2.3 Sizing of Safety Devices for Heat Exchangers

Jürgen Schmidt
BASF SE, Ludwigshafen, Germany

1 Introduction

Heat exchangers are either constructed to be inherently safe or equipped with safety devices. These devices are rated such that on an abnormal plant operation neither the pressure nor the temperature in the appliance rises above the permissible values for the appliance. As a rule, burst discs or safety valves (mechanical safety devices) are used. Alternatively, the relevant operating parameters (e.g., pressure and temperature) can be reliably limited with safety-related process control systems. In addition to these primary safety devices, secondary safety measures are also established so as to mitigate the consequences of hazardous incidents.

For many standard heat exchangers with no use of hazardous substances, for example, in heating technology, the protection of heat exchanger is standardized. Hazard and risk analyses and the discussion of the effects of hazardous incidents should already be adequately covered in these standards. In the chemical and petrochemical industries, on the other hand, protection mostly requires case-by-case treatment. Details that should be taken into account in the selection and sizing of such appliances are given below. Tube bundle heat exchangers are considered here. However, most of the points and procedures can often be transferred to other types of heat exchangers.

2 Hazard and Risk Analysis

During a hazard analysis, first, all possible hazards, that arise inter alia from the hazardous properties of the substance, the operating conditions (system-inherent hazard potential), and the possible deviations from normal operation of the heat exchanger that may lead to impermissible process conditions (process maloperations and system failures) are identified. Second, the causes triggering these deviations must be determined, and their probability of occurrence must be estimated. For each deviation of normal operation of the heat exchanger, the possible effects must be discussed, and the level of damage must be estimated. At the beginning, safety measures are not taken into account, only operating and monitoring devices should be considered. The risk associated with a hazard is determined in terms of the probability of occurrence of a maloperation or system failure and the possible level of damage. The requirements for the reliability of safety measures (safety integrity) can, thus, be defined.

The hazard and risk analysis is carried out systematically by a team of experts with specialist knowledge and operating experience. Various methods are available for this [see ISSA 2008], for example, the risk graph as a qualitative method, see IEC 61511, Appendix E, or VDI/VDE 2180 [IEC 61511, VDI 2180]. Depending on the magnitude of the risk as a result of a deviation from normal operation, the Safety Integrity Level (SIL level 1–4) is obtained as the requirement for the safety measure. Often, for standard heat exchanger with no use of hazardous substances, no level or the SIL 1 level is specified. Particularly, in the chemical and petrochemical industries, SIL 2 and SIL 3 requirements are also common. Safety integrity of the level SIL 4 (catastrophic effects cannot be excluded) should be avoided. As a rule, it can no longer be achieved with safety-related PCS devices such as safety interlocks alone; here other, or additional, safety measures are necessary.

Alternatively, as well as the qualitative methods for risk estimation, quantitative, or semiquantitative methods can also

be used, for example, IEC 61511, Appendix A. The predictive value of such methods is often limited due to lack of data on the probability of failure of components or entire safety devices. Particularly in the chemical industry, the probability of a maloperation or a failure is also dependent on the operating conditions (substance, pressure, temperature, etc.) and, thus, cannot always be unambiguously determined.

In the case of a standard protection with mechanical safety devices (safety valves and burst discs), no quantitative data as to their reliability were demanded in the past – the fittings were classified as devices proven in operation. With correct sizing, installation, and regular testing of a certified safety device, the safety integrity of this component corresponds at least to the level SIL 3.

After the completion of the risk analysis, suitable countermeasures to protect the heat exchanger should be defined in accordance with the legal requirements and the plant safety policy of the particular organization. With such measures, the hazard risk is decreased below the tolerable risk level. As a rule, several, independent measures for risk reduction are taken (layers of protection concept). A priority here is to check whether a risk can be avoided by alternation of reaction or process conditions (material selection, reaction procedure, and process parameters such as pressure and temperature); if this is not entirely possible, then the cost for controlling the hazard should be kept as low as possible. This can be effected by means of a pressure-resistant design (inherent safe system) or through process control system measures with a monitoring function. In addition, it might be necessary – depending on the safety integrity of the countermeasure – to use a safety function (see IEC 61511). This, for example, includes the safe interlock of material and energy flows. Finally, as a rule, there remains the emergency discharge of the heat exchanger contents to protect against an impermissible pressure. If the discharged products are capable of further reaction, combustible, or toxic, then their safe removal, storage, and disposal must also be ensured.

3 Deviations from Normal Operation (Credible Scenarios)

With heat exchangers, various deviations from normal operation of the appliance (maloperations and system failures) are conceivable; typical examples are given in Table 1.

Each of these deviations can be the cause of an impermissible pressure or temperature in the heat exchanger. Essentially, in each case, one (independent) fault must be considered and assessed in the risk analysis (single-fault tolerance principle). In

L2.3. Table 1. Typical examples of deviations from normal operations in heat exchangers

Deviation from normal operation	Causes (examples)	Effects (examples)
Internal leakage/rupture of one or more heat exchanger tubes	• Oscillations (flow, machines) • Inadequate material strength • Corrosion and/or erosion • Exceeding of permissible temperature load cycle change, e.g., during start-up/shutdown • Pressure peaks, e.g., (rapid) valve closing • Flow-related heat exchanger asymmetries, e.g., due to partial tube blockages • Hot spots due to dry tubes as a result of vapor formation	Overflow/mixing of materials, sometimes with changes in pressure/temperature due to: • Material incompatibilities • Corrosion • Erosion • Mixture volume expansion during liquid mixing (alcohols, acids, etc.) • Evaporation/condensation • Heat release due to mixing or chemical reactions • Vacuum formation in freezers
External leakage of heat exchanger (shell-side)	• Material incompatibilities • Corrosion and/or erosion • Dynamic loads (pressure and temperature changes) • Mechanical action from outside	• Discharge of liquids, gases/vapors into the surroundings • Suction of air into the heat exchanger during underpressure (explosion risk) · Fire hazard/auto-ignition in the case of inflammable liquids in insulation
Blockage of liquids, gases/vapors	• External heating, e.g., fire, exposure to sunlight with consequent expansion of a liquid • Cooling failure • Vacuum formation due to failure of heating/cooling	• Discharge of liquids, gases/vapors into the surroundings • Leakage (see above)
Overpressures due to external pressure sources	• Impermissibly closed outlet	• Discharge of liquids, gases/vapors into the surroundings
	• Maximum pressure due to pumps, networks	• Leakage (see above)
	• Maloperations or failures in an adjacent plant part, e.g., with backflows	
Overheating at maximal operating pressure	• External heating, e.g., due to fire, exposure to sunlight	• Discharge of liquids, gases/vapors into the surroundings
	• Impermissible internal heating	• Leakage

individual cases and in particular for high risks, however, several independent faults should also be assumed simultaneously or directly consecutively (multi-jeopardy consideration). Essentially, however, the deviation from normal operation of the heat exchanger should not be specified unnecessarily on the supposedly safe side, since an oversized safety device also frequently leads to risks that are difficult to estimate during the discharge of the material flows. For example, account should be taken of dynamic forces on the emergency release system and the downstream appliances.

4 Assessment of Effects and Countermeasures

4.1 Leakage

With heat exchanger, it is necessary to check whether internal leakages or leakages on the shell can occur. Internal leakages can only seldom be completely ruled out. Such leakages are predominantly influenced inter alia by the material, the number, nominal width, and length of the tubes in the heat exchanger, the operating conditions, dynamic loads, and the fluids. Details on the estimation of the size of the leakage and the discharged mass flow rate are given in the later chapters. In principle, the main possible safety measures are inherent protection, safety-based PCS devices, or a mechanical safety device.

Internal leakages in heat exchangers with very large pressure differences on both sides can lead to violent pressure peaks in the apparatus if the low-pressure side is full of liquid and a large quantity of rapid gas flows from the high-pressure level through the leak. These pressure peaks spread very rapidly in the apparatus. In this case, a safety valve is unsuitable for protection, since it does not open sufficiently rapidly. Burst discs can be sufficiently rapid [IP Guideline, Thyer 2001]. The dynamic loads must be taken into account in the design strength of the heat exchanger.

Shell-side leakage in a heat exchanger is very rare when mechanical influences from the exterior are avoided, and can if necessary be ruled out with appropriate and timely inspections.

4.1.1 Leakage Sizes

At present, precise determination of leakage sizes is only possible in a few isolated cases. On the basis of values from experience with industrial heat exchangers and measurements on model appliances [Thyer 2001], the leakage size can in most cases at least be conservatively estimated.

Commonly, a full rupture of one heat exchanger tube below the manifold base is considered as a typical sizing case [API 520, ISO 23521]. Double the cross section of one tube is thus the release area. In the calculation of the mass flow rate, flow contraction at the manifold base and the pressure drop in the ruptured tube may be taken into account. Alternatively, in the case of compact heat exchangers, the cross section of one flow channel can be assumed as an appropriate leakage size [IP Guideline].

Tube rupture is very rare with ductile materials; however, it cannot be entirely ruled out. Experience shows that this rupture does not occur with double-shell tubes [see ISO 23521 §5.19.6]. On the other hand, in a large heat exchanger with a few thousand tubes and small nominal tube diameter, rupture of more than one tube is conceivable. The assessment must be made case by case.

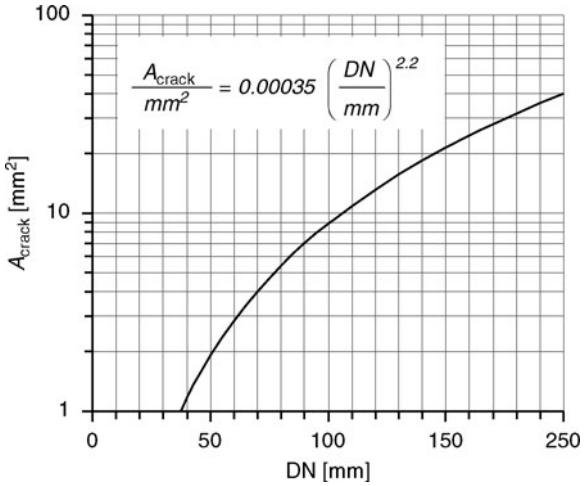
In general, it is less probable that a tube with a large diameter will rupture completely than a tube of small diameter under identical installation conditions. With a decreasing number of tubes a complete rupture of a tube also becomes less probable.

In the chemical and petrochemical industries, cracks rather than complete tube rupture have been observed (leakage before breakage). It is, thus, a current practice under certain preconditions to permit leakage sizes smaller than twice the tube cross section:

1. Proper design of the heat exchanger, that is, all operation loads are taken into account (pressure, temperature, dead weight, additional stresses, thermal expansion, vibrations)
2. Appropriate manufacture and adequate testing (e.g., testing of tube weld points, determination of the corrosion resistance)
3. Minimum nominal diameter DN50 for long single-tube heat exchangers (tube coils in vessels)
4. Adequate strength of tube connections, for example, minimum nominal pipe diameter DN50 for very hazardous substances – for example, toxic – and DN25 for the other hazardous substances, and/or protection against tube tear off due to external force
5. Ductile material (e.g., austenitic steel such as 1.4571)
6. No corrosion or erosion stress loads (e.g., stress concentrations near welds, concentration of components with corrosive action, degassing of oxygen, unsuitable material pairings, excessive flow velocities)
7. No periodic oscillation close to the resonance frequency
8. No regular, large dynamic loads, for example, temperature load cycles during start-up/shutdown of the heat exchanger
9. No major external mechanical stresses
10. Regularly repeated inspection program
11. Reliable and timely leak detection before serious consequences (e.g., pressure, temperature, level, and concentration monitoring) and possibility of suitable countermeasures, e.g., number 12
12. Possibility of separating the heat exchanger off from other plant components during incidents

The leak size must be estimated case by case. On the basis of incident studies, leaks with an equivalent diameter of 5 mm ($\sim$20 mm^2 area) are commonly assessed as large enough in standard heat exchangers.

A shell-side leakage in heat exchangers is very rare and can in individual cases be ruled out if necessary with a suitable and timely inspection program. However, for the case where a leakage is assessed to be sufficiently probable, the leak areas must often be determined by experience based on current knowledge sources. This includes, for example, a leak with an equivalent diameter of 5 mm ($\sim$20 mm^2 area) under the preconditions stated above mainly based on experience by



L2.3. Fig. 1. Crack size A_{crack} as a function of nominal diameter DN of the largest connection to a heat exchanger according to crack simulations of Strohmeier [Strohmeier 1990, 1993].

crack inspections. For installations with potentially water-contaminating subcooled liquids, hypothetical, and large leak areas are also described in the literature (about 11 mm diameter or 100 mm^2 area) [TAA1994, DVWK 131/1996]. On the other hand, the crack simulations of K. Strohmeier [Strohmeier 1990, Strohmeier 1993] gave leak areas of 4.4–7.9 mm^2 for cylindrical vessels with internal pressures up to 25 bar. For a vessel/flange joint with a pressure of 100 bar, 27 mm^2 was calculated. His simulations are fitted to a correlation and plotted in Fig. 1 [Ballast 2008].

For most chemical and petrochemical heat exchangers under moderate internal pressure the above-stated preconditions, an estimated leak area of 20 mm^2 appears to be sufficiently conservative.

4.1.2 Leak Mass Flow rate

For the precise calculation of the leak mass flow rate, the crack shape, the crack dimensions, and the wall roughness in the crack must be known. Detailed data on this subject and a model for the calculation of the leak mass flow rate with vaporizing two-phase flow are given by Westphal [1991].

When an approximate value – for example, the hole with a diameter of 5 mm – is taken as the basis for the leak area, the model of a frictionless flow through a nozzle with no heat transfer to the wall is adequate for the calculation of the leak mass flow rate. With vaporizing flow, homogeneously mixed phases are assumed to be in thermodynamic equilibrium. This is permissible for cracks, as Westphal has shown in his paper. Nozzle flow models are also the basis for other throttle devices such as control and safety valves. The leak mass flow rate can therefore be determined with the HNE-DS model [Diener and Schmidt 2004]. It applies for gases/vapors, liquids, and two-phase mixtures (see Sect. 6).

If a liquefied gas flows out of a leak, then in most cases only a part of the mass vaporises while flowing through the crack and the rest collects below the heat exchanger and forms a pool there. However, the liquid does not have to emerge in the direct vicinity of the leak if the heat exchanger is insulated. In addition to the vapor mass flow rate from the leak, which includes the flashing vapor, the mass flow rate as a result of the evaporation of liquid from the pool must then also be determined [Bosch 1997].

Example 1:

Exercise: How large is the leak mass flow rate through a leak area of 20 mm^2 (diameter 5 mm) for a highly subcooled methanol liquid with a temperature of 134.6°C under an initial pressure of 15 bar. The vapor pressure of the liquid at 134.6°C is 9.5 bar, and the density is 664.5 kg/m^3. The fluid discharges into the surroundings.

Solution: For a slightly subcooled liquid in front of the crack, which partially vaporises on flowing through the crack, the Bernoulli equation for non-vaporising, incompressible liquid flows may be used, see Table 3 ($F_F = 1$). Here, the vapor pressure of the liquid at inlet temperature may be used as the back pressure.

$$Q_m = 20 \cdot 10^{-6}\mathrm{m}^2 \cdot \sqrt{2 \cdot 664.5 \frac{\mathrm{kg}}{\mathrm{m}^3} \cdot 15 \cdot 10^5 \frac{\mathrm{N}}{\mathrm{m}^2} \cdot \left(1 - \frac{9.5}{15}\right)}$$
$$= 0.541 \frac{\mathrm{kg}}{\mathrm{s}}$$

4.1.3 Vapor Flash Fraction due to Shell-Side Leakages

Slightly subcooled or saturated liquids will partially vaporise while flowing through a crack. The vapor mass flow rate $Q_{m,g}$, based on the total mass flow rate, is defined as the flow mass quality:

$$\dot{x} = \frac{Q_{m,g}}{Q_{m,g} + Q_{m,l}} = \frac{Q_{m,g}}{Q_m}; \dot{x} \in [0..1] \quad (1)$$

For flows without appreciable heat loss to the wall, it can be approximately determined by an isenthalpic change of state between stagnation condition with the specific enthalpy $h(T_0)$, for example, in front of the crack, and the back pressure p of the surrounding.

$$\dot{x} = \frac{h(\mathrm{T}_0) - h'(\mathrm{T}''(p))}{h''(\mathrm{T}''(p)) - h'(\mathrm{T}''(p))} \quad (2)$$

Here, it was assumed that a homogeneous flow in thermodynamic equilibrium prevails in the crack and that therefore the boiling temperature adjusted itself to the local pressure p in each cross section under consideration (see Westphal 1991).

For the exact calculation of the mass flow quality, phase diagrams or equations of state are often used.

Example 2:

Exercise: How large are the mass flow quality at the exit from the crack and the vapor mass flow rate discharged, if the data from Example 1 are considered?

Solution: The specific enthalpy of methanol (liquid) at 134.6°C and 15 bar is 479 kJ/kg, and the specific enthalpies of boiling methanol at 1 bar (64°C) are 181 kJ/kg (liquid) and 1097 kJ/kg (vapor)

$$\dot{x} = \frac{479 - 181}{(1097 - 181)} = 0.272 = 27.2\%$$

The mass flow quality of the methanol after flowing through the crack is 27.2 wt.%. In the crack, the pressure at first decreases to the critical pressure and part of the liquid vaporises. Immediately upstream, there is a pressure jump to the ambient pressure with further vaporisation. Here the calculated vapor content is reached.

$$Q_{m,g} = \dot{x} \cdot Q_m = 0.272 \times 0.541 \frac{kg}{s} = 0.147 \frac{kg}{s}$$

The vapor mass flow rate due to flashing of methanol in the crack is 0.147 kg/s.

4.1.4 Dispersion Calculation

In those cases, where the release of hazardous substances, explosives, or flammable substances into the surroundings as a result of a shell-side leakage cannot be ruled out, dispersion calculation must be carried out to determine the time-dependent concentration distribution of the hazardous substances by means of the following steps:

1. Calculate the mass flow rate discharged due to a shell-side leakage as a function of time.
2. Estimate the pool size below the heat exchanger if liquid is discharged and not fully vaporized.
3. Calculate the released vapor mass flow rate. In case of flashing liquids it may consist of both the flow rate due to flashing in the crack and the flow rate vaporising from a pool below the heat exchanger. Special consideration must be taken if aerosols are created.
4. Near surrounding dispersion calculation for explosive substances: the area around the leakage where the concentrations of explosive substances may exceed the lower explosion limit must be estimated. An assessment of possible effects must be made (e.g. pressure wave propagation) and countermeasures should be discussed, for example, to avoid any ignition sources within this area and to keep a sufficient distance to neighbor plants and buildings. Typically, the dispersion of an explosive substance is estimated by means of a free jet calculation where the momentum of the released mass flow rate is taken into consideration [Schatzmann 1976, Bosch 1997]. If a gas or vapor is discharged with a molecular weight significant larger than that of air (heavy gas dispersion), the cloud will fall down and disperse around the heat exchanger. In this case the cloud size should be estimated by means of heavy gas dispersion calculations [VDI 3783Part2]
5. Dispersion calculation for hazardous substances: the concentration of the hazardous substances must not exceed the current exposure limits, for example, ERPG 2 value [TAAGS06]. In general, the maximum immission concentration is calculated and compared to the exposure limit. This concentration depends on several parameters like wind velocity and construction density in the surrounding of the leakage, which must be reasonably determined case by case. Far distance, immission calculations are generally done with simplified mixing models where the momentum of the free jet has almost no effect anymore and turbulent mixing of the hazardous substance with ambient air is dominant [VDI 3783Part1]. Special care must be taken if heavy case dispersion is considered [VDI 3783Part2].

In practice, there are a range of methods [e.g., Schatzmann 1976] containing the basic principles for corresponding computer programs [Witlox 1999] for carrying out dispersion calculations. The codes contain simplified models, which are, in most cases, conservative if they are physically meaningfully used. As long as the crack size can be conservatively estimated and the location and shape of a crack cannot be predicted, it seems not reasonable to use more precise computer codes for dispersion calculation.

In order to mitigate the consequences of such leakages, it is necessary to determine on a case-by-case basis whether concentration monitoring, segregation measures, the evacuation of areas with hazardous substances, or combustible substances and/or total containment concepts are suitable.

4.2 Blockage of Liquid and External Pressure Sources

If there is the possibility that liquid can be blocked in and heated in the heat exchanger, for example, by the following:

- Heat input from the surroundings (liquefied gases with a boiling point below the ambient temperature/supercritical liquids)
- Exposure to sunlight
- Internal heating
- In case of fire

then firstly it should be checked whether one of the valves cannot be locked open or mechanically blocked (organizational safety measure) to avoid an impermissible pressure build-up. If this is not the case or if this is not always possible, then the heat exchanger must be equipped with a mechanical safety device.

With very small liquid volumes blocked in, the risk to the surroundings as a result of a pressure build-up is mostly only slight. The tolerable discharge volume (minimum volume for protection) can be approximately estimated via a calculation of the dispersion of gases/vapors. Volumes between 5 l and 5000 l are typical, depending on the hazard potential of the fluid, the possible density change and the heating rate of the medium blocked in the appliance.

External pressure sources such as pumps or networks which are connected to a heat exchanger must not lead to a pressure or temperature larger than the permissible design values. If the permissible temperature or pressure of the heat exchanger is not sufficient, then it should first be checked whether the pressure source can be turned off by a safety interlock (see PCS safety device). If not, a mechanical safety device must be installed.

4.3 Overheating

The permissible design temperature of the heat exchanger must not be exceeded even in the event of a deviation from normal operation. Heating systems, for example, with saturated steam, must be adequately protected. This also applies for heat

exchangers in which exothermic chemical reactions, for example, as a result of an internal leakage or in a tubular reactor, cannot be ruled out. Heat exchangers should be protected against fire, if the risk of this breakdown scenario is assessed to be sufficiently high.

In the chemical industry, the risk due to heat input as a result of a fire is often decreased below the tolerable risk level by organizational and construction measures; such measures should be established in each individual case. They include, inter alia the following:

- Proper design, implementation, and installation of the appliance
- Regular inspection
- Timely and reliable leak and fire detection
- Construction of a tank pit with gradient for drainage of liquid into a separate area
- The possibility of segregating the appliance
- A fire service, which rapidly mitigates the consequences of a fire by effective countermeasures such as extinguishing the fire or cooling the appliance

Further safety measures are then, as a rule, not absolutely necessary.

According to the American regulation for petrochemical plant [API 520] a sufficiently great risk is always present when a combustible liquid or a combustible gas is present in the heat exchanger or in an adjacent part of the plant and a leakage cannot be ruled out. The protection of the appliance against an impermissible overpressure is then mostly ensured with a mechanical safety device. Depending on the material (e.g., aluminum), supplementary measures for minimization of the fire load and heat radiation (extinguishing and/or cooling) can also be necessary in order to prevent an impermissibly high temperature and thus, to ensure adequate strength and hermeticity of the appliance.

5 Sizing of Safety Devices

5.1 Inherently Safe Design of the Heat Exchanger

Safety devices on heat exchangers can be avoided if the appliances are inherently safely designed. For this, the permissible pressures of both sides of the heat exchanger are selected to withstand the maximum possible pressure resulting from the most credible maloperation or system failure, which has been determined during the risk analysis. Typically for standard tubular heat exchangers the permissible pressures of the inner-tube side and the shell-side are set equal to at least the maximum pressure that may occur during the worst case scenario. While in the case of larger heat exchangers, for economic reasons, the low-pressure side is designed at two thirds of the permissible pressure of the high-pressure side [API 521, p. 23]. Here, the material strength of the heat exchanger, which is tested at 150% of the permissible design pressure [see also ISO 23251 4.3.2], is exploited. Apart from the pressure resistance, essential care should also be taken that the permissible temperature of the appliance cannot be exceeded.

Essentially, a pressure- and temperature-resistant construction (inherently safe design) must include at least the connected pipes and appliances as far as the next possible shut-off point. All pipes connected to the heat exchanger must be installed such that the level of vibration (fluid induced and vibrations from rotating devices) is low, and should have adequate resistance to leakages and mechanical tube break-off. For larger plant heat exchangers, pipe nominal widths below DN25 should be avoided.

The heat exchanger must be made from a material with ductile properties under worst credible conditions (e.g., austenitic steel such as 1.4571), and which is technically resistant to the media under operating conditions. Shell-side leakages need not be assumed as a credible scenario if cracks can reliably be ruled out or the shell-side is regularly checked for cracks with critical crack lengths, so that firstly a crack is reliably and promptly detected before wall breakthrough and, secondly, effective countermeasures can be taken (leak-before break criterion).

Inherently safe design can be uneconomic for very large heat exchangers or appliances with very large pressure differences between tube interior and shell-side. In this case, mechanical safety devices are often used for the protection of the heat exchanger.

Inherent safety also includes both proper design and the suitable mode of operation and regular inspection and testing of the heat exchanger. In this way, incidents, for example, as a result of corrosion, can be prevented or – if necessary – promptly and reliably identified. Suitable countermeasures may be taken, so that the strength and hermeticity of the heat exchanger are maintained throughout the whole intended operating period. An efficient inspection and countermeasures policy can, for example, be drawn up analogously to the procedure, which is necessary for the regular extension of the inspection period for chemical plants [Hahn 2007].

Example 3:
Exercise: In a tubular heat exchanger, methanol at ambient pressure is heated with saturated steam from a 4 bar steam network. The safety device for the network activates at 4.5 bar. What design pressure should be selected for the heat exchanger in order to operate the appliance inherently safely?

Solution: At the maximum operating pressure (4.5 bar) in the steam network, the temperature of the steam is 147.7°C. This is the highest steam temperature that can be established in the heat exchanger (saturated steam) – the heat of mixing of the substances in case of an internal leakage is negligibly small. At this temperature, methanol has a vapor pressure of 13.2 bar. The permissible pressure of the heat exchanger must correspond to at least this pressure and the permissible temperature must be at least 150°C. Attached tubes and appliances are also designed for these permissible operating parameters.

5.2 Protection with Safety-Related PCS Devices

With process control systems, the causes and/or the effects of maloperations and system failures on heat exchangers can often be mitigated. Thus, for example, through emergency segregation of an appliance, the feed stream of material or

energy is stopped or the discharge is limited to a small partial volume. Such mitigation of consequence devices (secondary safety measures) are implemented with a reliability corresponding to the SIL requirement (SIL stage 1–3) depending on the hazard potential of a credible scenario.

Moreover, PCS devices can also be implemented as a primary safety device, when, for example, exceeding the permissible appliance pressure is reliably avoided by a safely interlock of a steam flow.

Essentially, the safety-related PCS devices should be simple and proven in operation [VDI 2180]. Pressure and temperature interlock systems are typical. In isolated cases, complex devices are also used, for example, concentration or conductivity measurements, when they satisfy the appropriate specification class for safety integrity.

A safety-related PCS device should be preferred to a mechanical pressure relief device if the cause of a deviation from normal operation of the heat exchanger can be prevented and if it ensures the safety of the appliance equivalently. In addition, it should be economically comparable to mechanical pressure relief devices and simply constructed.

A safety measure, which must satisfy the specification class SIL 4 should not correspond to a safety-related PCS device alone, but should also include further safety measures.

Example 4:
Exercise: In a tubular heat exchanger with a permissible pressure of 7 bar, methanol at ambient pressure is to be heated with saturated steam from a 5 bar steam network. The steam is throttled down to 1.5 bar in a pressure reducer. How must the heat exchanger be protected?

Solution: The pressure reducer is not a safety-related fitting, hence, it has no safety function and can fail. In practice, when such fittings are defective, they are often exchanged for other designs. Hence, on the steam side a temperature safety interlock must be installed, which safely blocks the steam flow at a temperature of maximum 123°C – this corresponds to the boiling temperature of methanol at the permissible design pressure of the heat exchanger (7 bar).

The level of reliability of the temperature interlock system is determined in accordance with the specification class (SIL level) from the risk analysis – in the present operating conditions with toxic methanol SIL 3. The safety function is realized with two independent channels (see VDI/VDE 2180). Here care must be taken that only two ball valves with one bleed device in-between (block-and-bleed system) are technically leak-proven. In the absence of a bleed device and above all with combinations of ball valve and control valve, residual leakages cannot be excluded. In practice, the leak volume flow rate can be conservatively estimated at, for example, 1–5% of the discharge coefficient k_{vs} of the control valve, provided the control valve is properly operated and regularly tested. The volume flow rate depends on the size and operating conditions of the heat exchanger. A mechanical safety device of small size can in addition be necessary, in order to remove residual leakages.

In general, the closure time of the temperature device should be selected such that no impermissible dynamic loads (pressure shocks) should be added on the heat exchanger.

5.3 Protection with Mechanical Safety Devices

The protection of a heat exchanger with a safety valve or burst disc is determined in five steps:

1. Hazard and risk analysis for the assessment of possible deviations from normal operation (see Sects. 2 and 3) and selection of a suitable type of the mechanical safety device
2. Calculation of the mass flow to be discharged through the safety device (inflow into the heat exchanger under worst case conditions)
3. Determination of the fluid state at the inlet to the safety device
4. Calculation of the mass flux through the safety device and hence the necessary size of the valve seat
5. Ensuring of safe operation under installation conditions

5.3.1 Calculation of the Mass Flow Rate to be Discharged

Inflow Due to Internal Leakage

As a rule, in tubular heat exchangers, the full rupture of a heat exchanger tube is assumed for the calculation of the mass flow rate [ISO 23251]. In individual cases, it can also be justified to assume the rupture of several tubes. On the other hand, for tube coils, double-mantle tubes and those heat exchangers, which are manufactured and operated subject to special quality requirements – for these, see the explanations in Sect. 3 – the assumption of leak-before-breakage behavior is permissible. In this case, the leak areas are smaller than for the full rupture of one tube. A typical leak area is 20 mm^2.

In case of a full rupture of a tube in a heat exchanger, this is assumed to be at the manifold base [IP Guideline], fluid flows through two tube cross sections into the shell-side of the heat exchanger and mixes with the medium which is there. The mass flow rate through these cross sections can be calculated with the nozzle flow model HNE-DS (see Sect. 6). The difference between the maximal (stagnation) pressure in the tube manifold and the opening pressure of the safety valve on the shell-side is as a rule assumed to be the driving pressure gradient. However, it is also permissible to calculate the mass flows through the two tube cross sections separately from one another: once with the maximal pressure in the tube manifold and next with a reduced pressure. The reduction corresponds to the pressure drop in the heat exchanger tube. Further, for example, for very long heat exchangers or with many baffles, a pressure drop in the shell-side of the heat exchanger can also be taken into account. The driving pressure gradient should be reduced by this pressure in order to calculate the mass flow rate.

With flashing fluids, the assumption of a homogeneous flow in thermodynamic equilibrium ($N \equiv 1$, see Sect. 6) can be justified when the flow time to the tube outlet is sufficiently great for the equilibrium to be established. This applies inter alia for the flow in the heat exchanger tube. For short tube ends, the boiling delay of the flow must also be taken into account ($N < 1$, see Sect. 6).

If a gas flows from the high-pressure side of the heat exchanger into a low-pressure part filled with liquid, then the gas displaces the liquid there. At the start of the incident, a liquid volume flow, which corresponds to the inflowing gas volume flow must be removed through the safety device. In the further course of the incident, the gas increasingly mixes with the liquid. The gas content before the safety valve changes continuously.

Inflow Due to Liquid Block-in

The minimum required mass flow rate to be discharged in the event of liquid block-in can be approximately calculated by the density change $d\rho/dT$ of the liquid at constant pressure and maximum heat input $\dot{Q}$, for example, maximum heating:

$$Q_{m,out} = V \cdot \frac{d\rho}{dT} \cdot \frac{dT}{dt} = \frac{\dot{Q}}{cp_l} \cdot \frac{1}{\rho} \cdot \frac{d\rho}{dT} \tag{3}$$

With very large heat exchangers or high-pressure heat exchangers with very large steel masses, it is permissible to additionally consider the changes in the heating temperature with time in Eq. (3) – for example, the daily change of the ambient temperature if the exposure to sunlight is assumed as worst credible scenario. The average temperature in the heat exchanger follows the ambient temperature with a time delay and damping.

Inflow from Pumps, Networks, and Other Pressure Sources

The minimum required mass flow rate to be discharged through the safety device $Q_{m,out}$ corresponds to the maximum feed into the heat exchanger $Q_{m,feed}$ with fully opened inlet valves and closed outlet valves.

$$Q_{m,out} = \sum Q_{m,feed} \tag{4}$$

In the case of an inflow via pumps or networks, the maximum operating pressure or (more conservative) the set pressure of the safety device in the network is taken as the basis. If the fluid flows into the heat exchanger through a control valve, then the minimum required mass flow rate to be discharged is determined by means of a nozzle flow model. The equivalent nozzle cross section A_{feed} can be calculated from the discharge coefficient of the control valve k_{vs}, which is determined experimentally with water at a temperature between 5°C and 50°C at a differential pressure of 1 bar [DIN EN 60534]:

$$A_{feed} \cong k_{vs} \sqrt{\frac{\rho_{H2O}}{2\Delta p_{H2O}}} = \frac{k_{vs}}{\sqrt{200}} \left[\frac{s}{m}\right] \tag{5}$$

$$\text{with} \sqrt{\frac{\rho_{H2O}}{2 \cdot \Delta p_{H2O}}} = \frac{1}{\sqrt{200}} \left[\frac{s}{m}\right] \tag{6}$$

The discharge coefficient is given by the control valve manufacturer in cubic meters per hour, it is dimensional. For the conversion from hours to seconds, the factor 1/3,600 must be taken into account.

The maximum inflow through the control valve can be calculated with the HNE-DS model (Sect. 6), wherein the pressure at the entrance of the control valve and the opening pressure of the safety valve represent the propulsive pressure difference. For longer tubes or other components with a significant pressure drop between the control valve and the heat exchanger, the pressure drop to the appliance may also be taken into account. The back pressure for the mass flow calculation then corresponds to the sum of the opening pressure of the valve and the pressure drop to the outlet of the control valve.

For gases/vapors or two-phase flows, it should be noted that a critical pressure condition can arise in the control valve. The back pressure in the nozzle flow model then corresponds to the critical pressure (see Sect. 6).

The calculation of the mass flow rate through control valves is also described in DIN EN 60534. However, the use of this standard is not recommended in the flow of two-phase mixtures. Mass flows, which are significantly too high or too low are calculated by DIN EN 60534, as has been shown by Diener [1999].

Control valves are components relevant to safety when the mass flow to be discharged through these fittings is specified for sizing the safety device. They must be correspondingly labeled and tested. In the event of an exchange, care must be taken that a fitting with a higher discharge coefficient k_{vs} is not installed. On the other hand, the control valve is no longer related to safety when a restriction orifice plate is connected upstream. In this case, the mass flow dischargeable through the plate without taking into account of the control valve is applied for the sizing of the safety device. It can also be calculated by means of the HNE-DS model [Diener 2005].

Example 5:

Exercise: Liquid methanol (density 671 kg/m^3) is cooled in a tubular heat exchanger. The heat exchanger is protected with a safety valve with a set pressure of 8.4 bar (abs). The liquid is fed by a pump, which can perform a pressure of 25 bar (abs). The feed is regulated with a control valve (k_{vs} = 6.4 m^3/h). The pressure drop between control valve and heat exchanger is 0.7 bar. How large is the mass flow rate to be discharged via the safety valve?

Solution: The maximum mass flow rate through the control valve is calculated with the nozzle flow model. The equivalent nozzle cross section is found to be:

$$A_{feed} = \frac{6.4 \frac{m^3}{h}}{3600 \frac{s}{h} \cdot \sqrt{200}} \left[\frac{s}{m}\right] = 1.26 \cdot 10^{-4} m^2$$

The pressure at the outlet of the control valve is calculated from the opening pressure of the safety valve, which corresponds to 1.1 times the set pressure (overpressure!) and the pressure drop in the tube:

$$p_{out} = (1.1 \cdot 7.4 \cdot bar + 1 \cdot bar) + 0.7 \cdot bar = 9.8 \cdot bar$$

Hence the maximum mass flow rate through the control valve with fully opened safety valve is as follows (see Table 3):

$$Q_{m,feed} = A_{feed} \cdot \sqrt{2 \cdot \rho \cdot p_{feed} \cdot (\eta_{feed} - \eta_{out})}$$

$$Q_{m,feed} = 1.26 \cdot 10^{-4} m^2 \cdot \sqrt{2 \cdot 671 \frac{kg}{m^3} \cdot 25 \cdot 10^5 \frac{N}{m^2} \cdot \left(1 - \frac{9.8}{25}\right)} = 5.68 kg/s$$

This mass flow rate must be discharged through the safety valve in order to avoid an impermissible overpressure in the heat exchanger.

Inflow in Case of Fire

According to the American legislation [ISO 23251] in the event of a fire about 108 kW/m^2 of heat is transferred into the heat exchanger through the surfaces wetted with liquid [Heller 1983]. This value may be decreased to 40.3 kW/m^2 if no flammable liquid can collect under the heat exchanger and a fire service can rapidly extinguish the fire. With very large heat exchangers or those installed high up, the heat input is only taken into account up to a height of 7.5 m. Furthermore, the value can be decreased by adequate fire protection insulation (see ISO 23251, Table 6). In the calculation of the wetted area, the feed and outlet tubes should also be included.

Essentially, the energy which is transferred into the heat exchanger through the fire must be removed with the mass flow rate through the fully opened valve. Thus, for vaporising liquids with pure vapor flow through the safety valve the following, for example, applies:

$$Q_{\mathrm{m,out}} = \frac{\dot{Q}}{\Delta h_{\mathrm{v},0}} \tag{7}$$

If, on the other hand, a gas/vapor–liquid mixture flows through the fitting, then a greater mass flow rate must be discharged (see, e.g., ISO 4126-10).

5.3.2 Fluid State at the Inlet of the Valve

The fluid state at the valve inlet results from the properties of the fluids involved on both sides of the heat exchanger, the possible operating conditions, and the deviation from normal operation of the heat exchanger assumed. For flashing liquids or when gases and liquids are mixed as a result of an internal leakage, large ranges of mass flow quality are often passed through, which must also be taken into account in the sizing procedure of a mechanical safety device. The change in the mass flow quality during significant pressure changes (flashes) can often be estimated on the basis of an isenthalpic change of state (see Sect. 4.1.3).

In general, the fluid state can only be established case by case.

5.3.3 Sizing of Safety Valves

The safety valve must be sized sufficiently large to safely discharge at least the maximum inflow into the heat exchanger:

$$Q_{\mathrm{m,SV}} = K_{\mathrm{dr}} \cdot Q_{\mathrm{m,nozzle}} \geq Q_{\mathrm{m,out}} \tag{8}$$

The dischargeable mass flow rate $Q_{\mathrm{m,SV}}$ is obtained from the mass flow rate through a frictionless nozzle with no heat transfer to the surroundings, corrected by the certified discharge coefficient of the valve K_{dr}. This discharge coefficient is published by the valve manufacturers for gases and liquids. For two-phase flow in a safety valve, an averaged discharge coefficient is recommended:

$$K_{\mathrm{dr,2ph}} = \varepsilon \cdot K_{\mathrm{dr,g}} + (1-\varepsilon) \cdot K_{\mathrm{dr,l}} \tag{9}$$

The weighting factor for averaging the discharge coefficient is the void fraction in the narrowest flow cross section of the valve:

$$\varepsilon = 1 - \frac{v_{\mathrm{l},0}}{v_0 \cdot \left[\omega \cdot \left(\frac{1}{\eta} - 1\right) + 1\right]} \tag{10}$$

The mass flow rate through the nozzle is determined using the HNE-DS model (Sect. 6).

The minimum necessary valve seat cross section is thus:

$$A \geq \frac{Q_{\mathrm{m,out}}}{K_{\mathrm{dr}} \cdot C \cdot \sqrt{2 \cdot \frac{p_0}{v_0}}} \tag{11}$$

5.3.4 Safe Operation under Installation Conditions

The size of the safety valve is initially carried out without taking into account the pipes in the valve inlet and exit. Such pipes in some cases affect the safe operation of the valve. For example, high frequency vibrations, so-called valve chatter, can be induced. For gases and liquids, the pressure loss in the inlet is therefore limited to 3% of the valve set pressure (overpressure) and the back pressure must not exceed 10% of the set pressure (overpressure). These values apply if the manufacturer does not specify more specific values.

For two-phase flow a physically meaningful criteria to ensure proper valve operation under installation conditions is not yet determined. As a consequence, an expansion bellow and a friction damper are recommended [ISO 4126-10].

6 The HNE-DS Model for the Calculation of Mass Flow Rates through Nozzles

The flow-through cracks, drill holes, nozzles, orifices, and control and safety valves is, as a rule, described by simple nozzle flow models. The differences in flow rate between the nozzle flow model and the mass flow rate through the actual geometry are taken into account by means of a correction factor, dependent on the particular geometry of the component. In addition, for flashing liquids, the thermodynamic nonequilibrium (boiling delay) and the mechanical nonequilibrium (slip) must be included in the model. The less the pressure in the fitting decreases and the longer the residence time of the flow, the sooner a thermodynamic equilibrium between the two phases will become established. Pipe flows and cracks of great depth are typical examples of this. On the other hand, in orifices and valves with very small or absolutely no gas content, a significant thermodynamic nonequilibrium is established, and has the effect that a markedly greater mass flow passes through these components than might be expected with equilibrium being assumed.

As the basis for the calculation of the mass flow rate through a nozzle, a one-dimensional, homogeneous, and frictionless flow with no heat transfer to the nozzle wall is assumed. The mass flow rate can be dimensionless defined as the flow coefficient:

$$C = \frac{Q_{\mathrm{m}}}{A \cdot \sqrt{2 \cdot \frac{p_0}{v_0}}}; A = \frac{\pi}{4} d^2; v_0 = \dot{x}_0 v_{g,0} + (1-\dot{x}_0) v_{l,0} \tag{12}$$

It can be derived from the momentum balance between the nozzle inlet and the narrowest cross section in the nozzle (nozzle throat):

$$C = \sqrt{\frac{-\int_{\eta_0}^{\eta} v^* d\eta}{(v^*)^2 - \beta^4}}; \eta = \frac{p}{p_0}; v^* = \frac{v}{v_0}; \beta = \frac{d}{d_0} \qquad (13)$$

The numerical solution of this equation gives the most exact results, irrespective of whether the flow in the nozzle is single-phase (gas or liquid), initially subcooled, or flashing (see Table 2).

The flow coefficient C reaches a maximum at the critical pressure ratio $\eta = \eta_{crit}$. This is the smallest physically possible pressure ratio between inlet and nozzle throat. It can be determined from the derivation of the flow coefficient (see Fig. 2):

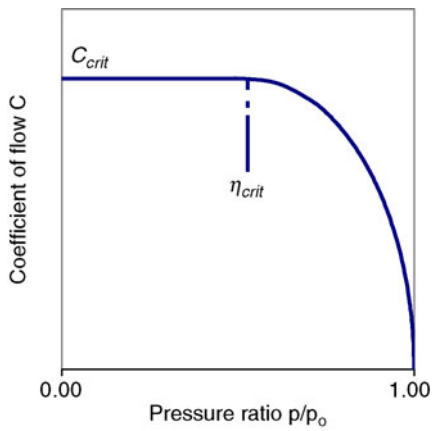
$$\frac{dC}{d\eta} = 0 \rightarrow \max[C(\eta); \eta \in (\eta_b..1)] \qquad (14)$$

For the integration of Eq. (13), the specific volume of the two-phase fluid – it is based on the specific volume at the inlet – must be known. A suitable equation must be stated, depending on the type of flow, incompressible liquid, gas/vapor, two-phase flow, or initially subcooled liquid, which flashes in the nozzle. For two-phase flow, Leung [1986] derived an equation of state:

$$v^* = \dot{x} \cdot \frac{v_g}{v_0} + (1 - \dot{x}) \cdot \frac{v_l}{v_0} = \omega(N) \left(\frac{1}{\eta} - \frac{1}{\eta_0} \right) - 1 \qquad (15)$$

L2.3. Table 2. Characterization of flow parameters for different types of flow

Flow at inlet	Flow characteristics
Liquid	$\dot{x}_0 = 0; v^* = 1; \eta_0 = 1; \eta = \eta_b$
Gas/vapor	$\dot{x}_0 = 1; v^* = v_g/v_{g,0}; \eta_0 = 1; \eta \geq \eta_{crit}$ & $\eta \geq \eta_b$
Initially subcooled liquid	$\dot{x}_0 = 0; \eta_0 = \eta_S; \eta \geq \eta_{crit}$ & $\eta \geq \eta_b$
Vapor/flashing liquid	$\dot{x}_0 \geq 0; \eta_0 = 1; \eta \geq \eta_{crit}$ & $\eta \geq \eta_b$
Gas/non-flashing liquid	$\dot{x} = \dot{x}_0 = \text{const}; \eta_0 = 1; \eta \geq \eta_{crit}$ & $\eta \geq \eta_b; N \equiv 1$



L2.3. Fig. 2. Flow coefficient as a function of the pressure ratio at subcritical and critical pressure ratio.

The thermodynamic nonequilibrium in the flow (boiling delay) must be allowed for by means of the compressibility factor $\omega(N)$. For this, Diener and Schmidt [Diener 2004] introduced a nonequilibrium factor N, which must be adapted to the measured data for the fitting considered:

$$\omega(N) = \frac{1}{\kappa} \frac{\dot{x}_0 \cdot v_{g0}}{v_0} + \frac{cp_{l0} \cdot T_0 \cdot p_0 \cdot \eta_0}{v_0} \cdot \left[\frac{v_{g0} - v_{l0}}{\Delta h_{v0}} \right]^2 \cdot N \qquad (16)$$

$$N = \left(\dot{x}_0 + cp_{l0} \cdot T_0 \cdot p_0 \cdot \eta_0 \cdot \left(\frac{v_{g0} - v_{l0}}{\Delta h_{v0}^2} \right) \cdot \ln\left(\frac{\eta_0}{\eta} \right) \right)^a \qquad (17)$$

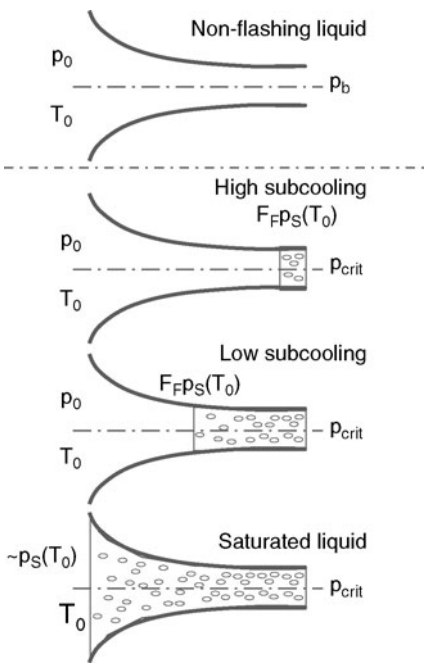
Both factors are dependent only on the property data at the entrance of the nozzle, which are, as a rule, known or can be measured.

For the flow of a non-vaporising two-phase mixture, for example, air/water under ambient conditions, the mechanical nonequilibrium (slip) is important. Diener and Schmidt [Diener 2004] adopted a recommendation by Simpson et al. [Simpson 1983], who have intensively studied the flow-through control valves:

$$Q_{m,slip} = \phi \cdot C \cdot A \cdot \sqrt{2 \cdot \frac{p_0}{v_0}} \qquad (18)$$

$$\phi = \sqrt{\frac{v_0}{v_{eq,0}}} = \sqrt{\frac{v_0}{v_{l,0}}} \cdot \left\{ 1 + \dot{x}_0 \cdot \left[\left(\frac{v_{g,0}}{v_{l,0}} \right)^{1/6} - 1 \right] \cdot \left[1 + \dot{x}_0 \cdot \left[\left(\frac{v_{g,0}}{v_{l,0}} \right)^{5/6} - 1 \right] \right] \right\}^{-\frac{1}{2}}$$

The Eqs. (13–17) can be analytically solved for relevant special cases. For this, the different flow types in Fig. 3 are considered and corresponding density models enlisted for the integration. The results – the flow coefficients for different types of flow in integral form – are shown in Table 3. The accuracy of the analytical solution is inadequate only in the case of slightly



L2.3. Fig. 3. Flow types during flow-through nozzles.

L2.3. Table 3. Flow coefficients for different flow types

Flow coefficient for nozzles depending on flow type at the inlet ($\beta = 0$)	Subcritical flow: $\eta_b > \eta_{crit} \Rightarrow \eta = \eta_b$
	Critical flow: $\eta_b \le \eta_{crit} \Rightarrow \eta = \eta_{crit}$
	$\eta_{crit} = \frac{p_{crit}}{p_0}; \eta_b = \frac{p_b}{p_0}$
Strongly subcooled liquid ($\eta_b \ge \eta_{crit}$) (no vaporisation before the vena contracta) ($\dot{x}_0 = 0$): $C_l = \sqrt{1-\eta}$	$\eta_{crit} = F_F \cdot \eta_S = F_F \cdot \frac{p_S(T_0)}{p_0}$ $F_F = \left[0.96 - 0.28\sqrt{\frac{\eta_S \cdot p_0}{p_c}}\right]$ Orifice plates, control valves/safety valves
	$F_F \cong 1$ Cracks
Slightly subcooled liquid ($\eta_b < \eta_{crit}$) fashing in the nozzle ($\dot{x}_0 = 0$)	See Schmidt (2007)
Gases/vapors ($\dot{x}_0 = 1$): $C_g = \sqrt{\frac{\kappa}{\kappa-1}\left[(\eta)^{2/\kappa} - (\eta)^{\kappa+1/\kappa}\right]}$	$\eta_{crit} = \left(\frac{2}{\kappa+1}\right)^{\frac{\kappa}{\kappa-1}}$
Flashing two − phase flow ($\dot{x}_0 > 0$): $C_{2ph} = \frac{\sqrt{\omega(N)\cdot\ln\left(\frac{1}{\eta}\right) - (\omega(N)-1)(1-\eta)}}{\omega(N)\left(\frac{1}{\eta}-1\right)+1}$	η_{crit} as per Eq. (19) or (20) $\omega(N)$ as per Eqs. (16) and (17) $a = 3/5$: orifice plates, control valves
	$a = 2/5$ Safety valves, control valves (small travel)
	$a \cong 0$ Cracks, tubes

subcooled to boiling liquid at the valve inlet. Here reference is made to the solution by Schmidt [Schmidt 2007, 2009].

A discussion of real gas effects to be accounted for when sizing a safety valve for gas service is given in Schmidt (2009b).

For the determination of the flow coefficient, it is first necessary in each case to check whether the ratio between back pressure and pressure at the valve inlet η_b is lower than the critical pressure ratio η_{crit}. In this case, the flow coefficient is calculated with the critical pressure ratio, and critical flow prevails in the narrowest cross section. In the alternative case, with subcritical flow, the back pressure ratio is used.

The critical pressure ratio in two-phase flow is determined using the compressibility factor at thermodynamic equilibrium $\omega_{N=1}$. With a factor greater than 1, an analytical correlation is sufficiently accurate, while with small compressibility factors the iterative solution must be chosen:

$\omega_{N=1} \ge 1$:

$$\eta_{crit} = 0.55 + 0.217 \cdot \ln\omega_{N=1} - 0.046 \cdot (\ln\omega_{N=1})^2 + 0.004 \cdot (\ln\omega_{N=1})^3 \quad (19)$$

$\omega_{N=1} < 1$:

$$\eta_{crit}{}^2 + \left(\omega_{N=1}{}^2 - 2\cdot\omega_{N=1}\right)(1-\eta_{crit})^2 + \ldots\ldots + 2\cdot\omega_{N=1}{}^2 \cdot \ln(\eta_{crit}) + 2\cdot\omega_{N=1}{}^2\cdot(1-\eta_{crit}) = 0 \quad (20)$$

Styles (1971) investigated the start of liquid flashing in control valves and figured out that flashing begins markedly below the saturation pressure of the fluid. He takes into account the difference by means of the flashing factor F_F, which is also introduced in the equations in Table 3.

Example 6:

Exercise: How large must the safety valve be sized in order to discharge the flow of liquid methanol (see Example 5), if the set pressure of the safety valve is 8.4 bar (abs) and the temperature of the methanol at opening of the valve corresponds to the boiling temperature of 130°C. Property data of the boiling liquid are: $cp_{l0} = 3.50\text{kJ/(kg·K)}, \Delta h_{v0} = 922.7\text{kJ/kg}$; $v_{l0} = 1.49\cdot 10^{-3}\text{m}^3/\text{kg}$; $v_{g0} = 0.0418\cdot\text{m}^3/\text{kg}$

Solution:

(1) Calculation of the degree of subcooling and mass flow quality at the entrance of the valve: the vapor pressure of the boiling liquid corresponds to the set pressure of the safety valve, i.e., $\eta_0 = \eta_S = 1; \dot{x}_0 = 0$. This lead to: $v_0 = v_{l,0}$

(2) Mass flow through an ideal nozzle

$$N = \left(cp_{l0}\cdot T_0\cdot p_0\cdot\left(\frac{v_{g0}-v_{l0}}{\Delta h_{v0}{}^2}\right)\cdot\ln\left(\frac{1}{\eta}\right)\right)^{\eta_s^{-0.6}} = 0.169\cdot\ln\left(\frac{1}{\eta}\right)$$

$$\omega(N) = \frac{cp_{l0}\cdot T_0\cdot p_0}{v_0}\cdot\left[\frac{v_{g0}-v_{l0}}{\Delta h_{v0}}\right]^2\cdot N = 2.33\cdot\ln\left(\frac{1}{\eta}\right)$$

$$C_{2ph} = \frac{\sqrt{2.33\cdot\ln\left(\frac{1}{\eta}\right)\cdot\ln\left(\frac{1}{\eta}\right) - \left(\ln\left(\frac{1}{\eta}\right)-1\right)(1-\eta)}}{\ln\left(\frac{1}{\eta}\right)\cdot\left(\frac{1}{\eta}-1\right)+1}$$

The equation will be solved graphically, starting with a pressure ratio of $\eta = 1$ in steps of 0.01 until the maximum of the flow coefficient is reached (see Fig. 4).

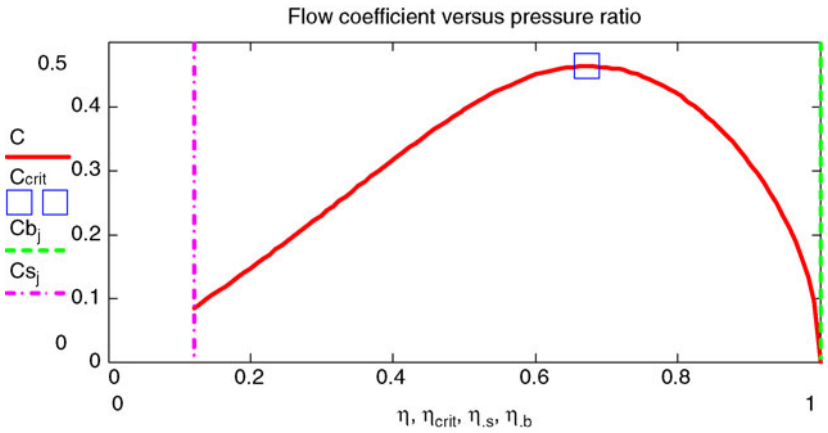
Figure 4 leads to the unknown parameters: $C_{2ph} = 0.4345$, $\eta_{crit} = 0.706$; $N(\eta_{crit}) = 0.05878$; $\omega(N) = 0.81$

The mass flux of the nozzle is therefore:

$$\frac{Q_m}{A} = C\cdot\sqrt{2\cdot\frac{p_0}{v_0}} = 14590\cdot\frac{\text{kg}}{\text{m}^2\cdot\text{s}}$$

(3) Calculation of the necessary seat cross-sectional area A and the minimum required seat diameter d_0:

$$\varepsilon = 1 - \frac{v_{l0}}{v_0\cdot\left[\omega\cdot\left(\frac{1}{\eta}-1\right)+1\right]} = 0.252$$



L2.3. Fig. 4. Graphical solution for the flow coefficient at the critical pressure ratio.

$$K_{\mathrm{dr,2ph}} = \varepsilon \cdot K_{\mathrm{dr,g}} + (1-\varepsilon) \cdot K_{\mathrm{dr,l}} = 0.568$$

$$A \geq \frac{Q_{\mathrm{m,out}}}{K_{\mathrm{dr,2ph}} \cdot C_{\mathrm{2ph}} \cdot \sqrt{2 \cdot \frac{p_0}{v_0}}} = 685 \cdot \mathrm{mm}^2$$

$$d \geq \frac{4}{\pi} \cdot \sqrt{A} = 29.5\,\mathrm{mm}$$

With a discharge coefficient of 0.568 for two-phase flow (based on the certified discharge coefficients for gas and liquid service of 0.5 and 0.77 taken from the valve manufacturer catalog), the minimum required seat diameter of the safety valve must be at least 29.5 mm. According to ISO 4126-10 it is recommended to install a bellow and friction damper in order to ensure safe operation of the safety valve.

In ISO 4126, Part 10, [ISO 4126], a further example of the sizing of a safety valve for two-phase flow is given.

L2.4 Calculating Critical Mass Flux

Florian Schmidt
Bayer Technology Services GmbH, Krefeld, Germany

1 Introduction

Keeping the pressure at the inlet cross section of a nozzle, an orifice, or any other duct constant and reducing step by step the pressure at the exit cross section results in an increased mass flux. If pressure falls below a certain value, no further increase in mass flux is observed (see Fig. 1). The resulting mass flux is called critical mass flux. It is dependent on the pressure at the inlet cross section p_0, the temperature T_0, the void fraction ε_0, the gas mass flow fraction $\dot{x}_0$, and the physical properties at the inlet cross section. At given inlet conditions the critical mass flux is the maximum possible mass flux through a valve (definitions of often used variables are to be found in Sect. 10).

For further explanation see Fig. 2. Also, in the following sections commonly used expressions and definitions are introduced. In Fig. 2, the pressure is plotted along the stream path from the inlet to outlet. Starting from the inlet pressure p_0 the pressure decreases along the pathway. The counterpressure in the exit cross section is called p_2. Due to the reduction of pressure the gas phase expands. The released potential energy and the pressure profile along the pathway lead to strong acceleration of the liquid and gas. This is why the pressure gradient increases along the pathway as shown in Fig. 2 and reaches its maximum in the so-called smallest cross section. This cross section (indexed 1) is to be found right upstream of the exit cross section (indexed 2).

For subcritical flow the pressure in the smallest cross section is

$$p_1 = p_2. \tag{1}$$

In the case of critical flow, a pressure jump occurs in the smallest cross section. It has been calculated (e.g., by Henry and Fauske [1]) that in the exit cross section a singularity can be found. The pressure in the smallest cross section is called critical pressure p_c and does not decease further even if the counterpressure p_2 is decreased.

$$p_1 = p_c \quad \text{(critical flow)}. \tag{2}$$

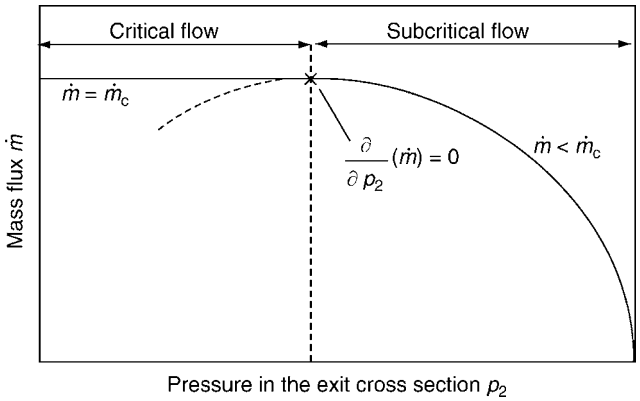
The ratio of the critical pressure p_2 and the pressure at the inlet p_0

$$\eta_c = \frac{p_c}{p_0} \tag{3}$$

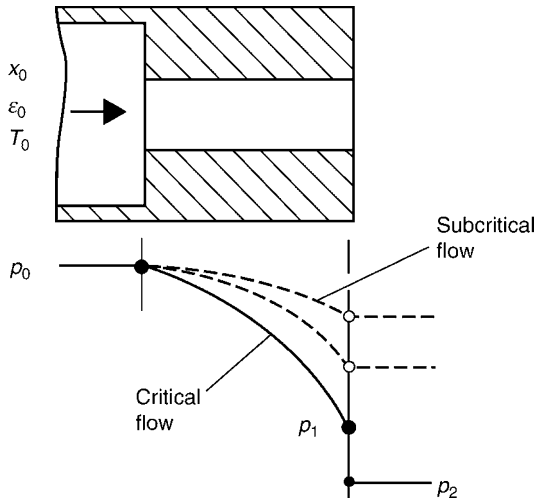
is the critical pressure ratio.

The reason for critical flow, in general, is the strong expansion of gaseous phases. The potential energy contained in the pressurized gas phase at the inlet is transformed into kinetic energy of the two-phase flow. The critical mass flux $\dot{m}_c$ cannot be exceeded though otherwise the kinetic energy in the exit cross section due to the high velocity would exceed the released potential energy. Thus, the mass flux is limited to the critical mass flux.

This fact is taken into account in various methods for calculating the critical mass flux from the energy balance for a



L2.4. Fig. 1. Mass flux depending on the pressure in the exit cross section for constant pressure, temperature, and void fraction at the inlet cross section.



L2.4. Fig. 2. Pressure as a function of the flow path for various exit pressures.

two-phase flow (also in this chapter). Due to simplifying assumptions (e.g., no friction, no slip between the gas and liquid, and adiabatic change of conditions) the calculated mass flux is corrected by introducing the discharge coefficient C_d. It concludes

$$\dot{M} = C_d A_1 \dot{m}\,. \tag{4}$$

A_1 is the area of the smallest cross section. The discharge coefficient corrects also the contraction of the flow in case of high void fractions. Predicting the critical mass flux $\dot{m}_c$ and the critical pressure ratio η_c becomes more important when designing safety valves for the discharge of two-phase flow. In the following chapter methods for calculating the mass flux $\dot{m}$ and the discharge coefficient C_d are explained.

2 Selecting the Appropriate Calculation Method

The values of the critical mass flux and the critical pressure ratio depend on a variety of parameters. They are mainly influenced by

1. The physical properties of the system:
   - Evaporating flow (vapor–liquid flow, e.g., water–steam)
   - Nonevaporating flow (gas–liquid flow, e.g., water–air)
2. The geometry of the flow channel:
   - Design of the channel, e.g., nozzle, orifice, or pipe
   - Length-to-diameter ratio as a major parameter
3. The operating conditions:
   - Pressure p_0, temperature T_0, void fraction ε_0, gas mass flow fraction $\dot{x}_0$ at the inlet, and counterpressure in the exit cross section p_2.

2.1 Influence of the Physical Properties of the System

The major criteria for choosing the right calculation method are listed under (1) in the previous section. For further differentiation of the calculation method the criteria under (2) and (3) are to be taken into consideration.

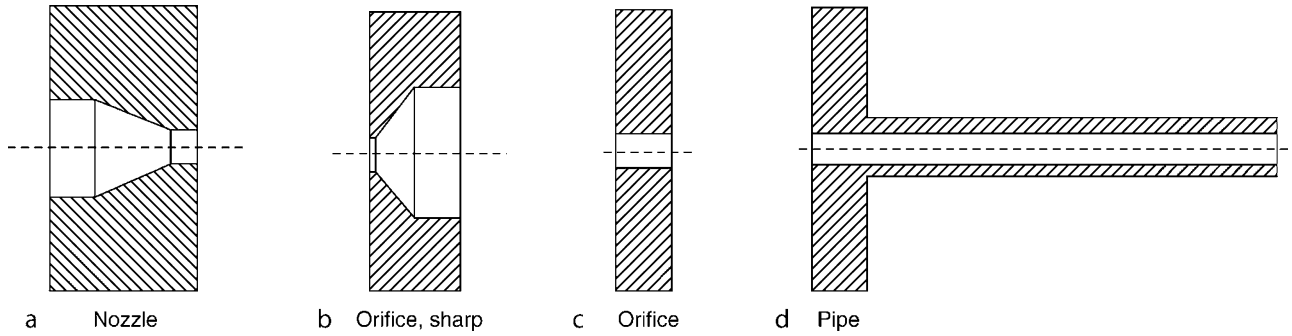
In many cases, the system can be seen either as an evaporating system or a nonevaporating system (in some special cases vapor and liquid flow together with a noncondensable gas – e.g., nitrogen with water–steam. Details on such hybrid systems are to be found in Sect. 8.2). Considering an evaporating or nonevaporating system, especially the heat and mass transfer between liquid and gas shows large differences. Because of this, different assumptions for the calculation of the critical mass flux and the critical pressure ratio in evaporating or nonevaporating flow have to be made:

- Evaporating systems.
  - Intensive mass transfer between liquid and gas phases.
  - Because of evaporation, increasing gas mass flow fraction along the flow path $\frac{\partial \dot{x}}{\partial z} > 0$ and $\dot{x}_1 > \dot{x}_0$.
  - Phase changes occur mostly at thermodynamic equilibrium, e.g., $T_g = T_l = T$ and $p = p_s(T)$.
- Nonevaporating systems.
  - No mass transfer between liquid and gas phases.
  - Due to no mass transfer constant gas mass flow fraction along the flow path: $\frac{\partial \dot{x}}{\partial z} = 0$ and $\dot{x}_1 = \dot{x}_0 = \dot{x}$.
  - Circumstances permitting nonthermodynamic equilibrium phase change. Expansion leads to cooling of the gas phase while the temperature of the liquid phase stays nearly constant: $T_{g,1} < T_{l,1} \cong T_{l,0}$.

Nearly all, from the literature, available calculation methods are based on energy and mass balance for the two-phase mixture. They only differ in their assumption made for the heat and mass transfer and the kind of phase change between the inlet and outlet.

For evaporating flow assuming thermodynamic equilibrium is suitable. The most common calculation method is the Homogeneous Equilibrium Model (Sect. 4).

For nonevaporating flow calculation methods with constant gas mass flow fractions are to be used. These calculation methods are subdivided into those taking temperature



L2.4. Fig. 3. Considered geometries.

differences between the phases into account and those which do not. A calculation method that works for both cases is introduced in Sect. 6.

2.2 Geometry of the Duct

Hardekopf and Mewes [2] did an extended literature study on "critical flow of evaporating systems." In this study, especially, the geometry of the duct is of interest. The investigated geometries – nozzles, orifices, and pipes – are depicted in Fig. 3.

The intensity of the influence of the duct's geometry depends on the thermodynamic conditions in the inlet cross section:

Overheated vapor, vapor mass flow fraction: $\dot{x}_0 = 1$

For the calculation of shorter ducts, $L/D < 15$ the equations given in Sect. 3 are suitable. Orifices with sharp edges at the inlet are an exception. Friedrich and Vetter [3] observed in their experiments no critical flow when reducing the pressure in the exit cross section. The explanation for this phenomenon is the strong inner friction due to the sharp edges and the induced eddies. However, for these kinds of orifices the mass flow can be calculated with the equations given in Sect. 3 (when using the appropriate discharge coefficient C_D).

For long ducts, the influence of the friction at the wall of the duct cannot be neglected. Thus, the critical flow condition is not only dependent on the ratio η_c of the pressure at the exit and the inlet, but also on the absolute values of the pressure at the inlet p_0 and on the ratio of the length and diameter of the pipe. Using empirical equations to obtain the ratio of the critical pressure in the pipes is not advisable. Instead, the balance of energy, momentum, and mass along the axial coordinate should be solved numerically.

Two-phase mixture consisting of saturated vapor and liquid, vapor mass flow fraction: $0 < \dot{x}_0 < 1$

In this case, the mass flux and the critical pressure ratio can be calculated with the Homogeneous Equilibrium Model. The Homogeneous Equilibrium Model is explained in Sect. 4. For very long ducts, friction at the wall should be taken into account. For a rough estimation the simplified method from Sect. 4.2 can be applied. With very low vapor mass flow fractions at the inlet of short ducts, the liquid becomes overheated. This leads to not enough liquid evaporating to establish thermodynamic equilibrium. The reason for this is the short residence time inside very short fittings. A calculation procedure for the case of very low vapor mass flow fractions is proposed in Sect. 8.1.

Subcooled liquid

If the exit pressure p_2 is reduced, the liquid will first evaporate in the exit cross section not depending on the fitting's geometry. As explained in Sect. 5, in this case a flow very similar to the critical flow is observed, though the flow is a single-phase liquid flow. If the liquid is too subcooled to evaporate in the exit cross section, no critical flow will occur. In both cases, the mass flux can be calculated with the equations for single-phase liquid flow because no evaporation takes place inside the duct. The mass flux for a subcooled liquid at the inlet cross section can be calculated with the equations in Sect. 5.

The more complex case of an evaporating liquid along the duct or the possibility of a pure vapor flow exiting the duct is not covered in this publication. This can be the case for high values of the ratio of length to diameter L/D (especially for pipes). Mayinger [4] and Kolev [5] propose a calculation method for this case. Evaporation along the duct can be predicted by calculating the pressure drop for a single-phase liquid flow. Evaporation takes place if the pressure along the duct falls below the vapor pressure and enough nuclei are present. This is the case in most technical applications.

3 Mass Flux for a One Component Gas–Vapor Flow

The mass flux for a single-phase gas–vapor flow is calculated from the energy balance of the fluid. Mayinger [4] describes the following equation in his paper briefly. For the calculation of the mass flux the following assumptions are made:

- The kinetic energy of the gas is negligibly small.
- No friction at the walls.
- The change of condition from the inlet to the exit of the fitting is adiabatic.
- The change of condition is described by the ideal gas law.

By assuming no friction and an adiabatic change of conditions of the flow, the change of condition is necessarily also isentropic for the flowing gas or vapor between the inlet and the exit cross sections.

The mass flux is thus calculated as

$$\dot{m} = C_{d,g}\psi\sqrt{\frac{2p_0}{v_{g,0}}} \tag{5}$$

with

$$\psi \equiv \sqrt{\frac{\kappa}{\kappa-1}\left[\left(\frac{p_1}{p_0}\right)^{2/\kappa} - \left(\frac{p_1}{p_0}\right)^{(\kappa+1)/\kappa}\right]} \tag{6}$$

the discharge function and the discharge coefficient C_D of the single-phase gas flow. The discharge coefficient C_D corrects the error when calculating the mass flow, without taking friction and contraction in the smallest cross section into account. $v_{g,0}$ is the specific volume of the gas or vapor in the inlet cross section and κ the isentropic exponent for an ideal gas.

If the pressure p_1 in the exit cross section is reduced, the value of the discharge function ψ will increase and thus, also the mass flow according to Eq. (5), until the critical pressure p_c is reached. The discharge function has, according to Eq. (6), for the critical pressure ratio

$$\eta_c = \left(\frac{p_1}{p_0}\right)_c = \left(\frac{p_c}{p_0}\right) = \left(\frac{2}{\kappa+1}\right)^{\kappa/(\kappa-1)} \tag{7}$$

between the pressure in the exit cross section p_1 and the pressure at the inlet p_0, a maximum. That means the constraint (Fig. 1)

$$\frac{\partial}{\partial p_1}(\dot{m}) = 0 \text{ for } p_1 = p_0 \tag{8}$$

for critical flow conditions is fulfilled.

For calculating the critical mass flux, it is best first to calculate the critical pressure ratio η_c with Eq. (7) or the critical pressure p_c. The derived value is then to be compared with the pressure at the exit p_2. For this value of the pressure p_2 in Eq. (6) applies

$$\begin{aligned} p_1 &= p_2, \quad \text{if } p_2 > p_c\,, \\ p_1 &= p_c, \quad \text{if } p_2 < p_c. \end{aligned} \tag{9}$$

After the calculation of the discharge function according to Eq. (6) the mass flux is calculated from Eq. (5).

The manufacturer of orifices, nozzles, and valves or other fittings often give the discharge coefficient C_d as a table or as an empirical equation. These values are, most of the time, fitted to meet the experimental investigation concerning the critical mass flux. If the manufacturer delivers a discharge coefficient with his product, it is often best to use it as the value for C_d in Eq. (5). If not available, the discharge coefficient for orifices C_d can be calculated as described in Sect. 7 using Eq. (54), according to Morris [6]. For nozzles, the discharge coefficient can be derived from the empirical equation

$$C_{D,g} = C_{D,0} + C_{D,1}\left(\frac{p_2}{p_1}\right)^2 + (2C_{D,0} - C_{D,0})\left(\frac{p_2}{p_1}\right)^3 \tag{10}$$

introduced by Sallet [7]. $C_{D,0}$ and $C_{D,1}$ are the thresholds for the discharge coefficients at an exit pressure $p_2 = 0$. That means $C_{D,0} = 0.84$ for very low exit pressures and $C_{D,1} = 0.66$ in case of no pressure difference between the inlet and exit. These equations to calculate the discharge coefficient are solemnly of an empirical nature. Depending on the operating conditions and the physical properties of the liquids the calculated values can differ from reality.

4 Homogeneous Equilibrium Model

The equations for the Homogeneous Equilibrium Model are briefly explained by Mayinger [4]. The following assumptions apply:

- Liquid and gas are in thermodynamic equilibrium along the whole stream path.
- Slip between the two phases equals one (no slip).
- Friction at the wall is neglected.
- The change of conditions between the inlet and exit of the fitting is adiabatic.

From the two latter assumptions it is concluded that the change of conditions for the two-phase flow is also isentropic along the stream path. Following these assumptions the equation for the two-phase flow mass flux

$$\dot{m} = \sqrt{\frac{2(\bar{h}_0 - (1-\dot{x}_1)h_{l,1} - \dot{x}_1 - h_{g,1})}{(1-\dot{x}_1)v_l + \dot{x}_1 v_{g,1}}} \tag{11}$$

is derived from the energy and mass balance. In Eq. (11), v_l is the specific volume of the liquid and v_g the specific volume of the vapor in the inlet cross section. The liquid is assumed to be incompressible. Therefore,

$$v_l = v_{l,0} = v_{l,1.} \tag{12}$$

Herein, h_0 represents the mean enthalpy of the two-phase flow mixture in the inlet cross section. It is

$$\bar{h}_0 = \dot{x}_0 h_{g,0} + (1-\dot{x}_0)h_{l,0} \tag{13}$$

with the vapor mass flow fraction $\dot{x}_0$, the specific enthalpy of the vapor $h_{l,0}$, and the specific enthalpy of the liquid $h_{g,0}$ in the inlet cross section.

The vapor mass flow fraction in the inlet cross section is derived from the assumption of isentropic change of conditions from the equation

$$\bar{s}_0 = \bar{s}_1 = \dot{x}\,s_{g,1} + (1-\dot{x}_1)s_{l,1} = \dot{x}_0\,s_{g,0} + (1-\dot{x}_0)s_{l,0} \tag{14}$$

depending on the entropy of the gas and the liquid $\bar{s}_{g,0}$ and $\bar{s}_{l,0}$, respectively, and the vapor mass flow fraction $\dot{x}_0$ in the inlet cross section.

Equation (11) is capable of calculating the mass flux $\dot{m}$ either for a critical or a subcritical flow. Therefore, an addition equation is necessary to calculate the critical pressure p_c

$$\frac{\partial}{\partial p_1}(\dot{m}) = 0, \quad \text{if } p_1 = p_c. \tag{15}$$

The pressure in the smallest cross section is called p_1. In case of subcritical flow, the pressure in the smallest cross section p_1 equals the counterpressure p_2 and

$$\eta > \eta_c; \quad p_1 > p_2 \tag{16}$$

apply. All variables in Eq. (11) carrying the index 1 are to be calculated consequently for the counterpressure p_2. In the case of critical flow with

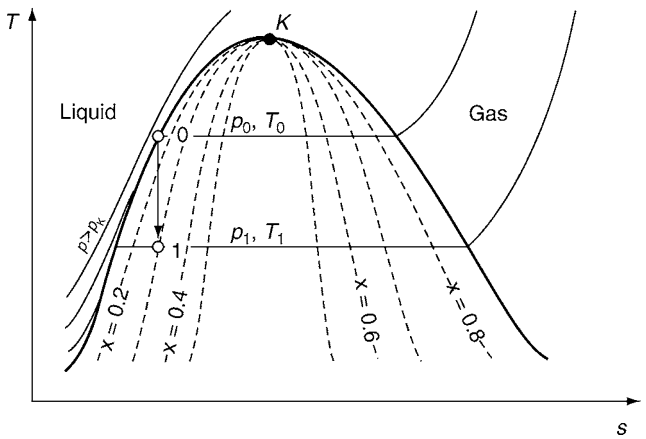
$$\eta > \eta_c; \quad p_1 > p_c \tag{17}$$

all variables in Eq. (11) carrying the index 1 are to be calculated for the critical pressure p_c.

Solving the Eqs. (11), (13), and (15) can be done iteratively. The pressure in the exit cross section p_1 is known in the first step, because it needs to be decided first whether the flow is critical or subcritical. The pressure p_1 is, therefore, stepwise reduced until the constraint according to Eq. (15) is met. As initial value for the pressure p_1 a high value should be chosen to ensure that the value is at the beginning not lower than the critical pressure. For each iteratively found value of the pressure p_1 another iteration needs to be done for the vapor mass flow fraction $\dot{x}_1$, before the mass flux $\dot{m}$ from Eq. (11) can be calculated.

The vapor mass flow fraction in the exit cross section $\dot{x}_1$ is then stepwise increased until the constraints according to the isentropic change of conditions in Eq. (14) are met. As initial value for the vapor mass follow fraction $\dot{x}_1$ the value at the inlet cross section $\dot{x}_0$ is likely to be chosen. The entropy can be derived from an equation of state or suitable tables. The procedure is illustrated in the temperature–entropy diagram in Fig. 4.

In this example the two-phase flow in the inlet cross section is in the state 0. The pressure in the exit cross section of the fitting equals the pressure p_1. p_1 is located in the T-s diagram on the isothermal curve, respectively, on the isochore curve. Starting at position 0, the orthographic line (isentropic change of condition $ds = 0$) leads to position 1, which represents the state of the two-phase flow in the exit cross section. The corresponding value of the vapor mass flow fraction in the exit cross section $\dot{x}_1$ can be read directly from the diagram. Using the T-s diagrams, one can avoid the stepwise iterative calculation of the vapor mass flow fraction $\dot{x}_2$. The iteration to obtain the critical pressure according to Eq. (15) needs to be carried out anyway. The above described method for solving the Homogeneous Equilibrium Model is rather complicated. Therefore, Leung [8] proposes a simplified calculation method. In his following publication various applications are featured (subcooled liquid in the inlet cross section [9], nonevaporating gas, or liquid flow [10]). A brief overview including some examples is then published by Leung in [11]. In the next section, the application of Leung's method for evaporating vapor or liquid flow is described.



L2.4. Fig. 4. Isentropic change of conditions for the Homogeneous Equilibrium Model in a T-s diagram.

4.1 Simplified Solving of the Homogeneous Equilibrium Model Equations

This simplified method introduced by Leung [8] is suitable in case the two-phase flow in the inlet cross section is a saturated vapor–liquid mixture or a slightly subcooled liquid. The influence of wall friction on the pressure loss and thus, on the mass flux can be neglected for shorter ducts. For convenience the discharge function Ψ is introduced. The mass flux is, therefore, calculated as follows:

$$\dot{m} = \sqrt{\frac{2p_0}{v_0}}\Psi. \tag{18}$$

Leung [8] uses in his method a simplified thermodynamic equation of state for the two-phase flow,

$$\frac{v}{v_0} = \omega\left(\frac{p_0}{p} - 1\right) + 1, \tag{19}$$

which is calculated by the mean specific volume

$$v = \dot{x}\, v_g + (1 - \dot{x}) v_l \tag{20}$$

at a certain position along the stream path depending on the mean specific volume at the inlet cross section

$$v_0 = \dot{x}_0\, v_{g,0} + (1 - \dot{x}_0) v_{l,0} \tag{21}$$

and the ratio of the local pressure p and the inlet pressure p_0. In Eq. (19), ω is introduced as a variable which is mostly called "compressibility factor." For vapor–liquid systems, it is

$$\omega = \dot{x}_0 \frac{v_{g,0} - v_{l,0}}{v_0} + \frac{\eta_S\, c_{p,}\, p_{l,0}\, T_0}{v_0}\left(\frac{v_{g,0} - v_{l,0}}{h_{lg,0}}\right)^2. \tag{22}$$

Leung [8] solves Eq. (11) analytically. The enthalpy difference in Eq. (11) is derived by integrating the fundamental equation for isentropic change of conditions

$$\mathrm{d}h = \int_{p_0}^{p_1} -v\, \mathrm{d}p \tag{23}$$

from the inlet pressure p_0 to the exit pressure p_1, whereas v is calculated from Eqs. (19) and (22).

Leung [8] presents an equation which allows the explicit calculation of the mass flux $\dot{m}$, considering physical properties such as pressure and temperature at the inlet cross section. The discharge function is, therefore,

$$\psi = \frac{\sqrt{(1 - \eta_s) + \left[\omega\, \eta_S \ln\left(\frac{\eta_s}{\eta}\right) - (\omega - 1)(\eta_S - \eta)\right]}}{\omega\left(\frac{\eta_S}{\eta} - 1\right) + 1}. \tag{24}$$

It means

$$\eta_S = \frac{p_s(T_0)}{p_0} \tag{25}$$

the ratio of the vapor pressure at the inlet cross section $p_s(T_0)$ and the pressure at the inlet cross section p_0, and

$$\eta = \frac{p_1}{p_0} \tag{26}$$

the ratio of the pressure in the smallest cross section and the pressure at the inlet cross section p_0.

The pressure ratio η_s is a measure of the degree of subcooling of the liquid at the inlet cross section:

- Slightly subcooled liquid: $\eta_{S,min} \leq \eta_S < 1$.
- Saturated vapor–liquid mixture: $\eta_S = 1$.

$\eta_{S,min}$ is the smallest possible pressure ratio where some evaporation occurs between the inlet and exit of the fitting. According to Leung [8], smaller values of $\eta_{S,min}$ lead to nonphysical solutions of the introduced equation. It is, therefore,

$$\eta_{S,min} = \frac{2\,\omega}{1 + 2\,\omega}. \tag{27}$$

The calculation of the mass flux for a strongly subcooled liquid at the inlet cross section is described in Sect. 5.

The pressure at the smallest cross section p_1 equals, in case of a subcritical flow, the given counter pressure p_2 in the exit cross section, or in case of a critical flow, the critical pressure p_c. It is, therefore,

$$p_1 = \max(p_2, p_c). \tag{28}$$

The introduction of Eq. (24) in Eq. (18) and the derivation with respect to the pressure in the smallest cross section p_1 lead the critical conditions in Eq. (15) to

$$0 = \frac{\omega^2 - 2\,\omega + 1}{2\,\eta_S\,\omega}\eta_S^2 - 2\,(\omega - 1)\,\eta_c + \omega\,\eta_S \ln\left(\frac{\eta_c}{\eta_S}\right) + \frac{3}{2}\omega\,\eta_S - 1 \tag{29}$$

for calculating the pressure ratio η_c of the critical pressure p_c and the inlet pressure p_0

$$\eta_c = \frac{p_c}{p_0}, \tag{30}$$

which gives directly the critical pressure p_c. For obtaining the mass flux $\dot{m}$ first the compressibility factor ω from Eq. (22) is calculated. With ω the critical pressure ratio η_c is then calculated from Eq. (29) and the critical pressure is calculated according to Eq. (30). The pressure in the smallest cross section follows from the constraint of Eq. (28). From this pressure and the inlet pressure η according to Eq. (26) and the discharge function according to Eq. (24) is calculated. Finally, the mass flux is calculated from Eq. (18).

4.2 Influence of Friction

Calculating a two-phase vapor–liquid flow in a long pipe is complex, because in this case friction between the fluid and the wall cannot be neglected. The pressure drop due to friction and acceleration, the vapor mass flow fraction, and the velocity interact with each other. These variables often undergo an intense change along the stream path. Therefore, they are difficult to be described with integral equations, taking only the inlet and exit conditions into account.

A two-phase flow mixture can only be calculated by solving the balance of mass, energy, and momentum, depending on the spatial coordinate. For detailed information about this, one should refer to more specialized publications. A brief introduction and the calculation of vapor–liquid flows in the case of critical and subcritical flows are given by Kolev [5].

For short pipes with a small length to diameter ratio or if roughly calculating the method proposed by Leung [11] can be applied to pipes as well.

The compressibility factor ω is like done for shorter ducts, calculated from Eq. (22). For the discharge function Leung [11] proposes

$$\psi = \sqrt{\frac{\frac{1-\eta}{1-\omega} + \frac{\omega}{(1-\omega)^2}\ln[(1-\omega)\eta + \omega] - \ln\left[\frac{1}{\eta}((1-\omega)\eta + \omega)\right]}{4f\,\frac{L}{D}}}. \tag{31}$$

The ratio of the critical pressure and the pressure at the inlet η_c follows from

$$\psi_c = \frac{\eta_c}{\sqrt{2\omega}}. \tag{32}$$

For calculation of the critical pressure p_c or the pressure ratio η_c the system of equation from Eqs. (31) and (32) has to be solved taking

$$\psi_c = \psi \tag{33}$$

into account. The suitable pressure p_1 for calculating the pressure ratio η is given by the constraint in Eq. (28). In the case of a critical flow, the mass flux can be calculated from Eq. (18) for the given value of ψ_c. In the case of a subcritical flow the discharge function needs to be recalculated from Eq. (31), considering the pressure ratio η and the pressure in the exit cross section p_2.

In Eq. (31) L is the length and D the diameter of the duct. The friction coefficient f is set to a constant value

$$f \cong 0.005 \tag{34}$$

according to Leung [11].

5 Mass Flux for a Strongly Subcooled Liquid at the Inlet

If the temperature T_0 in the inlet cross section is below the vapor pressure T_s according to the pressure at the inlet cross section p_0, the liquid is called "sub cooled." Consequently, no vapor exists in the inlet cross section. If the ratio η_s of vapor pressure p_s and pressure at the inlet cross section p_0 defined by Eq. (25) does not fall below the value $\eta_{S,min}$ according to Eq. (27), no evaporation will take place along the fitting. In this case, the flow is single-phase and the equations introduced in Sect. 4 apply for calculating the critical mass flux for both critical and subcritical conditions.

Various authors (see [12, 13]) have calculated the mass flux from the Bernoulli's equation. The discharge function is

$$\psi = \sqrt{1 - \eta} \tag{35}$$

using the pressure ratio η of the pressure in the smallest cross section p_1 and the pressure at the inlet p_0 defined by Eq. (26). The mass flux $\dot{m}$ is calculated analogously using the method

described by Eq. (11) and the mass flow is, therefore,

$$\dot{m} = \sqrt{\frac{2p_0}{v_0}}\sqrt{1-\eta}. \tag{36}$$

Equation (36) is not capable of calculating the mass flux for critical conditions. This is because evaporation due to expansion of the vapor phase, which limits the mass flux, is not considered in Eq. (36). In reality, also for a subcooled liquid a maximum mass flux is observed, if the pressure in the exit cross section is reduced to a certain value. If the pressure in the exit cross section p_2 is reduced below the vapor pressure p_s, evaporation of the liquid will occur. If the pressure p_2 is reduced further, the pressure upstream the smallest cross section p_1 equals the vapor pressure p_s and will not fall below it. The critical pressure ratio is, therefore,

$$\eta_c = \eta_S = \frac{p_s(T_0)}{p_0}. \tag{37}$$

The liquid evaporates due to its high heat capacity at thermodynamic equilibrium and thus, at a constant temperature for the set vapor pressure p_s.

6 Homogeneous Nonequilibrium Model

Under certain conditions the mass transfer between the liquid and gas phases is negligible. This is the case if the gas phase consists of a noncondensable gas and the vapor pressure p_{lg} of the liquid is comparatively low to the pressure levels along the stream path. These conditions apply for the co-current flow of water and air.

For the Homogeneous Nonequilibrium Model the following assumptions are made:

- No mass transfer takes place between the gas and liquid. In many cases, a remarkable amount of gas can be dissolved in the liquid and due to pressure reduction along the stream path, desorption can occur. Mostly, the time of residence inside the fitting is so short that the amount of desorbed gas can be neglected. The diffusive resistance of the gaseous component inside the liquid is comparatively high to the evaporation rate of a single component liquid and therefore, desorption does not play an important role.
- The liquid and gas have the same velocity, and the slip is one.
- The wall friction is zero.
- The change of conditions of the two-phase flow mixture between the inlet and exit of the fitting is adiabatic.

On the way through the fitting the temperature of the gas phase is reduced due to expansion and a temperature difference between the gas and liquid is the consequence. Depending on the volumetric ratio of the gas and liquid, heat exchange takes place between the two phases. This reduces the temperature difference partly. For small void fractions at the inlet cross section (e.g., bubbly flow) the heat exchange takes place due to the high amount of heat stored in the liquid. In this case the assumption of equal temperatures for gas and liquid along the stream path is justified. A different situation is a high void fraction at the inlet cross section (e.g., droplet flow). In this case the stored heat of the liquid is not sufficient to avoid cooling of the gas. It can be assumed that the gas and liquid end up in a thermal nonequilibrium.

The existing calculation methods differ the way they deal with heat transfer between the gas and liquid. Tangren et al. [14] assume an isentropic change of conditions and equal temperatures for the two-phase flow mixture along the stream path. Starkmann et al. [15] investigated the two-phase flow mixtures with very high void fractions. They postulate no heat transfer between the two phases. Some authors (e.g., Starkmann et al. [15]) neglect the contribution of acceleration of the liquid due to the pressure difference in the energy balance. This is also valid for the widely used "Homogeneous Frozen Flow Model" (for explanations see e.g., Mayinger [4]). Henry and Fauske [1] consider acceleration of the liquid, but their equations contain some implicit terms which make the calculation unhandy. In addition, their method is only capable of calculating the critical mass flux. Subcritical flow is not featured in their work. This is why the method of Leung and Epstein [13] is recommended. It takes into account all the contributions to the energy balance of the mixture. In addition, it features the full thermal nonequilibrium ("Frozen Flow") as well as the heat transfer between the phases. Further assumptions are made by Leung and Epstein [13]:

- The gas is described as an ideal gas.
- The change of conditions for the two-phase flow mixture is isentropic (Comment: This assumption is explicitly made by the authors, but already follows from assuming a frictionless and adiabatic flow.).

For calculating the two-phase mass flux, Leung and Epstein [13] introduce the following method:

$$\dot{m} = \frac{\sqrt{2\dot{x}p_0 v_{g,0}\frac{\Gamma}{\Gamma-1}\left[1-\left(\frac{p_1}{p_0}\right)^{(\Gamma-1)/\Gamma}\right]+2(1-\dot{x})v_l(p_0-p_1)}}{\dot{x}v_{g,0}\left(\frac{p_1}{p_0}\right)^{-1/\Gamma}+(1-\dot{x})v_l}. \tag{38}$$

As no mass transfer occurs along the stream path the gas mass flow fraction is constant. It is, therefore,

$$\dot{x} = \dot{x}_0 = \dot{x}_1. \tag{39}$$

In Eq. (38) Γ is the isentropic exponent of the two-phase flow, which was already introduced by Tangren et al. [14]. The two-phase isentropic exponent is then calculated from

$$\Gamma = \frac{\dot{x}c_{p,g}+(1-\dot{x})c_{p,l}}{\dot{x}c_{v,g}+(1-\dot{x})c_{v,l}} \text{ for } T_g = T_l. \tag{40}$$

If the isentropic exponent Γ according to Eq. (40) is introduced to Eq. (38), this means that the temperatures between the gas and liquid along the stream path are equal. In case of very high void fractions, $\dot{x} \to 1$ the isentropic exponent of the two-phase flow merges into the isentropic exponent of the gas phase κ.

If the isentropic exponent of the two-phase flow Γ is not calculated according to Eq. (40), but set to the isentropic exponent of the gas phase κ,

$$\Gamma = \kappa = \frac{c_{p,g}}{c_{v,g}} \quad \text{for } T_g \neq T_l. \tag{41}$$

This corresponds to the maximum thermal nonequilibrium between the gas and liquid (Homogeneous Frozen Flow). If in Eq. (38), the second term under the radical $(2(1-\dot{x})\nu_l(p_0-p_l))$ is neglected and the isentropic exponent of the gas phase κ is used instead of the isentropic exponent of the two-phase flow Γ, an equation known as the "Homogeneous Nonequilibrium Model" as described by e.g., Mayinger [4] or Starkman et al. [15] is obtained. They neglect the contribution of acceleration due to the pressure gradient to the kinetic energy.

The critical mass flux $\dot{m}_c$ can be calculated analogously using the Homogeneous Equilibrium Model with Eq. (15) according to Leung and Epstein [13].

To avoid iterative calculation of the mass flux in Eq. (15), Leung and Epstein [13] introduce the empirical equation

$$\eta_c = \left[\left(\frac{\Gamma+1}{2}\right)^{(3/4)(\Gamma/(\Gamma-1))} + \left(\frac{\Gamma}{2}\frac{1-\varepsilon_0}{\varepsilon_0}\right)^{(3/4)(\Gamma/(\Gamma+1))}\right]^{-3/4} \tag{42}$$

to obtain the critical pressure ratio η_c. This equation is used by Churchill and Usagi [16] for nonlinear interpolation of the critical pressure ratio between the limit cases of a single-phase gas or liquid flow. According to Leung and Epstein [13], the difference between the empirically found critical pressure ratio (Eq. (42)) and the exact solution (Eq. (15)) is maximal 5%.

7 Calculating the Discharge Function for a Two-Phase Flow

For many calculation methods it is assumed that the mass flux of a two-phase flow can approximately be obtained with the equations of the ideal nozzle. In an ideal nozzle, the flow is frictionless and no heat transfer occurs between the two phases and the surrounding. This leads to an isentropic change of conditions from the inlet to the exit of the duct.

Depending on the geometry and the operating conditions of the fitting, in reality the mass flux is different from the one calculated for the ideal nozzle. The measured mass fluxes of a real system are lower than the predicted ones. The reasons are as follows:

- Friction between the fluids and the wall of the duct
- Heat transfer between the fluids and the surrounding through the wall of the duct
- Bend loss in the fittings (especially in safety valves the flow is often redirected many times)
- Reduction of free cross sections due to contraction of the flow at or behind the geometrically smallest cross section

The error due to neglecting friction and heat transfer to the surrounding is corrected by the discharge coefficient C_d. In case of a single-phase flow of liquid or gas, the discharge coefficient covers also the effects of the contraction of the flow at the smallest cross section. For two-phase flow contraction is observed only for operating conditions near a single-phase gas or liquid flow.

The calculation for the two-phase flow mass flux is done in two steps. First, the mass flux $\dot{m}_{id}$ is calculated for a frictionless adiabatic flow. A suitable calculation method for the ideal mass flux can be found in Parts 4 and 6. Second the mass flux is multiplied with the discharge coefficient C_d and thus, the correction is made. The methods for calculating the discharge coefficient C_d are explained next.

The manufacturer of safety valves, orifices, and such fittings often provide the single-phase discharge coefficient for liquid or gas i.e., the so-called α_w. In praxis, the discharge coefficient

$$C_{d,i} = k\alpha_{w,i} \tag{43}$$

is then calculated considering a safety margin k (commonly $k = 1.1$). In Eq. (43), the index i is g (gas) or l (liquid). Especially for safety valves and orifices, it is advisable to use the calculation instructions of the manufacturer. For two-phase flow the discharge coefficient is strongly dependent on the flow patterns and thus, on the operating conditions. Because of the extended experimental effort most manufacturers do not provide two-phase flow discharge coefficients. In praxis, the so-called "mean discharge coefficient" is often used. It is empirically calculated from discharge coefficients provided for the single-phase flow of the gas $C_{d,g}$ or the liquid $C_{d,l}$.

7.1 Discharge Coefficient for a Vapor–Liquid Flow

The discharge coefficient for a fitting that is in use for a two-phase flow mainly depends on the vapor or gas fraction. In the direction of the flow the pressure inside the fitting decreases strongly and some liquid is likely to evaporate. The vapor fraction can, therefore, change a lot along the stream path. In addition, the vapor fraction inside the fitting depends on the degree of subcooling, the vapor fraction at the inlet, the number of nuclei, the geometry of the duct, and the morphology of the wall. This is why the development of a general calculation method for the discharge coefficient for vapor–liquid flow is very difficult. In praxis commonly, the mean discharge coefficient

$$C_d = \varepsilon_g C_{d,g} + (1-\varepsilon_g) C_{d,l} \tag{44}$$

is in use. ε_g is the mean volumetric gas or vapor fraction of the flow. Some authors (e.g., Schmidt and Westphal [17, 18]) conducted experiments that revealed that the discharge coefficients calculated with Eq. (44) are overpredicted. This leads to an overprediction of the effective cross section and thus, of the mass flux. According to Schmidt and Westphal [17, 18], the effect of Eq. (44) is compensated when calculating the ideal mass flux $\dot{m}_{id}$ with the Homogeneous Equilibrium Model. The Homogeneous Equilibrium Model is explained in Sect. 4. Comparison to experimental data reveals (see [1, 2, 19]) that the mass fluxes calculated according to the Homogeneous Equilibrium Model are often underpredicted. Therefore, it is recommended to use Eq. (44) only in combination with the

Homogeneous Equilibrium Model when calculating the mass flux with Eq. (4).

7.2 Discharge Coefficients for Gas–Liquid Flow

Extensive experimental investigations on critical mass flux of a two-phase gas–liquid flow in orifices and nozzles have been carried out by Morris [20] and Lenzing and Friedel [21]. For nozzles he found an empirical equation to calculate the discharge coefficient depending on the slip between the gas and liquid. According to Morris [20] and Lenzing and Friedel [21], in the case of no slip between the phases,

$$S = \frac{w_g}{w_l} = 1, \tag{45}$$

the discharge coefficient is

$$\alpha_{nozzle} = 1. \tag{46}$$

The momentum transfer between the gas and liquid in nozzles or orifices is very intense due to the high velocity and the redirection of the flow. The relative velocity between the gas and liquid may be negligible compared to the high absolute values of the velocities $\bar{w} = w_g = w_l$. Because of many uncertainties, concerning the calculation of the slip for strongly accelerated flow, it is recommended to neglect the slip (i.e., Eq. (45)) for the calculation of discharge coefficients for gas–liquid flows in nozzles, i.e., the discharge coefficient is assumed to be one (Eq. (46)).

In case of the flow through orifices the situation is different. Contrary to the nozzle the orifice's geometry is not optimized for low pressure loss. Especially at the exit eddies lead to high pressure loss and thus, to reduced mass fluxes compared to a nozzle. For orifices, Morris [20] and Lenzing and Friedel [21] proposes the empirical equation

$$C_d = (1.26 - 0.26\beta)C_{d,l} \tag{47}$$

for calculation of the discharge coefficient. β is the ratio of the diameter of the orifice and the duct's diameter in front of the orifice

$$\beta = \frac{D_1}{D_0} \tag{48}$$

$C_{d,l}$ is the mean discharge coefficient

$$C_{d,l} = \varepsilon_{g,1} C_{d,g} + \left(1 - \varepsilon_{g,1}\right) C_{d,l} \tag{49}$$

in the smallest cross section of the orifice. The definition is according to the vapor–liquid flow (see Eq. (44)). The volumetric void fraction in the smallest cross section $\varepsilon_{g,1}$ is due to expansion and due to the pressure gradient higher than at the inlet cross section. The change of condition of the gas phase can be assumed to be isentropic. This leads to the void fraction in the smallest cross section

$$\varepsilon_{g,1} = \frac{1}{1 + \frac{1-\dot{x}}{\dot{x}} \frac{v_l}{v_{g,0}} \left(\frac{p_1}{p_0}\right)^{1/\kappa}}. \tag{50}$$

The liquid phase can be considered to be incompressible, and thus the specific volume of the liquid is

$$v_{l,1} = v_{l,0} = v_l. \tag{51}$$

The gas mass flow fraction of a gas–liquid flow is analogous to that given in Sect. 6

$$\dot{x} = \dot{x}_1 = \dot{x}_2. \tag{52}$$

In Eq. (49) $C_{d,g}$ and $C_{d,l}$ are the discharge coefficients of the single-phase gas or liquid flow. Morris [20] and Lenzing and Friedel [21] proposes the empirical equation

$$C_{d,l} = 0.61375 + 0.13318\left(\frac{D_1}{D_0}\right)^2 - 0.26095\left(\frac{D_1}{D_0}\right)^4 + 0.51146\left(\frac{D_1}{D_0}\right)^6 \tag{53}$$

for the single-phase liquid flow. For a single-phase gas flow, Eq. (53) is extended to feature also the compressible properties of the fluid. It is

$$C_{d,g=} \frac{1 - (1-w)^{0.5}}{2f\left(\frac{p_1}{p_0}\right)^{1/\kappa}}. \tag{54}$$

For convenience the variables

$$f = \frac{1}{C_{d,l}} - \frac{1}{2C_{d,l}^2}, \tag{55}$$

$$w = 4\left(\frac{p_1}{p_0}\right)^{2/\kappa}\left(1 - \frac{p_1}{p_0}\right)\frac{f}{K_N^2} \tag{56}$$

and

$$K_N = \sqrt{2\frac{\kappa}{\kappa - 1}\left(\frac{p_1}{p_0}\right)^{2/\kappa}\left(1 - \left(\frac{p_1}{p_0}\right)^{(\kappa-1)/\kappa}\right)} \tag{57}$$

are introduced.

8 Exceptions

The previously explained calculation methods cover many technically relevant setups. In some cases, e.g., the flow of an evaporating mixture in the presence of a noncondensable gas, the assumptions made are not valid. In the following parts some exceptions are covered.

8.1 Partly Evaporating Liquid

The Homogeneous Equilibrium Model as explained in Sect. 4 leads to good results for a vapor–liquid flow. In certain cases, only partial evaporation of the liquid takes place along the stream path. This is true for very short ducts and very low vapor mass flow fractions of even zero in the inlet cross section. During the short time of residence inside the fitting only a part of the liquid can evaporate. The reason is the limited evaporation rate due to the heat conduction inside the liquid bulk

L2.4. Table 1. Limitations for applying the Homogeneous Equilibrium Model according to Henry and Fauske [1]

Length/ diameter	Partial evaporation (=limitation for applying the Homogeneous Equilibrium Model)
$\frac{L}{D} \leq 12$	$\dot{x} < 14\%$
$\frac{L}{D} > 12$	$\dot{x} < 5\%$

phase. This leads to a certain amount of the dynamic nonequilibrium and consequently, the liquid becomes overheated along the stream path.

In such a case, neither the Homogeneous Equilibrium Model (Sect. 4) assuming thermodynamic equilibrium nor the Homogeneous Nonequilibrium Model (Sect. 6) assuming total thermodynamic nonequilibrium is suitable.

In cases where the degree of mass transfer is in between the total thermodynamic equilibrium and nonequilibrium, Henry and Fauske [1] propose a calculation method. A brief summary of this method can be found in the work by Lenzing and Friedel [21].

The limit of applying the Homogeneous Equilibrium Model is, according to Henry and Fauske [1], dependent on the vapor mass flow fraction at the inlet cross section $\dot{x}_0$ and the ratio of length and diameter of the duct. The authors recommend the following limits for the Homogeneous Equilibrium Model (Table 1).

Outside these limits the calculation method proposed by Henry and Fauske [1] is preferred compared to the Homogeneous Equilibrium Model (Sect. 4). The disadvantage of the method according to Henry and Fauske [1] is that only critical mass flux can be calculated, and subcritical flow is not covered.

8.2 Combined Gas–Vapor–Liquid Flow

If a liquid, its vapor, and a noncondensable gas are flowing together, the mass flux and the critical pressure ratio are different from the case of a two-phase gas–liquid or vapor–liquid flow due to the partial pressure of the gas in the gas phase. Mostly, this leads to higher values of the critical pressure ratio η_c due to the higher volume of the gas compared to an evaporating flow. Reducing the counter pressure at the exit cross section leads to critical conditions at higher pressures. Leung extends the calculation method ([11] in [22]) to consider the effect of a noncondensable gas. The resulting system of equation is relatively complex and can only be solved iteratively. An explanation of this method can be found in German in the work by Schmidt and Westphal [18].

8.3 Non-negligible Slip Between Gas and Liquid

In some cases, the velocity difference between gas and liquid is not to be neglected. Slip is mostly observed in longer ducts, if both phases – like for annular flow – flow separately. The appearing slip depends mainly on the flow pattern, the geometry of the duct, and the physical properties. Calculating the slip is, therefore, only possible with large uncertainties. For calculating the critical mass flux considering slip, Moody [23] proposes an extension to the Homogeneous Equilibrium Model (Sect. 4). The method of Morris [20] is suitable for nonevaporating gas–liquid systems.

9 Examples

9.1 Example 1: Discharge of an Evaporating Vapor–Liquid Mixture

The reactor is filled with Cyclohexane at saturated conditions and at a known temperature. In an emergency situation, the whole content of the reactor is to be discharged within a certain time period. For this purpose, a safety valve is mounted to the bottom of the reactor. The task is to calculate the diameter of the smallest cross section. It is assumed that the change of conditions takes place at thermodynamic equilibrium. The calculations are carried out using the Homogeneous Equilibrium Model. To minimize the effort the simplified method according to Leung [9] (see Sect. 4.1) is applied.

Given is

Volume of reactor	$V = 10\ \mathrm{m}^3$
Initial filling level	$\phi_0 = 85\%$
Temperature	$T_0 = 150°\mathrm{C}$
Counterpressure in discharge tank	$p_t = 0.12\ \mathrm{MPa}$
Required time period for discharge	$t_{ovr} = 5\ \mathrm{min}$
Discharge coefficient for liquid flow	$C_{d,l} = 0.6$
Discharge coefficient for gaseous flow	$C_{d,g} = 0.6$

In addition, the physical properties of Cyclohexane in the gaseous and liquid phases are known.
In the first step, the mass flow is calculated from the available

Vapor pressure at T_0	$p_0 = 0.55\ \mathrm{MPa}$
Density of the liquid at T_0	$\rho_{1,0} = 643.7\ \mathrm{kg/m}^3$
Density of the vapor at T_0, p_0	$\upsilon_{g,0} = 13.1\ \mathrm{kg/m}^3$
Evaporation enthalpy at T_0	$h_{v1,0} = 302.4\ \mathrm{kJ/kg}$

time period and the mass of Cyclohexane contained in the reactor. The mass of liquid Cyclohexane is

$$M_l = \phi V \rho_{l,0} = 5471.2\ \mathrm{kg},$$

and the mass contained as vaporous Cyclohexane is

$$M_g = (1 - \phi) V \rho_{g,0} = 19.7\ \mathrm{kg}.$$

Consequently, the mass flow during discharge is

$$\dot{M}_{ges} = \frac{M_{ovr}}{t_{ovr}} = \frac{M_g + M_l}{t_{ovr}} = 18.3\ \mathrm{kg/s}.$$

In the next step, the mass flux through the safety valve is calculated. It is yet not clear if the flow becomes critical or remains subcritical. Therefore, the critical pressure ratio η_c is calculated first.

The safety valve is mounted to the bottom of the reactor. This is why a single-phase liquid flow enters the valve and this leads to the vapor mass flow fraction

$$\dot{x}_0 = 0.$$

With these values the mean specific volume at the inlet cross section of the valve is calculated according to Eq. (21)

$$v_0 = 1.5536 \times 10^{-3}\ \mathrm{m^3/kg}.$$

From Eq. (22) the compressibility factor is obtained

$$\omega = 16.39.$$

The relatively high value for the compressibility factor is because of the low evaporation enthalpy $h_{v1,0}$ of Cyclohexane. This is evidence for a strong evaporation of Cyclohexane between the inlet and the exit of the valve.

The critical pressure ratio is calculated from Eq. (29)

$$\eta_c = 0.88$$

and with Eq. (30) the critical pressure

$$p_c = 0.484\ \mathrm{MPa}$$

is obtained. The given counterpressure $p_2 = p_t = 0.12$ MPa is below the critical pressure and thus, critical conditions are present in the smallest cross section. Therefore,

$$p_1 = p_c = 0.484\ \mathrm{MPa}$$

is set. From Eq. (24), the discharge function

$$\psi = 0.154$$

is calculated. So the mass flux

$$\dot{m} = \dot{m}_c = 4094.4\ \mathrm{kg/m^2 s}$$

can finally be calculated with Eq. (18). This calculation is carried out up to now for an ideal nozzle. Before the diameter of the valve can be calculated the discharge coefficient C_d has to be calculated first. As only liquid Cyclohexane enters the valve, from Eq. (44), it is found that the discharge coefficient for the single-phase liquid flow

$$C_d = 0.6$$

can be used. The diameter of the valve can now be calculated

$$D_1 = \sqrt{\frac{\dot{M}_{ges}}{C_d \dot{m} \frac{\pi}{4}}} = 97.4\ \mathrm{mm}.$$

When choosing the diameter of the safety valve one should pick the next bigger available size from the manufacturer. In praxis sometimes an additional safety margin has to be taken into account. It is in any case advisory to follow the calculation methods or recommendation of the manufacturer.

9.2 Example 2: Water–Air Flow through an Atomizer

(a) Water is to be atomized in very fine droplets by means of a twin-fluid atomizer. The atomization gas is air. Water and air are internally mixed inside the atomizer. It should be checked whether the chosen inlet pressure is sufficient to establish critical flow and thus create the pressure jump at the exit cross section. In the next step the diameter of the nozzle should be determined.

Given is

Pressure in the inlet of the nozzle	$p_0 = 0.5$ MPa
Pressure in the surrounding of the nozzle	$p_2 = 0.1$ MPa
Temperature at the inlet of the nozzle	$T_0 = 25°C$
Liquid mass flow	$\dot{M}_l = 1,000$ kg/h
Gas mass flow	$\dot{M}_g = 10$ kg/h

In addition, the physical properties of water and air are given:

Isentropic exponent	$k = 1.4$
Density of the liquid in the inlet of the nozzle	$\rho_1 = 997.05\ \mathrm{kg/m^3}$
Density of the gas in the inlet of the nozzle	$\rho_g = 5.858\ \mathrm{kg/m^3}$

For this nonevaporating system of water/air the calculation method for critical and subcritical mass fluxes proposed by Leung and Epstein [13] (Sect. 6) is suitable.

From the mass flow of water and air, the gas mass flow fraction $\dot{x}_0 = 0.9901$ % can be directly calculated (see Sect. 10).

To apply the method of Leung and Epstein [13] the slip must equal one. This assumption is justifiable due to the intense momentum transfer inside the mixing chamber of the atomizer. From the gas mass flow fraction and the densities of the two fluids, the volumetric gas fraction

$$\varepsilon_0 = 0.6299$$

at the inlet cross section is obtained. For the conversion between gas mass flow fraction and volumetric gas fraction, see Sect. 10. From the volumetric gas fraction ε_0 and the isentropic exponent κ of air according to Churchill and Usagi [16] and Eq. (42) follows the critical pressure ratio

$$\eta_c = 0.457.$$

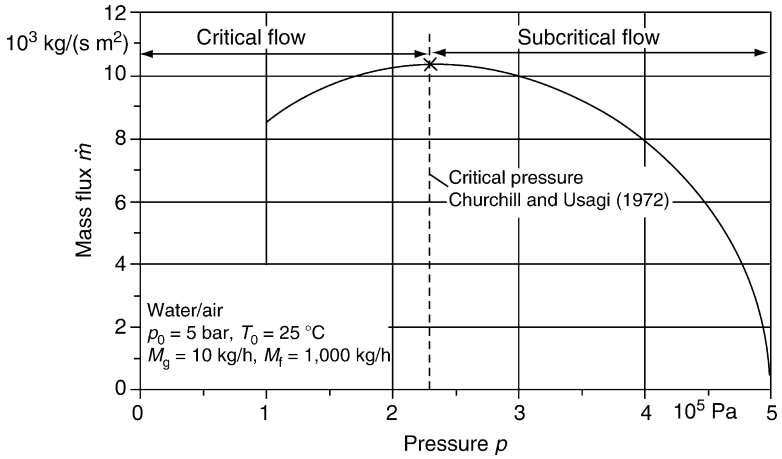
From the definition of the critical pressure ration η_c in Eq.(3) the critical pressure

$$p_c = 0.2284\ \mathrm{MPa}.$$

is obtained. As $p_2 < p_c$ it can be concluded that – as for a reasonable operation of an atomizer necessary – the flow is critical. The pressure jump at the exit cross section is then

$$\Delta p = p_c = p_2 = 0.2284\ \mathrm{MPa} - 0.1\ \mathrm{MPa} = 0.1284\ \mathrm{MPa}.$$

To determine the diameter of the nozzle the mass flux needs to be calculated depending on pressure p_0, temperature T_0, and gas mass flow fraction $\dot{x}_0$ at the inlet cross section. According to Leung and Epstein [13], from Eq. (38) the mass flux



L2.4. Fig. 5. Mass flux according to Leung and Epstein [13], calculated from Eq. (38) as a function of the counterpressure p_1.

$$\dot{m} = 10.515 \times 10^3 \text{ kg/m}^2\text{s}$$

can be calculated. The diameter is obtained from the constraint

$$\dot{M} = C_d \dot{m} \frac{\pi}{4} D_1^4 \quad \text{with } \dot{M} = \dot{M}_g + \dot{M}_l.$$

The conditions inside the atomizer are more or less similar to the ones inside an ideal nozzle. According to Morris [6], in this case the discharge coefficient for the two-phase flow is

$$C_d \cong 1.$$

The diameter can now be calculated as follows:

$$D_1 \sqrt{\frac{\dot{M}}{\frac{\pi}{4}\dot{m}}} = 5.8 \text{ mm}.$$

(b) The critical pressure ratio according to Churchill and Usagi [16] as used in task (a) is only an approximation. It is now to be investigated how much the exact solution described by Leung and Epstein [13] differs from the approximation.

The mass flux is calculated depending on the counterpressure p_1 according to Eq. (38) with the given values for p_0, T_0 and the in (a) obtained value for $\dot{x}_0$. The calculated values for the mass flux are shown in Fig. 5 as a function of the counterpressure p_1. From the constraint that under critical conditions the derivative of the mass flux with respect to the counterpressure becomes zero (Eq. (15)), the critical pressure is

$$p_{c,\text{Leung u. Epstein}} = 0.23 \text{ MPa}.$$

For higher values of the counterpressure the flow becomes subcritical. The areas of critical and subcritical flows are marked in Fig. 5. For comparison, the approximation of the critical pressure p_c by Churchill and Usagi is also noted in Fig. 5 as a vertical dashed line. The graph by Leung and Epstein [13] is in good agreement with Churchill and Usagi's results. This is valid for the area where the derivative with respect to the pressure becomes zero. The difference between the exact and approximately found results is small

$$f_p = \frac{0.2284 \text{ MPa} - 0.23 \text{ MPa}}{0.23 \text{ MPa}} = 0.7\%$$

9.3 Calculation of the Discharge Coefficient of an Orifice for Two-Phase Flow

A pressurized tank should be discharged through a short pipe containing an orifice into the surrounding. The pipe is connected to the tank's head. Inside the tank water is provided with dissolved CO_2 in thermodynamic equilibrium. If the liquid is discharged, the dissolved CO_2 will leave the water and form bubbles, so that a bubbly flow enters the pipe through the orifice. The tank is relatively large compared to the discharging mass flow so that the discharge process can be considered to be stationary. The discharge coefficient should be calculated for the case of two-phase flow.

Given is

Pressure inside the tank	$p_0 = 0.5$ MPa
Pressure of the surrounding	$p_2 = 0.1$ MPa
Diameter of the pipe	$D_0 = 50$ mm
Diameter of the orifice	$D_0 = 5$ mm
Volumetric gas fraction in the pipe's inlet	$\varepsilon_0 = \varepsilon_{g,1} = 0.4$
Isentropic exponent of CO_2	$\kappa = 1.3$

In the first step the critical pressure ratio is calculated according to Leung and Epstein [13] with Eq. (42)

$$\eta_c = 0.4157.$$

From the definition of the critical pressure ratio in Eq. (3) the critical pressure

$$p_c = 0.2079 \text{ MPa}$$

is obtained. As $p_2 < p_c$, the pressure at the exit cross section is $p_1 = p_c$. This means that critical conditions for the flow exist.

For this case the discharge coefficient for the single-phase liquid flow is calculated according to Morris [20] and Henzing and Friedel [21] with Eq. (53)

$$C_{d,f} = 0.6151.$$

The value D_0 is only of importance for $(D_1/D_0) < 15$, because if $(D_1/D_0) < 15$ it has only minor influence on the discharge coefficient. The discharge coefficient for the single-phase gas flow is calculated according to Morris [20] and Henzing and Friedel

[21] with Eq. (54). To do so, the values for K_N, w, and f have to be calculated first using Eqs. (55–57). These values are

$$K_N = 0.6418$$
$$w = 0.4773, \text{and}$$
$$f = 0.3041.$$

Taking into account K_N, w, and f, the discharge coefficient for the single-phase gas flow becomes according to Eq. (54)

$$C_{d,g} = 0.8285.$$

It is always $C_{d,g} > C_{d,f}$. If the discharge coefficients for the single-phase gas and liquid flows are weighted with the volumetric gas fraction, the mean discharge coefficient for the two-phase flow is obtained according to Eq. (49)

$$C_{d,l} = 0.7004.$$

For orifices, in general, Morris [21] proposes in Eq. (47) a discharge coefficient of

$$C_{d,l} = 0.8643.$$

10 Symbols

A	area (m^2)
c_p	specific isochore heat capacity (J/kg K)
C_d	discharge coefficient for a two-phase flow (–)
D	diameter (m)
f	frictional coefficient for a two-phase flow (–)
h	specific enthalpy (J/kg)
$h_{f,g}$	evaporating enthalpy (J/kg K)
k	safety margin (–)
L	length (m)
M	mass (kg)
$\dot{M}$	mass flow (kg/s)
$\dot{m}$	mass flux (kg/s m^2)
p	pressure (Pa)
p_s	vapor pressure (Pa)
s	specific entropy (J/kg K)
$S \equiv \frac{w_g}{w_l}$	slip (–)
T	temperature (°C, K)
t	time (s)
v	specific volume (m^3/kg)
V	volume (m^3)
w	velocity (m/s)
$\dot{x} = \frac{\dot{M}_g}{\dot{M}_g + \dot{M}_l}$	vapor or gas mass flow fraction (–)
x,y,z	coordinates (m)
α_w	discharge coefficient provided by the manufacturer (–)
$\varepsilon \equiv \frac{V_g}{V_g + V_l}$	volumetric gas fraction (–)
$\eta \equiv \frac{p_1}{p_0}$	pressure ratio (–)
$\eta_c \equiv \frac{p_c}{p_0}$	critical pressure ratio (–)
Γ	isentropic exponent of the two-phase flow mixture (–)
κ	isentropic exponent of a singe-phase gas (–)
ω	compressibility factor (–)
ψ	discharge function (–)
ρ	density (kg/m^3)

Indices

0	quiescent condition, inlet cross section
1	smallest cross section
2	exit cross section
c	Critical
d	Discharge
g	gaseous, gas
l	Liquid
ovr	Overall
s	evaporating condition
t	Tank

Conversion of gas or vapor mass flow fraction to volumetric gas fraction:

$$\varepsilon = \frac{1}{1 + S\frac{\rho_g}{\rho_f}\frac{1-\dot{x}}{\dot{x}}}.$$

L2.5 Flooding and Pressure Drop of Counter Current Gas-Liquid Flow in Vertical Pipes

Dieter Mewes
Leibniz Universität Hannover, Hannover, Germany

1 Introduction

The counter current flow of gases/vapors and liquids occur in so-called film columns, such as condensers with vertical tube bundles and film flow of the condensed liquid phases. Very often, the liquid phases are distributed by specially designed devices in the entrance section of the vertically positioned tubes in order to keep the films flowing downward along the inner surface of the tubes. Depending on the mass and heat flux governing of the concentration and temperature gradients, the contacting gaseous phase is either directed upward for counter current flow or downward for concurrent flow. The concurrent flow is described in Subsect. L2.2. Examples from technical applications are the condensation of vapors inside the vertically positioned tubes or tube bundles as well as the selective absorption of components from gaseous mixtures into liquid film flow. In both cases, the phase flows are counter currently directed to obtain maximum concentration or temperature gradients along the surface of the films.

In designing this type of equipment, besides the knowledge about heat and mass transfer, which is given in Chaps. J1 and M3, the engineer has to predict the pressure losses as well as the limits for counter current flow operation. Known methods are based on empirical equations, which are valid only for a limited field of experimentally varied parameters such as construction, material, and flow field.

Brauer [1] was the first who derived a model for counter currently directed gas and liquid flow in vertical tubes assuming laminar film flow and neglecting wavy surfaces. The theoretically derived results are confirmed experimentally by Feind [2]. Pressure drops and flooding points are given by equations using the following physics-based parameters:
The phase superficial velocities are given by

$$j_i \equiv \frac{4\dot{V}_i}{\pi D^2} \qquad (1)$$

$\dot{V}_i$ indicates the volume flows with i = g, f as subscripts for the gaseous or liquid phase respectively.

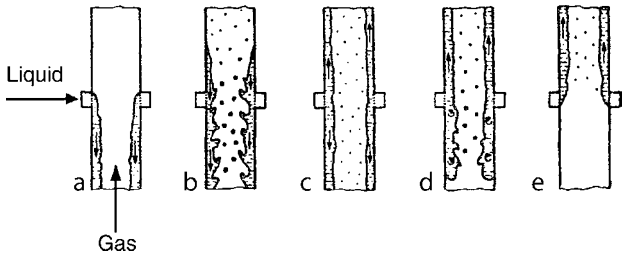
There are many published results on pressure drop and flooding point predictions available. Review articles are published by Bankoff and Lee [3], Hewitt and Wallis [4], McQuillan, Whalley and Hewitt [5, 6], Govan, Hewitt, and Richter and Scott [7] as well as the Ph.D. thesis by von Zhang [8] and Stephan [9].

j_g	-	Gas superficial velocity	m/s
j_f	-	Liquid superficial velocity	m/s
D	-	Inner tube diameter	m
g	-	Gravitational acceleration	m s^{-2}
η_f	-	Liquid viscosity	N m^{-2} s
η_g	-	Gas viscosity	N m^{-2} s
ρ_f	-	Liquid density	kg m^{-3}
ρ_g	-	Gas density	kg m^{-3}
Δp	-	Pressure drop of gaseous phase	N m^{-2}
σ	-	Surface tension	N m^{-1}

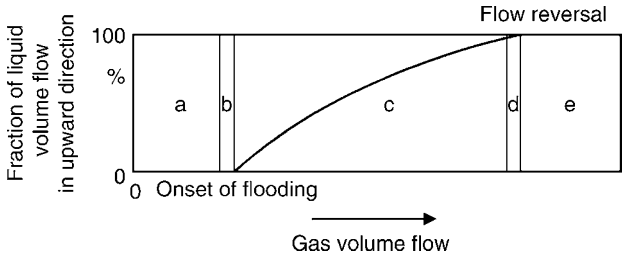
2 Counter Current Two-Phase Flow Phenomena

The possible flow patterns which can occur in adiabatic counter current gas–liquid flow in a single pipe are given in Fig. 1 schematically. At low liquid injection velocities and low superficial gas velocities, the liquid flow is directed downward as annular film with a relatively smooth surface (*a*). The disturbance waves at the film surface grow at higher gas velocities and medium liquid velocities until a critical wave amplitude is reached, beyond which liquid droplets are torn off from the wave crests. They are entrained into the gas stream (*b*), increasing the gas velocity further; part of the smooth falling film can reverse its flow direction from downward to upward, which results in a split film flow at the film entrance (*c*). At very high gas velocities, no more liquid can penetrate the tube and a liquid film hangs at a wall below the liquid entrance. This is the limiting case of counter current flow operation by increasing the gas velocity at a given liquid velocity (*d*). At sufficiently high gas velocities, the injected liquid flows upward concurrently with the gas flow above the liquid entrance, whereas a single-phase gas upward flow exists below the liquid entrance (*e*).

In Fig. 2 the vertically upward carried fraction of the injected liquid volume flow is given as a function of the gas



L2.5. Fig. 1. Flow patterns of gas–liquid flow in a vertical pipe at the transition between counter current and concurrent flow (**a**) counter current film flow; (**b**) onset of flooding indicated by counter current wavy film flow with dispersed droplets; (**c**) flooding indicated by counter current flow with a considerable fraction of liquid volume flow in upward direction; (**d** and **e**) flow reversal indicated by concurrent upward flow.



L2.5. Fig. 2. Fraction of upward directed liquid volume flow as function of gas volume flow.

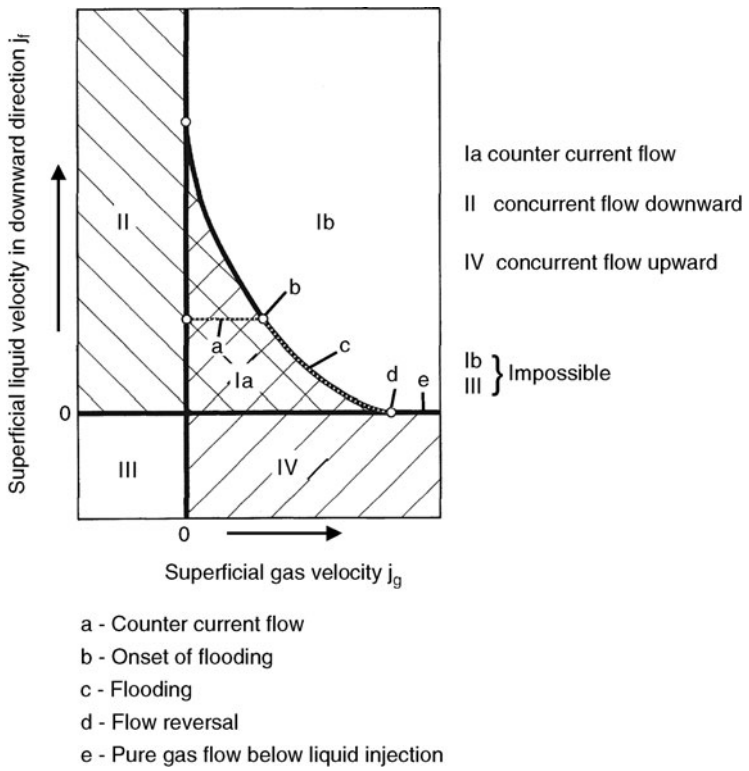
volume flow. The liquid velocity is diminished to zero at the counter current flow limitation, marked by *d* in Fig. 2. In stationary operation flow patterns like *c* (Fig. 2), with liquid partly carried upward, are to be observed. The remaining downward carried liquid volume flow is a function of the gas volume flow, which is named as flooding curve and plotted in Fig. 3. The flooding curve divides the marked areas Ia and Ib for which counter current flow operations are either possible or not.

3 Flooding Point

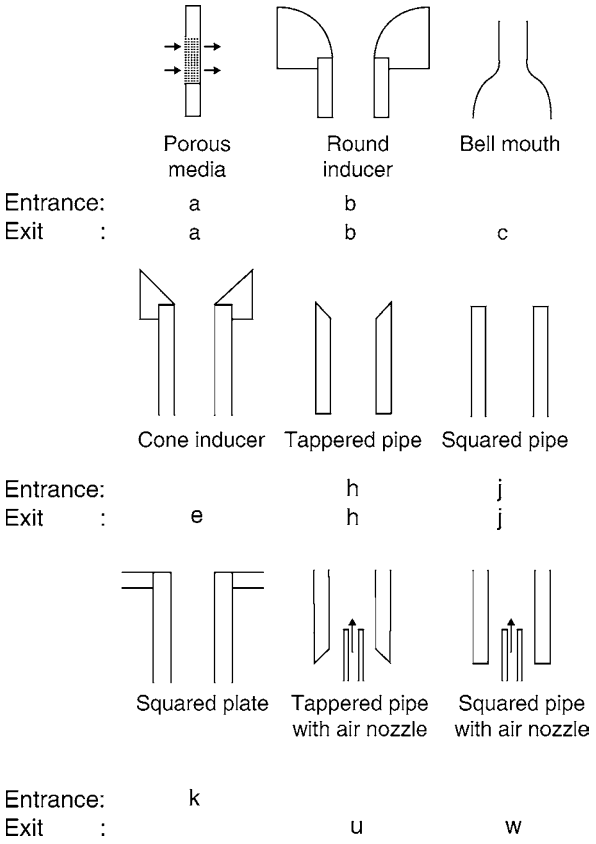
The existing results from experiments on flooding are very sensitive to the construction of the entrance and outlet sections of the investigated tubes. Many results are summarized by Jeong and No [10] for different designed tubes. The mechanisms which cause flooding depend on the cross section designs, which are given in Fig. 4. The flooding mechanisms are extensively discussed by Stephan [9] and Zang [8].

They divide between

- Surface wave induced flooding: Large waves grow in amplitude that the waves meet each other in the tube cross section to form liquid bridges which disintegrate into liquid droplets or are carried upward by the gas flow.
- The increase of wave amplitude in the surrounding of the outlet, which starts as pressure induced up flow of the stationary hanging liquid torus dripping from the borderline of the tube outlet section.
- The dispersion of single droplets from the wavy film surface.



L2.5. Fig. 3. Flow pattern map and flooding function given by the liquid superficial velocity in downward direction in dependence of the superficial velocity of the gas/vapor flow.



L2.5. Fig. 4. Description of the geometry identifiers for the inlet and outlet sections of experimentally tested pipes [10].

Experimental results give evidence that flooding is merely a result of instabilities caused by the design of the outlet section of the pipe. Flooding starts from there at much lower gas velocities than predictable from instabilities inside the tube. This explains the large deviations between the experimentally derived flooding curves according to Fig. 3. The construction of the tube entrance and outlet sections, the tube length and diameter, and the viscosity and surface tension of the investigated liquids are parameters.

Jeong and No [10] report from a survey of 2,500 data sets valid for liquids with similar viscosities like water the following empirically derived equation

$$j_g^{*1/2} = a\, j_f^{*} + b j_f^{*1/2} + c \qquad (2)$$

The superficial phase velocities are

$$j_i^{*} = j_i \left(\frac{\rho_i}{\left(\rho_f - \rho_g\right) D_g} \right)^{1/2} \qquad (3)$$

Subscripts i = g, f indicate the gaseous and the liquid phase.

Jeong and No [10] extracted 536 data points with the following experimental conditions: low upper head injection mode, air–water system, and vertical circular pipe test sections which are 0.7–1.5 m in pipe length and 2–5 cm in diameter. The best fit coefficients for the experimental results derived from selected data sets are
